13. ABSTRACT

This program was designed to develop three dimensional nonlinear viscoelastic equations that could describe the stress-strain response of solid propellant materials for complex loading conditions. The approach used was to identify and mathematically model the underlying mechanisms contributing to the constitutive nonlinearity and to then include these effects within the framework of a continuum constitutive theory.

The program was successful in meeting its objectives and some of the program developments and conclusions are as follows. The dominant mechanisms leading to the nonlinear stress-strain response is microstructural damage in the form of the Mullins' stress-softening effect and vacuole dilatation. Reversible nonlinearities were found to be of secondary importance. These effects have been modeled and combined into a constitutive theory that works very well for fitting the distortional stress-strain behavior under complex loading conditions. This theory is a permanent memory constitutive theory and contains irreversible effects of the past history on the current response. Time effects are included through time-dependent structural damage as well as the ordinary viscous energy dissipation. The experimental work consisted of determining the three dimensional strain response due to complex stress histories at temperatures from -65°F to +150°F and superimposed hydrostatic stress-states from 0 to 1000 psi. To handle the large masses of data generated on this contract computerized characterization techniques were developed wherein the equations could be fit to large masses of data.

FOREWORD

This program was sponsored by the

Air Force Rocket Propulsion Laboratory
Director of Science and Technology
Air Force Systems Command
Edwards, California, 93523

The technical effort reported herein was accomplished under Contract F04611-71-C-0046 and covered the period from May 1971 through June 1973. Mr. Norman Walker was the Air Force project engineer at the start of this contract until he left AFRPL. Dr. Randy L. Peeters was the Air Force materials engineer for the remainder of this contract.

The program was completely successful in meeting its objectives. The success of the program was due to the combined efforts of key personnel at two facilities, the Aerojet Solid Propulsion Company and the Texas A&M Research Foundation. The Aerojet team performed an extensive experimental effort, developed computerized characterization techniques, and performed theoretical work in developing constitutive equations which accurately model the multi-axial behavior of composite propellants. The team at the Texas A&M Research Foundation supported the effort by performing theoretical and experimental work to develop mathematical models for characterizing solid propellants under realistic states of strain. The emphasis of their work was to develop simple constitutive equations based on thermodynamic principles for visco-elastic materials having microstructural damage.

The key technical personnel on this program were: Dr. Richard J. Farris who directed the Aerojet effort and coordinated the overall effort as the Program Technical Manager, and Dr. Richard A. Schapery who directed the Texas A&M effort. Mr. Frederick H. Davidson performed all of the experimental work at Aerojet and Mr. Dennis F. Vronay was primarily responsible for the computerized characterization work. Mr. L. E. Lewis and Mr. R. T. Shankle performed the Texas A&M experimental effort which was under the guidance of Mr. Scott Beckwith.

This technical report has been reviewed and is approved.

Dr. Randy L. Peeters (MKPB)
Materials Engineer, AFRPL
Edwards, California

ABSTRACT

This program was designed to develop three dimensional nonlinear viscoelastic equations that could describe the stress-strain response of solid propellant materials for complex loading conditions. The approach used was to identify and mathematically model the underlying mechanisms contributing to the constitutive nonlinearity in these highly filled polymeric materials and to then include these effects within the framework of a continuum constitutive theory. Also considerable theoretical work was done showing how the resulting mathematical representations could be contained within the framework of a thermodynamic theory and viscoelastic fracture mechanics. During the course of this contract considerable experimental as well as theoretical work were performed since the development of the theory was based on modeling observable effects. The experimental work consisted of determining the three dimensional strain response due to complex stress histories at temperatures from -65°F to +150°F and superimposed hydrostatic stress-states from 0 to 1000 psi. In total over 250 experiments were run using uniaxial and biaxial volumetric dilatometers and the stress-strain-strain invariant-time history of each experiment is stored on magnetic tape and can be made available for others to use.

The program was successful in meeting its objectives and some of the program developments and conclusions are as follows. The dominant mechanisms leading to the nonlinear stress-strain response is microstructural damage in the form of the Mullins' stress-softening effect and vacuole dilatation. Reversible nonlinearities such as second order hereditary strain effects were found to be of secondary importance. These effects have been successfully modeled and combined into a relatively simple constitutive theory that works very well for fitting the distortional stress-strain behavior under complex loading conditions. This theory is a permanent memory constitutive theory and contains irreversible effects of the past history on the current response which are not included in the usual fading memory viscoelastic theories. Time effects are included in the permanent memory theory through time-dependent structural damage as well as the ordinary viscous energy dissipation. The bulk effects were also modeled and good agreement could be obtained only when the vacuole gas phase compressibility was included in the constitutive theory which resulted in a mixed stress-invariant-strain invariant representation. To handle the large masses of data generated on this contract computerized characterization techniques were developed wherein the equations could be fit to large masses of data to determine the applicability of the theory. For constant temperature conditions the theory could be fit within a standard deviation of ± 12% of the observed distortional stress data for approximately forty complex experiments using the entire response curve to failure. The overall accuracy dropped when all the temperature data was analyzed together to about ± 15%. The bulk response predictions were poorer and typical deviations were ± 25% nevertheless all of the proper trends were in the predictions and much of these errors were no doubt experimental.

FOREWORD TO APPENDIX A

Appendix A, "Studies on the Nonlinear Viscoelastic Behavior of Solid Propellant," represents the final technical report from Texas A&M University subcontract effort to the Aerojet Solid Propulsion Company. The work at Texas A&M was performed under the direction of Professor R. A. Schapery. The intent of this subcontract was to (1) support the theoretical and experimental efforts being conducted at Aerojet, (2) provide an independent laboratory and technical staff to test and verify constitutive assumptions, (3) study the relation between Farris' non-fading memory constitutive theory and Schapery's thermodynamic theory, and (4) compare the relation, if any, between Farris' model for the Mullins' effect and Knauss' theory for the influence of microstructural cracks on the mechanical response of propellants.

The work performed at Texas A&M not only provided support for the work and representations used at Aerojet but recommended alternate inverse representations using L_p norms in stress rather than strain. In particular, the energy approach used by Schapery was instrumental in suggesting simplified three dimensional representations using only two strain invariants, the dilatation and the octahedral shear strain and bringing out the coupled dependency of dilatation and mean pressure on octahedral shear strain.

STUDIES ON THE NONLINEAR VISCOELASTIC BEHAVIOR OF SOLID PROPELLANT

R. A. Schapery

May 1973

I. INTRODUCTION AND SUMMARY

The state-of-the-art of nonlinear viscoelastic characterization of solid propellant existing just prior to the start of this investigation was reviewed in [1]. Although some promising models had been proposed, such as Farris' representation of microstructural damage [2], little experimental verification existed for propellant with vacuole dilatation. The present study was undertaken in cooperation with Aerojet Solid Propulsion Company in order to develop mathematical models for characterizing solid propellant under realistic states of strain. Emphasis of the study at Texas A&M University was on the development of simple constitutive equations for propellant having very large amounts of vacuole dilatation and on the application of viscoelastic fracture mechanics to constitutive theory.

In Section II, constitutive equations based on thermodynamic principles are examined for elastic and viscoelastic media with microstructural damage. These equations provide the framework for establishing some special cases which apply to solid propellant. The role of fracture

mechanics in constitutive theory is brought out using the theory developed in [3].

The experimental investigations described in Section III cover uniaxial, strip biaxial, and poker chip tests. Dilatation was measured in all three modes; a dilatometer was used for the former two tests and changes in circumference were monitored to obtain dilatation in the poker chip test [4]. The strip biaxial and uniaxial data were found to support the proposed constitutive model. Poker chip test results turned out to be of rather limited quantitative use, especially with compressive loading, because of the strong nonlinearities exhibited by the propellant.

II. THEORETICAL INVESTIGATIONS

Three-dimensional constitutive equations for nonlinear media with microstructural damage are developed in this section. Results from thermodynamic theory are used to establish the general form of the equations, while possible measures of damage are examined in the light of viscoelastic fracture mechanics theory. As a means of clearly bringing out certain physical aspects of the problem we first derive equations for damaged elastic media. Viscoelastic equations are then developed. In order to provide a sufficiently general theory for incorporating physical models of microstructural damage and to be able to examine the relative merits of different specific representations, we examine both the case in which stresses are expressed as functions of strains and in which strains are functions of stresses.

For simplicity of notation, infinitesimal strain theory is used in the theoretical development of constitutive equations. However, at the end of Section II we show how the results can be immediately extended to finite strain theory by simply making a change in the notation.

A. Constitutive Equations for Elastic Media with Microstructural Damage

Introductory comments: Consider first a nonlinear elastic body with an arbitrary distribution of cracks with fixed length. Derivation of the overall stress-strain equations can be accomplished by following the same steps used for uncracked bodies. Specifically, by combining the First and Second Laws of Thermodynamics, with strains and temperature being the independent state variables, there results for isothermal processes [5]:

$$\sigma_{ij} = \frac{\partial F_e}{\partial \varepsilon_{ij}} \tag{1}$$

where F_e is the Helmholtz free energy/initial volume ("strain energy"). It is a function of the strains, ε_{ij}, temperature, T, and a set of parameters (β_K, say) which are needed to define the geometry (size, shape, orientation, location) of all cracks. The inverse strain-stress equation for isothermal processes likewise can be derived from thermodynamics by taking stresses and temperature as the independent variables [5]:

$$\varepsilon_{ij} = \frac{\partial F_s}{\partial \sigma_{ij}} \tag{2}$$

where $-F_s$ is the Gibbs free energy per unit initial volume ("complementary strain energy"). The energy F_s is, in general, a function of the stresses, σ_{ij}, temperature, T, and the crack parameters β_K.

Berry [6] has used the one-dimensional form of Eq. (2) to derive the overall Young's modulus, E_e, of a large linear elastic sheet under uniformly applied tensile stress, σ_{11}, and with one crack perpendicular to the external load. He obtained:

$$\varepsilon_{11} = \frac{\partial F_s}{\partial \sigma_{11}} = \frac{\sigma_{11}}{E}\left(1 + \frac{2\pi a^2}{A}\right) \tag{3a}$$

where E is the uncracked Young's modulus, 2a is the constant crack length, and A = sheet length x width. Thus,

$$E_e \equiv \frac{\sigma_{11}}{\varepsilon_{11}} = \left(1 + \frac{2\pi a^2}{A}\right)^{-1} E \tag{3b}$$

If there are N noninteracting cracks of length $2a_K$, instead of one crack, then a^2 in Eq. (3b) is simply replaced by $\sum_{K=1}^{N} a_K^2$ [7]; viz.

$$E_e = (1 + \frac{2\pi}{A} \sum_{K=1}^{N} a_K^2)^{-1} E \tag{3c}$$

Equations (1) - (3) are obviously valid for moving cracks in an elastic body as long as the velocities are small enough for kinetic energy to be negligible. With this case one must still perform the differentiation in Eqs. (1) and (2) with the parameters β_K (e.g. a_K) held constant.

Predictions of time-dependent crack lengths and more realistic overall properties will be taken up in a later subsection. For now we shall assume the instantaneous values of β_K are known.

<u>Equations for isotropic media with strains as the independent variables</u>: Let us return to Eq. (1) and assume that it is valid regardless of the types of damage (e.g., submicroscopic polymer chain failure, binder cracks, and dewetting) which are characterized by the parameters β_K. For notational simplicity, explicit dependence of free energy on T and β_K will not be shown; <u>but this dependence is to be assumed unless stated otherwise</u>. Also, as noted previously, the partial derivatives with respect to strain are taken while holding damage (viz. β_K) constant. Furthermore, we will assume that the body, with or without damage, is statistically homogeneous and isotropic. (The body is defined to be statistically isotropic if, after the external loads are removed, there are no preferred directions; the response to a new set of loads will be independent of the material's orientation. If, for example, all of the cracks in a body are parallel, it is <u>not</u> statistically isotropic; if, however, cracks and other flaws are sufficiently random in their orientation isotropy can be assumed.)

Under the above assumptions, the free energy will depend on strain at most through any three independent invariants of the strain tensor. If, for example, we use the three invariants

$$
\begin{aligned}
I_1 &\equiv \varepsilon_{ii} \\
I_2 &\equiv \varepsilon_{ij}\,\varepsilon_{ij} \\
I_3 &\equiv \varepsilon_{ij}\,\varepsilon_{jm}\,\varepsilon_{mi}
\end{aligned}
\tag{4}
$$

where repeated indices imply summation over the range 1, 2, 3, then Eqs. (1) and (4), together with the use of the chain rule and the assumption $F_e = F_e(I_1, I_2, I_3)$, yield (where δ_{ij} is the Kronecker delta),

$$
\sigma_{ij} = \frac{\partial F_e}{\partial I_1}\,\delta_{ij} + 2\,\frac{\partial F_e}{\partial I_2}\,\varepsilon_{ij} + 3\,\frac{\partial F_e}{\partial I_3}\,\varepsilon_{im}\,\varepsilon_{mj} \tag{5}
$$

The damage parameters β_K, which are implicitly included in F_e, may depend on the history of the invariants (and their current values), but not directly on the individual components of the strain tensor.

For physical reasons, it is often desirable to use instead the invariant I_1 and the two strain-deviator invariants:

$$
\begin{aligned}
\tilde{I}_2 &\equiv e_{ij}\,e_{ij} \\
\tilde{I}_3 &\equiv e_{ij}\,e_{jm}\,e_{mi}
\end{aligned}
\tag{6}
$$

where e_{ij} are the deviatoric strains,

$$
e_{ij} \equiv \varepsilon_{ij} - \frac{1}{3}\,\delta_{ij}\,I_1 \tag{7}
$$

By substituting Eq. (7) into (6) we find

$$
\begin{aligned}
\tilde{I}_2 &= I_2 - \frac{1}{3}\,I_1^2 \\
\tilde{I}_3 &= I_3 - I_1 I_2 + \frac{2}{9}\,I_1^3
\end{aligned}
\tag{8}
$$

Equation (5) can be transformed to the deviator strains by using definition (7) and by applying the chain rule to the derivatives in (5); with $F_e = F_e(I_1, \tilde{I}_2, \tilde{I}_3)$ we find

$$s_{ij} = -\frac{\partial F_e}{\partial \tilde{I}_3} \tilde{I}_2 \delta_{ij} + 2 \frac{\partial F_e}{\partial \tilde{I}_2} e_{ij} + 3 \frac{\partial F_e}{\partial \tilde{I}_3} e_{im} e_{mj} \tag{9}$$

and

$$\frac{\theta}{3} = \frac{\partial F_e}{\partial I_1} \tag{10}$$

where s_{ij} are the deviatoric stresses,

$$s_{ij} \equiv \sigma_{ij} - \frac{1}{3} \delta_{ij} \theta \tag{11}$$

and θ is the dilatational stress,

$$\theta \equiv \sigma_{ii} \tag{12}$$

Note that when we set $i = j$ in Eq. (9) and sum the three equations ($j = 1, 2, 3$), the resulting equation is identically zero. Therefore, Eq. (9) defines five, rather than six, independent equations. These five equations, together with the dilatational Eq. (10), form a set which is equivalent to the set of six equations defined by Eq. (5). However, they are now separated into relations which express distortion, Eq. (9), and dilatation, Eq. (10).

For many metals and polymers (with or without filler particles), it is often possible to neglect the dependence of mechanical properties on $\tilde{I}_3$ [8]; <u>this simplification will be used in all of the following discussion</u> as present indications are that it is valid for solid propellant. Thus, from Eq. (9) with $F_e = F_e(I_1, \tilde{I}_2)$:

$$s_{ij} = 2 \frac{\partial F_e}{\partial \tilde{I}_2} e_{ij} \tag{13}$$

while the form of dilatational Eq. (10) is unchanged.

An important point is that if dependence on $\tilde{I}_3$ is not neglected, the deviatoric stresses in Eq. (9) are linear with respect to the square of the strain tensor, i.e. $e_{im}\, e_{mj}$. This dependence implies the deviatoric stress tensor is definitely not a homogeneous function to degree one. On the other hand, without $\tilde{I}_3$, Eq. (13) shows that it is at least possible (but not necessary) to select F_e such that the stress tensor satisfies this homogeneity condition.

<u>An elastic free energy function for propellant</u>: In this subsection we shall propose a specific free energy function which will be shown to predict actual nonlinear behavior of dewetted propellant. Specifically, we assume

$$F_e = \int_0^{I_T} K_1 I_T dI_T + \int_0^{\tilde{I}_2} G_2 d\tilde{I}_2 + N_1 N_2 \tag{14a}$$

where

$$I_T \equiv I_1 - 3\alpha\Delta T \tag{14b}$$

and the term $3\alpha\Delta T$ is the volumetric thermal expansion due to temperature change ΔT. Also,

$$K_1 = K_1(I_T) \quad , \quad G_2 = G_2(\tilde{I}_2)$$

$$N_1 = N_1(I_T) \quad , \quad N_2 = N_2(\tilde{I}_2)$$

are four nonlinear material property functions, each of which depends on only one invariant.

Substitute Eq. (14) into (10) and (13); thus

$$\frac{\theta}{3} = K_1 I_T + \frac{dN_1}{dI_T} N_2 \tag{15a}$$

$$s_{ij} = 2(G_2 + N_1 \frac{dN_2}{d\tilde{I}_2}) e_{ij} \tag{15b}$$

In the linear range of behavior, these equations must reduce to

$$\frac{\theta}{3} = K_e I_T \tag{16a}$$

$$s_{ij} = 2 G_e e_{ij} \tag{16b}$$

where K_e and G_e are the linear elastic bulk and shear moduli, respectively. Hence, K_1 and G_2 can be interpreted as the nonlinear generalizations of K_e and G_e, while N_1 and N_2 produce coupling between dilatational and shear phenomena. The product $N_1 N_2$ must be selected such that, at small strains, it is at least of third order in the strains in order that the proper linear limiting case, Eq. (16), is obtained.

Let us now go one step further and assume

$$K_1 = K_e \quad , \quad G_2 = G_e$$
$$N_1 = K_e I_T \tag{17}$$

and

$$N_2 = 0 \qquad \text{for} \quad \tilde{I}_2 < b^2$$
$$N_2 = -a(\sqrt{\tilde{I}_2} - b) \qquad \text{for} \quad \tilde{I}_2 \geq b^2 \tag{18}$$

where a and b are non-negative quantities.* Substitution of Eqs. (17) and (18) into (15) yields, for $\tilde{I}_2 \geq b^2$:

$$\frac{\theta}{3} = K_e[I_T - a(\sqrt{\tilde{I}_2} - b)] \tag{19a}$$

---

*If $b = 0$, then the free energy function will be positive definite if and only if

$$a < \sqrt{2G_e/K_e}$$

$$s_{ij} = 2[G_e - \frac{aK_e I_T}{2\sqrt{\tilde{I}_2}}]\, e_{ij} \tag{19b}$$

while the linear relations (16) apply for $\tilde{I}_2 < b^2$.

It is of interest to examine Eq. (19) in some detail as these relations turn out to agree with a large amount of propellant data. First, observe that if G_e, K_e, and a depend at most on constant damage parameters β_K and/or are homogeneous to degree zero in the invariants (through β_K), then the deviatoric constitutive Eq. (19b) is homogeneous to degree one, and, in this regard, it agrees with Farris' observations [9]. However, the dilatational Eq. (19a) is not homogeneous to degree one unless (i) $\tilde{I}_2 < b^2$ and K_e depends on β_K as noted above or (ii) $\tilde{I}_2 >> b^2$ and K_e and a both depend on β_K as noted above.

If the dilatational stress θ is either known or is negligible, Eq. (19a) enables dilatation to be easily predicted; viz., for $\tilde{I}_2 \geq b^2$:

$$I_T \equiv I_1 - 3\alpha\Delta T = \frac{\theta}{3K_e} + a(\sqrt{\tilde{I}_2} - b) \tag{20}$$

The significance of this result in predicting dilatation in three common tests will be discussed in Section II-D.

Consider the simple shear test ($\varepsilon_{12} \neq 0$) in which $\Delta T = 0$ and the propellant is constrained such that all normal strains vanish, which implies $I_T \equiv 0$. Equation (19a) yields, for $\sqrt{\tilde{I}_2} = \sqrt{2}\,|\varepsilon_{12}| \geq b$,

$$\frac{\theta}{3} = -K_e\, a(\sqrt{2}\,|\varepsilon_{12}| - b) \quad . \tag{21}$$

Also, Eq. (19b) yields $\sigma_{11} = \sigma_{22} = \sigma_{33}$, and predicts that the effective shear modulus is G_e. Thus, the shear strain produces compressive normal stresses, which is consistent with experimental results [10]. Moreover, if the propellant is permitted to expand during shearing, Eq. (19b) predicts that the effective shear modulus will be less than that for no dilatation; this result, again, is consistent with propellant data [10].

Let us now return to Eq. (19b) and specialize it to uniaxial loading. Assuming $\varepsilon_{11} >> |I_T|$, we find

$$\sigma_{11} = 3\, G_e\, \varepsilon_{11}\, [1 - \beta \frac{I_T}{\varepsilon_{11}}] \tag{22}$$

where

$$\beta \equiv \frac{aK_e}{\sqrt{6}\, G_e} \tag{23}$$

As long as

$$1 - \beta \frac{I_1}{\varepsilon_{11}} \approx e^{-\beta I_1/\varepsilon_{11}} \tag{24}$$

predicted stress (22) is the same as that reported by Farris [11], where $\beta \approx 2 - 3$.

We have assumed the quantities K_e, G_e, a, and b are constant insofar as the comparison with experimental data was concerned. The influence of damage parameters β_K on these quantities will be discussed in Section II-E.

It should be pointed out that the relations in Eq. (15), instead of those in Eq. (19), may be needed to characterize propellant subjected to moderate and high pressures. Alternatively, use of the method described in Section II-F together with Eq. (19) may prove to be better.

Equations for isotropic media with stresses as the independent variables: Constitutive equations corresponding to the isotropic version of Eq. (2) are completely analogous to those given in terms of strains. We introduce the dilatational stress invariant

$$\theta \equiv \sigma_{ii} \tag{25a}$$

and the two deviatoric stress invariants

$$\tilde{J}_2 = s_{ij}\, s_{ij} \tag{25b}$$

$$\tilde{J}_3 = s_{ij}\, s_{jm}\, s_{mi} \tag{25c}$$

The deviatoric strains are found to be

$$e_{ij} = -\frac{\partial F_s}{\partial \tilde{J}_3}\tilde{J}_2\,\delta_{ij} + 2\frac{\partial F_s}{\partial \tilde{J}_2}s_{ij} + 3\frac{\partial F_s}{\partial \tilde{J}_3}s_{im}\,s_{mj} \tag{26}$$

and the dilatational strain I_1 is

$$\frac{I_1}{3} = \frac{\partial F_s}{\partial \theta} \tag{27}$$

If F_s is independent of the third stress invariant $\tilde{J}_3$, then Eq. (26) becomes simply

$$e_{ij} = 2\frac{\partial F_s}{\partial \tilde{J}_2}s_{ij} \tag{28}$$

B. Constitutive Equations for Viscoelastic Media with Microstructural Damage

Equations for isotropic media with strains as the independent variables: The above considerations can be generalized to include viscoelastic behavior by drawing upon the irreversible thermodynamic theory in [12]. As before, we will assume that the dependence of material properties on $\tilde{I}_3$ can be neglected. Furthermore, the strain measures $q_1,\ldots,q_6$, in [12]

will be assumed as follows:

$$
\begin{aligned}
q_1 &= \phi + \varepsilon_{11} & q_4 &= \varepsilon_{12} \\
q_2 &= \phi + \varepsilon_{22} & q_5 &= \varepsilon_{23} \\
q_3 &= \phi + \varepsilon_{33} & q_6 &= \varepsilon_{13}
\end{aligned}
\tag{29}
$$

where $\phi = \phi(I_T, \tilde{I}_2)$ is a material property which is assumed to vanish in the absence of vacuole dilatation; at small strains, this function must be at least of second order in the strains in order for the measures of strain to reduce to the strains in the linear range of behavior. The significance of ϕ will be seen by examining the resulting constitutive equations.

The use of Eq. (29) in the theory in [12] yields, after much rearrangement,

$$\frac{\theta}{3} = \frac{\partial F_e}{\partial I_T} + a_F \frac{\partial q}{\partial I_T} \int_0^t \Delta K(\psi - \psi') \frac{dq}{d\tau} d\tau \tag{30a}$$

$$
\begin{aligned}
s_{ij} = {} & 2 \frac{\partial F_e}{\partial \tilde{I}_2} e_{ij} + 2 a_F \int_0^t \Delta G(\psi - \psi') \frac{de_{ij}}{d\tau} d\tau \\
& + 2 a_F \frac{\partial q}{\partial \tilde{I}_2} e_{ij} \int_0^t \Delta K(\psi - \psi') \frac{dq}{d\tau} d\tau
\end{aligned}
\tag{30b}
$$

where

$$q = q(I_T, \tilde{I}_2) \equiv 3\phi + I_T \tag{31}$$

is the nonlinear dilatational strain measure which may be a function of both I_T and $\tilde{I}_2$. Also, ΔG and ΔK in these relations are the LVE transient components of the shear and bulk relaxation moduli, respectively. In general, there may be four different nonlinear material property functions

in Eq. (30); viz., F_e, a_F, q (or ϕ), and a_ε, where a_ε appears in the definition of reduced time ψ,

$$\psi = \psi(t) \equiv \int_c^t dt/a_\varepsilon \quad ; \; \psi' \equiv \psi(\tau) \quad ; \; a_\varepsilon = a_\varepsilon(I_T, \tilde{I}_2, T) \tag{32}$$

The term in Eq. (30b) involving ΔK gives rise to dependence of deviatoric stress on volume-change history, even when the deviatoric strain is constant.

These same equations could have been derived more directly from the underlying thermodynamic theory, Eq. (19) in [12], without making use of the constitutive equations in [12] in terms of strains ε_{ij} and stresses σ_{ij}. This alternative approach would consist of assuming that

$$q_1 = e_{11}, \ldots, q_6 = e_{13} \tag{33a}$$

and

$$q_7 \equiv q = q(I_T, \tilde{I}_2) \tag{33b}$$

where all seven q_i are treated as independent state variables. The virtual work δW, which is used to derive the constitutive equations, is written in the form,

$$\delta W = s_{ij}\delta e_{ij} + \frac{1}{3}\theta\delta I_T + \lambda\delta_{ij}\delta e_{ij} = \sum_{m=1}^{7} Q_m \delta q_m \tag{34}$$

It is to be noted that $\delta_{ij}e_{ij} = e_{ii} \equiv 0$, and therefore out of the six e_{ij}, only five are actually independent; however, all six can be treated as independent quantities in the virtual work condition (34) as long as the term $\lambda\delta e_{ii}$ is added to the equation (where λ is a Lagrange multiplier).

The main point we want to make here is that constitutive equations

(30) can be viewed as being based on the assumption that the thermodynamic measures of deviatoric strain, $q_1,\ldots,q_6$, are equal to the deviatoric strains themselves, while the thermodynamic measure of dilatation, q_7, is a function of the actual dilatation, I_T, and the deviatoric strains (through $\tilde{I}_2$).

The present constitutive theory (30) can be simplified even further by assuming that when all strains are constant in time (generalized relaxation test) the form of the constitutive nonlinearity is independent of time.

For constant strains applied at $t = 0$, and using the relations

$$\Delta K(\psi) \equiv K(\psi) - K_e \tag{35a}$$

$$\Delta G(\psi) \equiv G(\psi) - G_e \tag{35b}$$

where

$$K_e \equiv K(\infty) \text{ and } G_e \equiv G(\infty) \quad ,$$

we find that Eq. (30) reduces to

$$\frac{\theta}{3} = [\frac{\partial F_e}{\partial I_T} - \frac{a_F}{2}\frac{\partial q^2}{\partial I_T} K_e] + \frac{a_F}{2}\frac{\partial q^2}{\partial I_T} K(\psi) \tag{36a}$$

$$\begin{aligned} s_{ij} = {} & [2\frac{\partial F_e}{\partial \tilde{I}_2} - 2a_F G_e - a_F \frac{\partial q^2}{\partial \tilde{I}_2} K_e]\, e_{ij} + 2a_F G(\psi) e_{ij} \\ & + a_F \frac{\partial q^2}{\partial \tilde{I}_2} K(\psi) e_{ij} \end{aligned} \tag{36b}$$

The nonlinear form of Eq. (36) at short times, $\psi \approx 0$, will be different from that long time, $\psi \to \infty$, unless the sums in square brackets vanish; viz.,

$$\frac{\partial F_e}{\partial I_T} = \frac{a_F}{2} \frac{\partial q^2}{\partial I_T} K_e \tag{37}$$

$$2 \frac{\partial F_e}{\partial \tilde{I}_2} = 2a_F G_e + a_F \frac{\partial q^2}{\partial \tilde{I}_2} K_e \tag{38}$$

Define a new function g,

$$g \equiv q^2 + 2 \frac{G_e}{K_e} \tilde{I}_2 \tag{39}$$

and then combine Eqs. (37) and (38) to obtain a single equation for g:

$$\frac{\partial g}{\partial I_T} \frac{\partial F_e}{\partial \tilde{I}_2} - \frac{\partial g}{\partial \tilde{I}_2} \frac{\partial F_e}{\partial I_T} = 0 \quad . \tag{40}$$

This equation is solved by a standard method [13] to yield $g = g(F_e)$. Namely, g is an (almost) arbitrary function of the single quantity, F_e; in the linear range of behavior q must reduce to I_T, which implies g must be such that

$$g = \frac{2}{K_e} F_e \qquad \text{when} \qquad |F_e| << 1 \tag{41}$$

which is the only restriction on the function $g(F_e)$. From Eq. (39),

$$q^2 = g(F_e) - 2 \frac{G_e}{K_e} \tilde{I}_2 \tag{42a}$$

and from Eq. (37),

$$a_F = - \frac{2}{K_e (dg/dF_e)} \tag{42b}$$

and Eq. (36) for constant strains becomes

$$\frac{\theta}{3} = \frac{\partial F_e}{\partial I_T} \frac{K(\psi)}{K_e} \tag{43a}$$

$$s_{ij} = 2a_F[G(\psi) - G_e \frac{K(\psi)}{K_e} + \frac{1}{a_F} \frac{\partial F_e}{\partial \tilde{I}_2} \frac{K(\psi)}{K_e}] \, e_{ij} \tag{43b}$$

and Eq. (30) for transient strains becomes

$$\frac{\theta}{3} = a_F \frac{\partial q}{\partial I_T} \int_0^t K(\psi - \psi') \frac{dq}{d\tau} d\tau \tag{44a}$$

$$s_{ij} = 2a_F[\int_0^t G(\psi - \psi') \frac{de_{ij}}{d\tau} d\tau + \frac{\partial q}{\partial \tilde{I}_2} e_{ij} \int_0^t K(\psi - \psi') \frac{dq}{d\tau} d\tau] \tag{44b}$$

where, in Eqs. (43) and (44), a_F and q are to be expressed in terms of the auxiliary function g, which, in turn, is an arbitrary function of F_e (except for condition (41)).

Thus, the constitutive equations now contain <u>three</u> independent material property functions: F_e, g, and a_ε, each of which may depend on a set of damage parameters, β_K.

As one further simplification, assume

$$K(\psi) = A'G(\psi) \tag{45}$$

where A' is a constant; this behavior was reported in [4] for propellant, as determined from poker-chip tests. Relaxation relations (43) become

$$\frac{\theta}{3} = \frac{\partial F_e}{\partial I_T} \frac{G(\psi)}{G_e} \tag{46a}$$

$$s_{ij} = 2 \frac{\partial F_e}{\partial \tilde{I}_2} \frac{G(\psi)}{G_e} e_{ij} \quad . \tag{46b}$$

When Eq. (44) is specialized to a uniaxial relaxation test, and

condition (45) is used, we find that the dilatation is independent of time; this behavior for one propellant was reported by Farris [14]. However, for the PBAN propellant studied on this program, as well as for an 82 wt% CTPB propellant studied at the Naval Ordnance Station [15], some change in volume occurred during relaxation. Equation (44) is sufficiently general to predict such behavior, as long as condition (45) is not invoked.

Finally, attention is called to the fact that Eq. (44) is capable of predicting a history-dependent pressure build-up due to shear straining, even when $I_T = 0$. This behavior is a result of the dependence of q on $\tilde{I}_2$.

<u>Equations for isotropic media with stresses as the independent variables</u>: From the theory in [16] we deduce a set of constitutive equations which are similar to those in Eq. (30); viz.

$$\frac{I_1}{3} = \frac{\partial F_s}{\partial \theta} + \frac{1}{9}\frac{\partial Q}{\partial \theta}\int_0^t \Delta B(\psi - \psi')\frac{d(Q/a_G)}{d\tau}\,d\tau \tag{47a}$$

$$e_{ij} = 2\frac{\partial F_s}{\partial \tilde{J}_2}s_{ij} + \frac{1}{2}\int_0^t \Delta J(\psi - \psi')\frac{d(s_{ij}/a_G)}{d\tau}\,d\tau$$

$$+ 2\frac{\partial Q}{\partial \tilde{J}_2}s_{ij}\int_0^t \Delta B(\psi - \psi')\frac{d(Q/a_G)}{d\tau}\,d\tau \tag{47b}$$

where F_s, Q, and a_G are material functions of the invariants θ and $\tilde{J}_2$. Also ΔB and ΔJ are the transient components of the linear viscoelastic creep compliances in bulk and simple shear, respectively. Special forms of Eq. (47) analogous to those in Eq. (44) can be deduced; but, we shall

not pursue these cases here.

C. On Constitutive Equations which are Homogeneous to Degree One

This subsection is concerned with the following questions: (1) given constitutive equations in which the stress tensor σ_{ij} is expressed as a homogeneous functional to degree one in the strain tensor ε_{ij}, and assuming unique inverse relations exist (i.e., strain tensor is a unique functional of the stress tensor) are they homogeneous to degree one?; and (2) under what conditions do inverse relations exist?

We shall prove first that the answer to question (1) is "yes" and then state a general criterion as the answer to question (2).

Write the given functional constitutive equations as

$$\sigma_{ij} = g_{ij}(\varepsilon_{kl}) \tag{48}$$

where

$$g_{ij}(a\varepsilon_{kl}) = ag_{ij}(\varepsilon_{kl}) \tag{49}$$

with a = constant scalar. We assume unique inverse relations exist, i.e.,

$$\varepsilon_{ij} = f_{ij}(\sigma_{kl}) \tag{50}$$

By definition of f_{ij},

$$\sigma_{ij} = g_{ij}[f_{kl}(\sigma_{mn})] \tag{51}$$

It will now be proved that f_{ij} is homogeneous to degree one in the stresses; viz.

$$f_{ij}(c\sigma_{kl}) = cf_{ij}(\sigma_{kl}) \tag{52}$$

where c = constant scalar. Write Eq. (51) for stresses σ'_{ij},

$$\sigma_{ij}' = g_{ij}[f_{kl}(\sigma_{mn}')] \tag{53a}$$

where

$$\sigma'_{ij} = c\sigma_{ij} \tag{53b}$$

Substitute (53b) into (53a),

$$\sigma_{ij} = \frac{1}{c}\, g_{ij}[f_{kl}(c\sigma_{mn})] \quad . \tag{54}$$

Upon using (49), with $a = 1/c$, we find

$$\sigma_{ij} = g_{ij}[\frac{1}{c}\, f_{kl}(c\sigma_{mn})] \quad . \tag{55}$$

In view of equations (51) and (55), and the uniqueness assumption (i.e., for a given stress tensor, there exists only one strain tensor), we observe,

$$\frac{1}{c}\, f_{kl}(c\sigma_{mn}) = f_{kl}(\sigma_{mn}) \tag{56a}$$

or

$$f_{kl}(c\sigma_{mn}) = cf_{kl}\,(\sigma_{mn}) \tag{56b}$$

which, according to equation (52), completes the proof.

Now, consider the question (2). If the quantities g_{ij}, Eq. (48), are algebraic we can use the well-known result from the theory of coordinate transformations that the inverse relations exist and are unique if [5]:

i. The six functions g_{ij} are single-valued, continuous, and possess continuous first partial derivatives throughout the body of interest.

ii. The Jacobian determinant,

$J \equiv |\partial g_{ij}/\partial \epsilon_{kl}|$, does not vanish at any point in the body.

A simple example for which a unique inverse does not exist is the one-dimensional uniaxial case for which $\sigma = \sigma(\epsilon)$ has a maximum point at

$\varepsilon = \varepsilon_m$, say; for all strains $\varepsilon \geq \varepsilon_m$, a unique single-valued relation $\varepsilon = \varepsilon(\sigma)$ does not exist.

In the actual case of interest, g_{ij} represents a set of six functionals; i.e., it depends on strain history. However, this set of functionals can be reduced to algebraic functions, which can then be subjected to the above stated conditions for invertability. This reduction is easily accomplished (in principle) by approximating the strain histories by piecewise linear or step functions of time. In this form the original functionals g_{ij} become algebraic functions of the constants defining the approximate strain histories. If, for example, we consider all six strains and let each strain history be represented by ten constants, there will be 60 x 60 terms in the Jacobian determinant.

In view of the last comment, a completely general study of invertability would be impractical. However, significant insight into the problem could be gained by examining simple situations, such as the stress-strain equations defining the behavior of a bar under confining pressure and uniaxial tension.

D. The Dilatational Constitutive Equation

Characterization of the effect of vacuole formation and growth on the relation between dilatational stress, θ, and dilatational strain, I_T, is an important and very difficult part of the overall nonlinear viscoelastic characterization problem. In this section, the so-called dilatational constitutive equation is therefore singled-out for special study. Recall that some forms of this equation for the elastic case,

e.g. Eqs. (10) and (19a), and the viscoelastic case, e.g. Eqs. (30a) and (47a), have already been given.

We first <u>define</u> the vacuole dilatation I_v by the following equation:

$$I_v \equiv I_1 - 3\alpha\Delta T - \frac{\theta}{3K_e} = I_T - \frac{\theta}{3K_e} \tag{57}$$

where K_e = bulk modulus in the unstressed state; voids may exist in this state. (Note that, in the linear elastic range of behavior

$$I_1 = 3\alpha\Delta T + \frac{\theta}{3K_e} \tag{58}$$

and therefore $I_v = 0$.) Also by definition, I_v is never negative.

In general, I_v can be expressed as a function of the history of the three <u>stress</u> invariants and temperature <u>or</u> the three <u>strain</u> invariants and temperature. We chose the latter four scalars here, and write

$$I_v = F\{I_T, \tilde{I}_2, \tilde{I}_3, T\} \tag{59}$$

Now, substitute Eq. (57) for I_v and find

$$I_T = \frac{\theta}{3K_e} + F\{I_T, \tilde{I}_2, \tilde{I}_3, T\} . \tag{60}$$

In order to obtain a form which is useful for application to experimental data we solve Eq. (60) for mechanical dilatation:

$$I_T = G\{\frac{\theta}{3K_e}, \tilde{I}_2, \tilde{I}_3, T\} \tag{61}$$

where G {} is a function of the history of its arguments.

Let us now examine some special cases of Eq. (61). Assume first vacuole formation and growth depends only upon I_T, T, and the maximum shear strain ε_s (instead of $\tilde{I}_2$ and $\tilde{I}_3$ separately); the maximum shear

strain is given by

$$\varepsilon_s = \frac{\varepsilon_1 - \varepsilon_3}{2} \tag{62}$$

where ε_1 and ε_3 are, by definition, the algebraically largest and smallest principal strains, respectively; note that $\varepsilon_s \geq 0$. Equation (61) Becomes

$$I_T = G\left\{\frac{\theta}{3K_e}\ ,\ \varepsilon_s\ ,\ T\right\}\ . \tag{63}$$

A special case of G, which turns out to fit the general form of Farris' uniaxial, constant strain-rate data [11] is the piecewise linear algebraic function

$$I_T = \begin{cases} \dfrac{\theta}{3K_e} & : \varepsilon_s < b_s \\[2ex] \dfrac{\theta}{3K_e} + a_s(\varepsilon_s - b_s) & : \varepsilon_s \geq b_s\ ;\ (a_s,\ b_s) \geq 0 \end{cases} \tag{64}$$

where a_s and b_s may be functions of θ, T, and $\dot{\varepsilon}_s$. It is seen that the material is idealized such that vacuoles do not form until the maximum shear strain, ε_s, reaches b_s; thus, large positive values of θ are precluded.

Alternatively, we could, as in Section A, suppose that the constitutive function is independent of $\tilde{I}_3$. For easy reference we record here the special result derived earlier (see Eq. (20)):

$$I_T = \begin{cases} \dfrac{\theta}{3K_e} & : \tilde{I}_2 < b^2 \\[2ex] \dfrac{\theta}{3K_e} + a(\sqrt{\tilde{I}_2} - b) & : \tilde{I}_2 \geq b^2 \end{cases} \tag{65}$$

Equations (63) and (64) will be called the <u>maximum shear strain</u>

theory (MSS) while Eq. (61), without dependence on $\tilde{I}_3$, and Eq. (65) will be called the octahedral shear strain theory (OSS) because this strain invariant is proportional to $\sqrt{\tilde{I}_2}$. We now examine the implications of Eq. (64) for the uniaxial, strip-biaxial, and double-lap simple shear tests.

Uniaxial test (MSS): For this test, with or without a confining pressure, the principal strains ε_1, ε_2, and ε_3 are

$$\varepsilon_1 \equiv \varepsilon_u = \text{applied axial strain} \tag{66a}$$

and

$$\varepsilon_2 = \varepsilon_3 \tag{66b}$$

The invariants I_1 and ε_s are

$$I_1 = \varepsilon_u + 2\varepsilon_3 \text{ and } \varepsilon_s = (\varepsilon_u - \varepsilon_3)/2. \tag{67}$$

Substituting Eq. (66) into (64) and solving for ε_3 yields, for $\varepsilon_s \geq b_s$:

$$\varepsilon_3 = \frac{3\alpha\Delta T + \frac{\theta}{3K_e} - a_s b_s - (1 - \frac{a_s}{2})\,\varepsilon_u}{(2 + a_s/2)} \quad . \tag{68}$$

Also for $\varepsilon_s \geq b_s$, the dilatation becomes

$$I_1 = 3\alpha\Delta T + \frac{\theta}{3K_e} + \frac{3a_s}{4+a_s}\left[\varepsilon_u - \frac{4b_s}{3} - \alpha\Delta T - \frac{\theta}{9K_e}\right] \tag{69}$$

When $\varepsilon_s < b_s$, set $a_s = 0$ to obtain the dilatation.

Note that the last term in Eq. (69) is the vacuole dilatation; viz,

$$I_v = \frac{3a_s}{4+a_s}\left[\varepsilon_u - \frac{4b_s}{3} - \alpha\Delta T - \frac{\theta}{9K_e}\right] \tag{70}$$

which applies when the condition

$$\varepsilon_s = \frac{\varepsilon_u - \varepsilon_3}{2} \geq b_s \tag{71a}$$

is satisfied. Upon substitution of ε_3, Eq. (68), into Eq. (71a) we find

$$\varepsilon_u \geq \frac{4b_s}{3} + \alpha\Delta T + \frac{\theta}{9K_e} \tag{71b}$$

which is simply the requirement that the vacuole dilatation be non-negative.

Strip-biaxial test (MSS): The strip is assumed to be clamped in place at the reference temperature, for which $\Delta T = 0$. Further, the grips are assumed to be so rigid that the strain in the length direction, ε_2, is essentially zero for all loading conditions. The principal strains are, therefore

$$\varepsilon_1 \equiv \varepsilon_b = \text{applied strain} \tag{72a}$$

$$\varepsilon_2 = 0 \tag{72b}$$

$$\varepsilon_3 = \text{thickness strain} \tag{72c}$$

The invariants are

$$I_1 = \varepsilon_b + \varepsilon_3 \quad , \quad \varepsilon_s = \frac{\varepsilon_b - \varepsilon_3}{2} \tag{73}$$

The basic dilatational Eq. (64) yields for $\varepsilon_s \geq b_s$:

$$\varepsilon_3 = \frac{3\alpha\Delta T + \frac{\theta}{3K_e} - a_s b_s - (1 - \frac{a_s}{2})\,\varepsilon_b}{(1 + a_s/2)} \tag{74}$$

and

$$I_1 = 3\alpha\Delta T + \frac{\theta}{3K_e} + \frac{2a_s}{2+a_s}\left[\varepsilon_b - b_s - \frac{3}{2}\alpha\Delta T - \frac{\theta}{6K_e}\right] \tag{75}$$

where the last term is the vacuole dilatation:

$$I_v = \frac{2a_s}{2 + a_s} [\varepsilon_b - b_s - \frac{3}{2} \alpha\Delta T - \frac{\theta}{6K_e}] \tag{76}$$

which is valid when $\varepsilon_s \geq b_s$; i.e.

$$\varepsilon_b \geq b_s + \frac{3}{2} \alpha\Delta T + \frac{\theta}{6K_e} \tag{77}$$

When Eq. (77) is not satisfied, the vacuole dilatation is given by Eq. (76) with $a_s = 0$.

Simple shear test (MSS): The specimen is assumed to be clamped in position at the reference temperature for which $\Delta T = 0$. It is also assumed that the outer two plates are rigidly fastened together and the specimen is thin with respect to the dimensions in the plane of shearing and is long in the direction of shearing. Under these assumptions, the specimen is in a state of simple shear in the plane of shearing. The principal strains are

$$\varepsilon_1 = \gamma/2 \tag{78a}$$

$$\varepsilon_2 = \text{thickness strain} \tag{78b}$$

$$\varepsilon_3 = -\varepsilon_1 = -\gamma/2 \tag{78c}$$

where

γ = applied shear strain

= shear displacement/specimen dimension normal to displacement.

The invariants I_1 and ε_s become

$$I_1 = \varepsilon_2 \quad \text{and} \quad \varepsilon_s = \gamma/2 \quad . \tag{79}$$

We find the thickness strain (for $\varepsilon_s \geq b_s$) from Eq. (64):

$$\varepsilon_2 = 3\alpha\Delta T + \frac{\theta}{3K_e} + a_s(\frac{\gamma}{2} - b_s) \tag{80}$$

and, in terms of the maximum principal strain, ε_1:

$$I_1 = 3\alpha\Delta T + \frac{\theta}{3K_e} + a_s(\varepsilon_1 - b_s) \quad . \tag{81}$$

where the vacuole dilatation is now

$$I_v = a_s(\varepsilon_1 - b_s) \tag{82}$$

The condition $\varepsilon_s \geq b_s$ is the same as $\varepsilon_1 \geq b_s$; also, set $a_s \equiv 0$ whenever $\varepsilon_1 < b_s$.

<u>Representation of vacuole dilatation in terms of strains due to externally applied loads (MSS)</u>: If after clamping, but prior to loading in a test machine, the specimens are subjected to a temperature change, ΔT, and pressurization, $p = -\theta/3$, the strains in this state are:

$$\varepsilon_u = \alpha\Delta T + \frac{\theta}{9K_e} = \alpha\Delta T - \frac{p}{3K_e} \qquad \text{(uniaxial test)} \tag{83a}$$

$$\varepsilon_b = \frac{3}{2}\alpha\Delta T + \frac{\theta}{6K_e} = \frac{3}{2}\alpha\Delta T - \frac{p}{2K_e} \qquad \text{(biaxial test)} \tag{83b}$$

$$\varepsilon_1 = 0 \qquad \text{(shear test)} \tag{83c}$$

where, for the biaxial and shear tests, we have assumed $\nu \approx \frac{1}{2}$, which implies the three principal stresses under external pressure, p, are all approximately equal to -p.

If the specimens are now strained in the test machine, the principal strains ε_{ue}, ε_{be}, ε_{se}, say, due to the externally applied load are equal

to the difference between ε_u, and ε_b, and ε_1 and the respective initial strains (83):

$$\varepsilon_{ue} = \varepsilon_u - \alpha\Delta T + \frac{p}{3K_e} \qquad \text{(uniaxial test)} \qquad (84a)$$

$$\varepsilon_{be} = \varepsilon_b - \frac{3}{2}\alpha\Delta T + \frac{p}{2K_e} \qquad \text{(biaxial test)} \qquad (84b)$$

$$\varepsilon_{se} = \varepsilon_1 \qquad \text{(shear test)} \qquad (84c)$$

Now, θ for the uniaxial test is

$$\theta = -3p + \sigma_u \qquad (85a)$$

and for the biaxial test

$$\theta = -3p + \frac{3\sigma_b}{2} \qquad (85b)$$

where σ_u and σ_b are the stresses applied by the testing machine to the uniaxial and strip-biaxial specimens, respectively.

Upon substituting Eqs. (84) and (85) into Eqs. (70), (76), and (82) we find

$$I_v = \frac{3a_s}{4+a_s}\left[\varepsilon_{ue} - \frac{4}{3}b_s - \frac{\sigma_u}{9K_e}\right] \qquad \text{(uniaxial test)} \qquad (86a)$$

$$I_v = \frac{2a_s}{2+a_s}\left[\varepsilon_{be} - b_s - \frac{\sigma_b}{4K_e}\right] \qquad \text{(biaxial test)} \qquad (86b)$$

$$I_v = a_s[\varepsilon_{se} - b_s] \qquad \text{(shear test)} \qquad (86c)$$

Recall that K_e is the bulk modulus in the unstressed state. Thus, the terms $\sigma_u/9K_e$ and $\sigma_b/4K_e$ are expected to be relatively small, and therefore will be neglected in the remainder of Section D. Analogous terms will be neglected in the OSS theory.

We now turn to the application of Eq. (65) to prediction of dilatation in the three tests. Essentially the same steps as in the MSS theory are followed in predicting vacuole dilatation from the OSS theory; consequently, we shall omit the details of the derivations. The strains ε_{ue}, ε_{be}, and ε_{se} are defined in the same way in both theories.

Uniaxial test (OSS): The vacuole dilatation is found to be

$$I_v = \frac{3a}{\sqrt{6}+a}\left(\varepsilon_{ue} - \sqrt{\frac{2}{3}}\, b\right) \tag{87}$$

when $\varepsilon_{ue} \geq \sqrt{\frac{2}{3}}\, b$; for smaller strains set $a \equiv 0$.

Strip-biaxial test (OSS): The vacuole dilatation is not predicted to be piecewise linear for this test. Instead, for $\varepsilon_{be} \geq b/\sqrt{2}$ it is defined by the quadratic equation,

$$\left(\frac{1}{a^2} - \frac{2}{3}\right) I_v^2 + 2I_v\left(\frac{b}{a} + \varepsilon_{be}\right) I_v + \left(b^2 - 2\varepsilon_{be}^{\,2}\right) = 0 \tag{88a}$$

with the positive root being

$$I_v = \frac{ab}{\left(1 - \frac{2a^2}{3}\right)}\left[-1 - \frac{a}{b}\,\varepsilon_{be} + \sqrt{\frac{2}{3}\,a^2 + \frac{2a}{b}\,\varepsilon_{be} + \left(2 - \frac{a^2}{3}\right)\frac{\varepsilon_{be}^2}{b^2}}\,\right] \tag{88b}$$

Simple shear test (OSS): A quadratic relation is also found for the vacuole dilatation in the shear test:

$$\left(\frac{1}{a^2} - \frac{2}{3}\right) I_v^2 + 2\,\frac{b}{a}\, I_v + b^2 - 2\varepsilon_{se}^{\,2} = 0 \tag{89a}$$

The positive root of this equation is

$$I_v = \frac{ab}{\left(1 - \frac{2a^2}{3}\right)}\left[-1 + \sqrt{\frac{2a^2}{3} + \left(2 - \frac{4}{3}\,a^2\right)\frac{\varepsilon_{se}^{\,2}}{b^2}}\,\right] \tag{89b}$$

Comparison of MSS and OSS theories: Figures 1-3 illustrate vacuole dilatation predicted by Eqs. (86) and (87)-(89). The quantity a_u

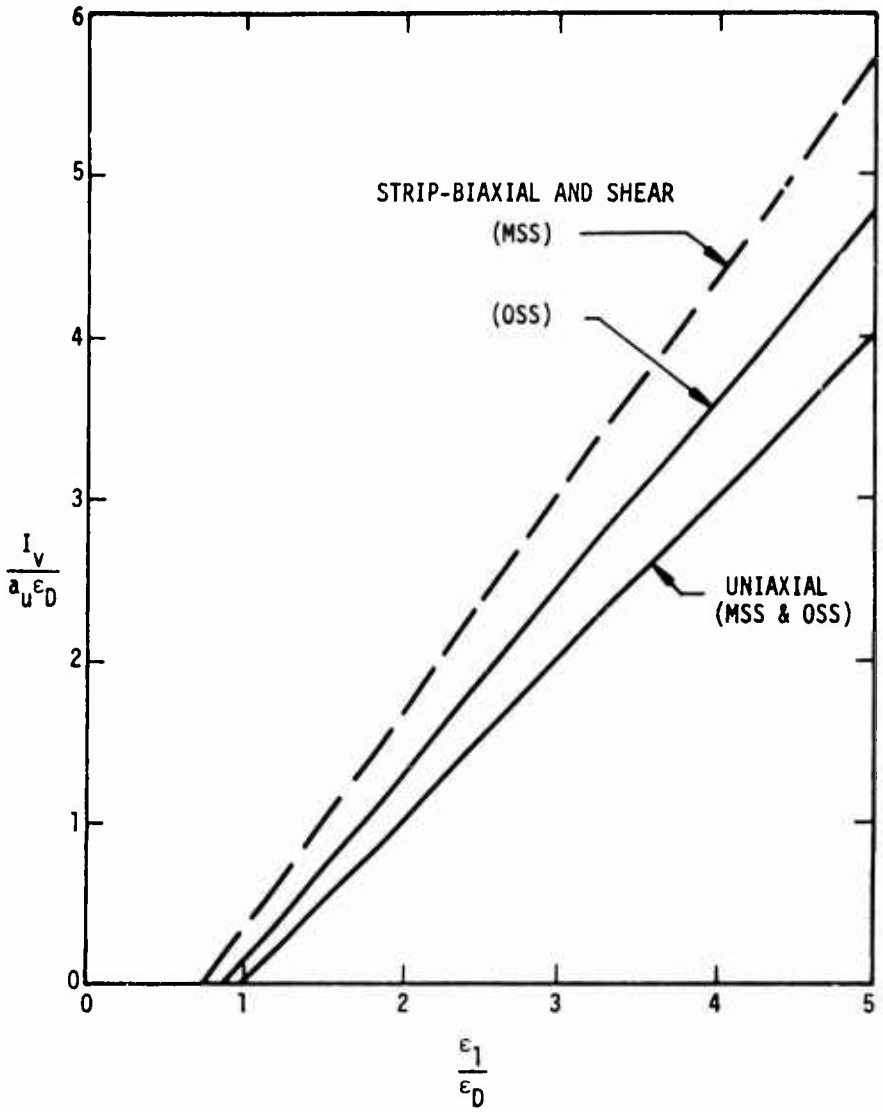

Figure 1. Comparison of Octahedral and Maximum Shear Strain Theories for $a_u << 1$.

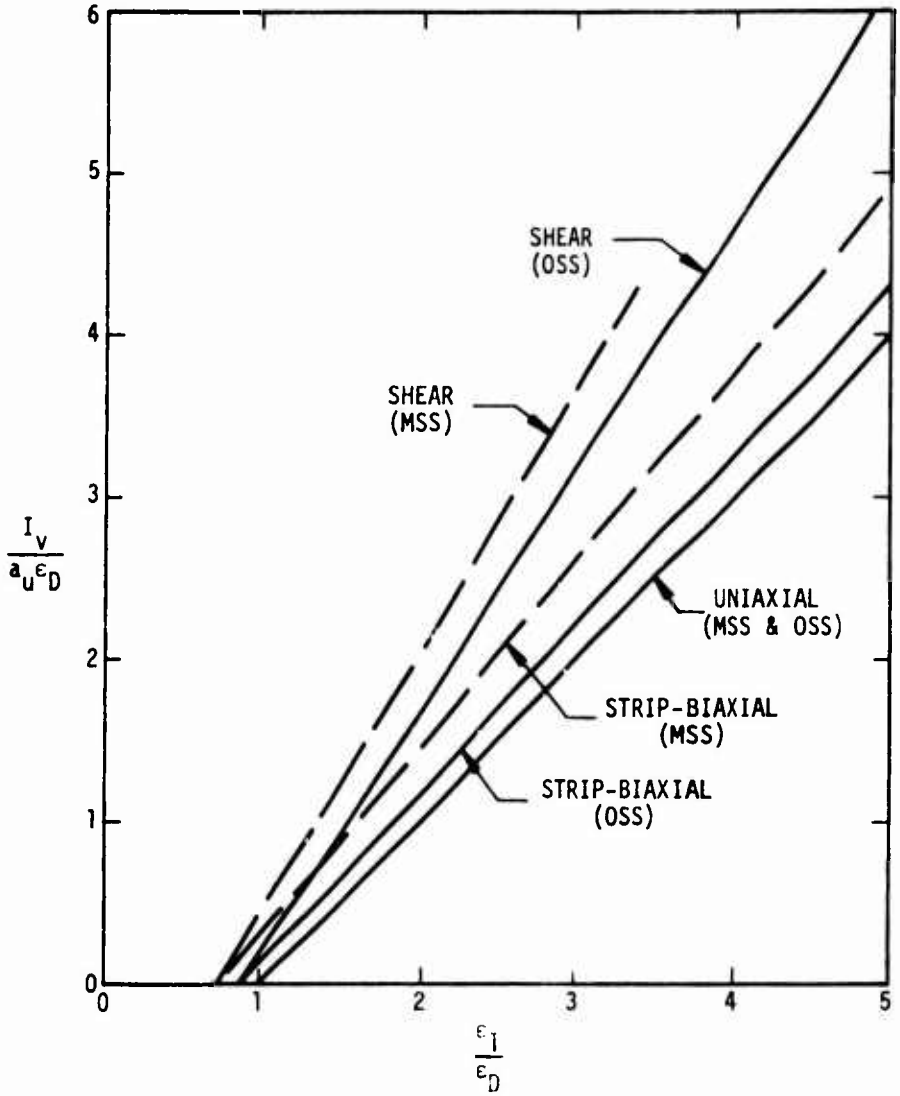

Figure 2. Comparison of Octahedral and Maximum Shear Strain Theories for $a_u = 0.5$.

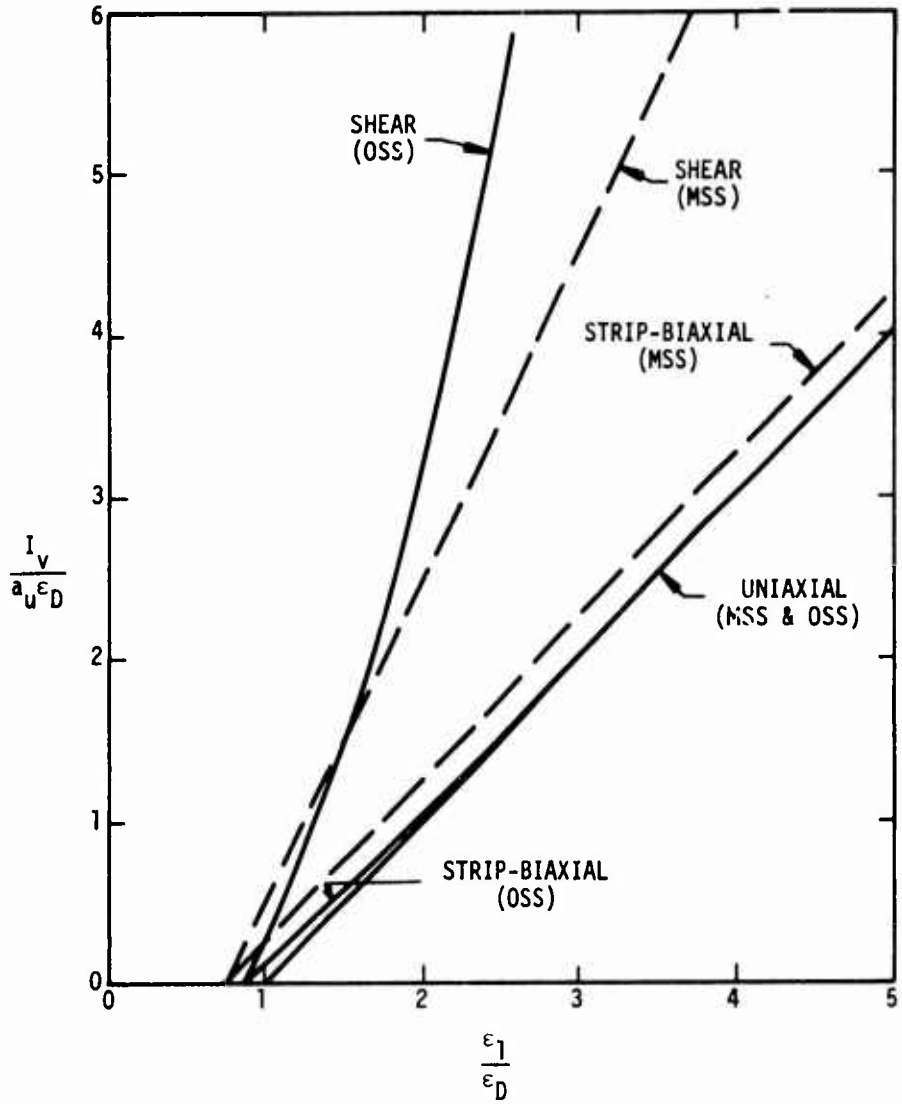

Figure 3. Comparison of Octahedral and Maximum Shear Strain Theories for $a_u = 1$.

is the slope of the dilatation vs. strain line in uniaxial tension; also, ε_D is the value of uniaxial strain at which the dilatation line intersects the strain axis. The same values of a_u and ε_D were used in both theories so that the same vacuole dilatation would be predicted for the uniaxial test. With the normalized variables used in Figs. 1-3, the graphs are independent of ε_D and the predictions in Fig. 1 are independent of a_u as well; the range $0 < a_u \leq 1$ in these figures brackets the range of values a_u observed for solid propellant under constant strain rate.

It is seen that, for given a_u and ε_D, the following inequality is true for each theory:

$$I_v \text{ (uniaxial)} < I_v \text{ (biaxial)} \leq I_v \text{ (shear)} \tag{90}$$

Moreover, except for the shear prediction in Fig. 3, the MSS theory predicts a greater dilatation than the OSS theory in each test. These observations provide a basis for evaluating the relative accuracy of each theory from experimental data. Note that, according to these figures, use of shear and uniaxial data is better for this purpose than biaxial and uniaxial data when a_u is close to unity.

E. Microstructural Damage Theory

In this section the damage parameters and their effect on constitutive equations are examined in the context of viscoelastic fracture mechanics theory. First, however, we shall consider their role in the special dilatational constitutive equations (64) and (65), and in the shear equation (19b) with respect to vacuole dilatation.

Vacuole dilatation: According to Farris' microstructural model for vacuole dilatation [11], the volume fraction of solids about which vacuoles exist is proportional to the slope of the vacuole dilatation vs. uniaxial strain curve; experimental studies showed that this constant of proportionality is approximately unity [11]. Thus, the increase of dilatation with strain when $dI_v/d\varepsilon_u$ = constant is attributed to expansion of the cavities around the particles. With this model as motivation, let us now suppose for the sake of argument that (i) the relative change in damage parameters β_K is small when $dI_v/d\varepsilon_u$ is constant and (ii) this change per cycle remains small in subsequent unloading and loading cycles. We are assuming, in effect, that the major change in β_K occurs during the first loading as the invariant $\tilde{I}_2$ (or ε_s) is increased from zero to its value when $dI_v/d\varepsilon_u$ first becomes constant, and that there is little, if any, rehealing when the speciment is unloaded.

In Farris' model [11] and in the model proposed above it is not actually necessary to assume the microstructural damage is entirely in the form of dewetting. The case in which many (or all) particles have a skin of binder adhering to them is not precluded and, as a result, the term vacuole dilatation, rather then dewetting, is used in this report.

Referring now to the simple constitutive relations Eq. (19) we see that if the above two suppositions are valid then the parameters K_e and G_e are the bulk modulus and shear modulus, respectively, in the range $\tilde{I}_2 < b^2$, after the sample has undergone strains for which $\tilde{I}_2 > b^2$. Some change in these parameters from cycle-to-cycle can be expected as additional damage occurs with each cycle. The bulk modulus K_e will be less than that for the undamaged propellant since the specimen, after being unloaded,

will have a larger void volume fraction than existing in the undamaged propellant; this point is supported by the experimental data in Section III.

The above model can be easily incorporated into viscoelastic constitutive equations. For example, referring to Eq. (44), in which all three material property functions depend on the elastic free energy F_e, we would simply use for F_e the special form in Eq. (14) together with Eqs. (17) and (18).

Microcrack initiation and growth: The state of the propellant at strains for which $dI_v/d\varepsilon_u$ is constant is the end result of an extensive amount of micro-flaw growth which occurs within the binder and/or between binder and filler particles. In this subsection we model the initial flaws as cracks and examine the implications of viscoelastic fracture mechanics theory in predicting the dependence of damage parameters on applied loading history. Thus, while the preceding subsection dealt with the final stage of damage, this subsection is concerned with the initial stage. Through a combination of the two models a constitutive theory applicable to all strains is proposed.

In the following theoretical development we assume, for simplicity, that the viscoelastic body is subjected to external uniaxial tensile stress, $\sigma = \sigma(t)$, and that the cracks propagate in only the so-called opening mode. Proposed generalizations to an arbitrary state of applied stress and to other crack propagation modes are given at the end of this subsection.

We suppose that there exists an initial distribution of cracks within the binder and possibly between binder and filler; the size of each crack

is assumed to be defined by a single parameter, $2a_o$, representing the length or diameter of the crack. As the loading on the body is increased from zero a given crack will start to grow when the stress intensity factor* at the tip, N_o, exceeds a certain critical value, N_{or}. This value is identical to that for an elastic continuum whose Young's modulus, E, and Poisson's ratio, ν, are equal to the long-time (rubbery) values E_r and ν_r respectively, for the actual viscoelastic material [3]; thus

$$N_{or} = \sqrt{\frac{\Gamma E_r}{\pi(1 - \nu_r^2)}} \tag{91a}$$

where Γ is the fracture energy. If the stress intensity factor equals or exceeds the value based on initial (glassy) modulus E_g and Poisson's ratio

$$N_{og} = \sqrt{\frac{\Gamma E_g}{\pi(1 - \nu_g^2)}} \tag{91b}$$

then the crack velocity is predicted to be very high, and is limited only by wave action. We shall say the material surrounding a given crack is "failed" if $N_o \geq N_{og}$; the time at which N_{og} is first reached will be called the <u>failure time</u>.

The fracture theory in [3] can be used to predict time-dependent

---

*The stress intensity factor is defined in the singular stress distribution near the crack tip,

$$\sigma_y = N_o/\sqrt{x}$$

where σ_y is the stress normal to the crack plane and x is the distance ahead of the tip.

crack size when $N_{or} < N_o < N_{og}$ and failure time for each crack in a propellant specimen under the following assumptions: (i) the rubber binder is linearly viscoelastic; (ii) the Poisson's ratio of the binder is constant (we shall assume $\nu = 1/2$); (iii) all filler particles are rigid relative to the binder; and (iv) the propellant specimen is linearly viscoelastic with crack sizes fixed, and is under a spacewise uniform temperature.

Now the crack velocity, $\dot{a}$, when $N_{or} < N_o < N_{og}$ is governed by the equation [3]

$$D(t_\alpha) = \frac{4\Gamma}{3\pi N_o^2} \tag{92a}$$

with

$$t_\alpha = \alpha/3\dot{a} \tag{92b}$$

and

$$\alpha = \pi^2 N_o^2/\sigma_m^2 I_1^2 \tag{92c}$$

where existing information on rubber indicates that the fracture energy Γ and the stress distribution in the failure zone behind the tip, $\sigma_m I_1$, are constant. The quantity $D(t_\alpha)$ is the creep compliance in uniaxial tension expressed in terms of the "effective time," t_α; also, α is the length of the failure zone behind the tip.

It is further assumed that during <u>most</u> of the time required for local failure, the creep compliance is given by the power law,*

$$D(t) = D_1(t/a_T)^n \tag{93}$$

where D_1 and n are constants. Also, from the time the body is first loaded, $t = 0$, to the failure time for a given crack we assume the crack is isolated.

---

*However, at very short and long times, $D(t) \to E_g^{-1}$ and $D(t) \to E_r^{-1}$, respectively.

That is, the crack is assumed to be so small that the only geometric parameter affecting crack growth is its own instantaneous size, 2a; in support of this point for cracks which are <u>initially</u> isolated, it is shown in [3] that the crack size at 90 percent of the failure time is only $10^n \times (2a_o)$; e.g., if n = 0.3, most of the time required for failure is consumed while the crack doubles in size. The stress intensity factor for the $i^{\underline{th}}$ isolated crack satisfying the assumptions (i) - (iv) listed just above Eq. (92) can be written in the form [3]

$$N_{oi} = \sqrt{a_i}\, f_i\, \sigma \tag{94}$$

where $2a_i$ is the size of the $i^{\underline{th}}$ crack and the coefficient f_i is a measure of state of stress existing in the binder in the neighborhood of the $i^{\underline{th}}$ crack relative to the applied stress; f_i, which will be called a <u>stress concentration factor</u>, is independent of material properties and depends only on the local particle geometry and spacing. According to the theory in [3], Eq. (94) is identical to the stress intensity factor in an <u>elastic</u> binder; thus, in principle, elastic analysis can be used to derive f_i if desired.

We combine Eqs. (92-4) and find the instantaneous size of the $i^{\underline{th}}$ crack at time t:

$$\frac{1}{a_{oi}^{1/n}} - \frac{1}{a_i^{1/n}} = f_i^{\,q} \int_o^t \left\{ \frac{3^{(1-n)}\, D_1\, \pi^{(2n+1)}}{4n^n \Gamma\, \sigma_m^{2n}\, I_1^{2n}} \right\}^{1/n} \frac{\sigma^q}{a_T}\, dt \tag{95a}$$

where the curly bracket in the integrand will be a function of time if chemical aging occurs and/or if there is rehealing (which are accounted for through time-dependent properties). Also,

$$q \equiv 2(1 + \frac{1}{n}) \tag{95b}$$

The failure time of this crack is denoted by t_i, and is obtained by letting $a_i \to \infty$; it can be written in the form of a linear cumulative damage relation:

$$1 = \int_0^{t_i} \frac{dt}{t_{ci}} \tag{96a}$$

where t_{ci} would be the failure time for the $i^{\underline{th}}$ crack if the specimen had been subjected to a timewise constant stress, σ, (applied at $t = 0$) equal to the actual stress at the time t, and had constant material and fracture properties equal to those actually existing at the time t:

$$t_{ci} = (A^{-\frac{1}{n}})(f_i^{-q})(a_{oi}^{-\frac{1}{n}})(M^{-\frac{1}{n}})(\sigma^{-q})a_T \tag{96b}$$

where A is a constant and is the group of terms in curly brackets in Eq. (95a) at a preselected reference state, and M is the ratio of this group at time t to the reference value. <u>Without</u> aging and rehealing M is unity; otherwise $M = M(t)$, and, although not essential, we assume M is the same function for all cracks.

We substitute Eq. (96b) into (96a) and solve for the stress concentration factor required to produce failure at time t_i:

$$f_i = \frac{Ba_{oi}^{-\frac{1}{nq}}}{||\sigma||_{Mq}} \tag{97a}$$

where

$$B \equiv A^{-\frac{1}{nq}} \tag{97b}$$

and $||\sigma||_{Mq}$ is a "weighted" Lebesgue norm,

$$||\sigma||_{Mq} \equiv \left\{ \int_0^{t_i} M^{\frac{1}{n}} \sigma^q \frac{dt}{a_T} \right\}^{\frac{1}{q}}$$

$$= \left\{ \int_0^{\xi_i} M^{\frac{1}{n}} \sigma^q \, d\xi \right\}^{\frac{1}{q}} \tag{97c}$$

in which ξ is reduced time,

$$\xi \equiv \int_0^t \frac{dt}{a_T} \tag{97d}$$

Of course, without aging and rehealing we set $M = 1$ and obtain the Lebesque norm itself in terms of reduced time. Note also that, from Eq. (95b),

$$\frac{1}{nq} = \frac{1}{2(n+1)} = \frac{1}{2} - \frac{1}{q} \tag{97e}$$

Thus, for all cracks in which $f \geq f_i$ failure of the surrounding material has occurred. Cracks with smaller concentration factors have not yet failed. When the time t_i is exceeded for a given crack, the growth will be very rapid until the tips are arrested at filler particles and/or the tips move into a region of low stress concentration. We shall assume that the increase in the $i^{\underline{th}}$ crack size from the time t_i to the time the crack is arrested, t_{ai}, say (or, at least, until its velocity reduces to a relatively small value) is much larger than $2a_o$, and that the time difference $t_{ai} - t_i$ is negligible compared to t_i. Let us denote the crack size at time t_{ai} as $2a_{ai}$; since $a_{ai} >> a_{oi}$ and in view of the comments immediately following Eq. (93) we conclude that the influence of the $i^{\underline{th}}$ crack on overall mechanical response is felt approximately at the time t_i, and the magnitude of this influence is directly related to the total growth, $2a_{ai} - 2a_{oi} \approx 2a_{ai}$. <u>Interaction between cracks when $t > t_i$ is allowed</u>.

Let us now predict the increment in specimen strain that results when the $i^{\underline{th}}$ crack grows to length $2a_{ai}$ at the time t_i. In view of the linearity assumption this increment can be calculated by superposition. Specifically, consider the normal stress distribution that acts across an imaginary surface, where this surface is identical to the fracture surface which is later formed when the crack grows to length $2a_{ai}$. The increment in specimen strain due to actual crack growth is identical to that resulting from a sudden superposition of a pressure distribution at time t_i, whose magnitude is equal to the normal stress distribution existing across the imaginary surface following failure. This pressure is proportional to applied stress σ. Linearity plus dimensional analysis yield the following strain increment for a thermorheologically simple material if the applied stress is constant for $t > t_i$:

$$\varepsilon_i = S_i \, \sigma \, D(\xi - \xi_i) \tag{98a}$$

where ξ is defined in Eq. (97d) and

$$\xi_i \equiv \int_0^{t_i} \frac{dt}{a_T} \tag{98b}$$

Also, $D(\xi)$ is the uniaxial creep compliance of the propellant in terms of reduced time; it should be added that with rigid particles and linearity, dimensional analysis can be used to show that this creep compliance is proportional to the insitu compliance of the binder. The coefficient S_i is a constant.

Extension of Eq. (98) to a time varying stress following time t_{ai} is readily accomplished by superposition as long as further change in crack length is small compared to $2a_{ai}$. Specifically, introduce the

Heaviside unit-step function,

$$H(\xi - \xi_i) \equiv \begin{cases} 1, & \xi > \xi_i \\ 0, & \xi < \xi_i \end{cases} \tag{99}$$

where $\xi_i \equiv \xi(t_i)$. Then the strain is

$$\varepsilon_i = S_i \int_0^{\xi} D(\xi - \xi') \frac{d[H(\xi' - \xi_i)\sigma]}{d\xi'} d\xi' \tag{100}$$

Since the Dirac delta function, δ, is given by

$$\delta(\xi - \xi_i) = \frac{d\, H(\xi - \xi_i)}{d\xi} \tag{101}$$

Eq. (100) can be written explicitly as

$$\varepsilon_i = S_i \sigma_i D(\xi - \xi_i) + S_i \int_{\xi_i}^{\xi} D(\xi - \xi') \frac{d\sigma}{d\xi'} d\xi' \tag{102}$$

where $\sigma_i \equiv \sigma(\xi_i)$.

We now turn to a statistical description of the microcracking problem, and thereby derive a constitutive equation by summing over the strains given by Eq. (102). First, define g_i as

$$g_i \equiv \frac{f_i (a_{oi})^{\frac{1}{nq}}}{B} \tag{103}$$

The stress concentration factor f_i and initial flaw size are random variables which, in turn, imply g_i is a random variable. Likewise, S_i is a random variable. Dropping the subscript (i) we write the expression for the <u>number</u> of cracks, N_c, having g-values between g and g + dg, <u>and</u> S-values between S and S + dS in the form

$$N_c = n(S, g)\, d\, S\, d\, g \tag{104}$$

The distribution function $n = n(S, g)$ can be calculated from a distribution function in terms of the three random variables a_o, f. and S, which will be demonstrated later. Equation (104) will be used in the constitutive theory development.

It is to be noted that g and failure time are directly related through a deterministic relation, which is obtained by combining Eqs. (97a) and (103),

$$g(\xi_f) = \frac{1}{||\sigma||_{Mq}} \equiv \left\{ \int_o^{\xi_f} M^{\frac{1}{n}} \sigma^q d\xi \right\}^{-\frac{1}{q}} \tag{105}$$

where ξ_f is now used as the generic variable representing reduced failure time.

The strain due to all microcracking, ε_m, say, at reduced time ξ, is obtained by multiplying Eq. (100) by (104), replacing ξ_i by ξ_f, and integrating over all possible S-factors ($-\infty < S < \infty$) and all possible g-values corresponding to $0 \leq \xi_f \leq \xi$. There results, finally,

$$\varepsilon_m = \int_o^{\xi} D(\xi - \xi') \frac{d}{d\xi'} \left\{ \sigma \int_{g'}^{\infty} G(g)\, dg \right\} d\xi' \tag{106}$$

where

$$g' \equiv g(\xi') = \left\{ \int_o^{\xi'} M^{\frac{1}{n}} \sigma^q\, d\xi \right\}^{-\frac{1}{q}} \tag{107}$$

and $G = G(g)$ is the following distribution function:

$$G \equiv \int_{-\infty}^{\infty} S\, n(S, g)\, dS \tag{108}$$

In view of the linearity assumption, the total axial strain, ε, is

that due to the externally applied stress acting on <u>undamaged</u> propellant,

$$\varepsilon_u \cong \int_0^{\xi} D(\xi - \xi') \frac{d\sigma}{d\xi'} d\xi' \tag{109}$$

plus the strain ε_m; viz, from Eqs. (106) and (109),

$$\varepsilon = \int_0^{\xi} D(\xi - \xi') \frac{d}{d\xi'} \left\{ \sigma[1 + \int_{g'}^{\infty} G(g)\, dg] \right\} d\xi' \tag{110}$$

where g' is given by Eq. (107) in terms of a weighted Lebesque norm at time ξ'. In view of Eq. (107), we see $\int_{g'}^{\infty}$ is a <u>non-decreasing</u> function of time (without rehealing).

A distribution function G(g) of particular interest is the power law

$$G = \begin{cases} G_1\, g^{-r} & , \quad g \leq g_m \\ 0 & , \quad g > g_m \end{cases} \tag{111}$$

where g_m, G_1, and r are constants; this function will be used later.

Before examining some special cases of Eq. (110) we shall derive the relation between n = n(S, g) in Eq. (104) and the dist-ibution function for stress concentration factor and initial crack size. The distribution function m = m(S, a_o, f) is defined by the condition that N_{fa} is the number of cracks having S-values between S and S + dS, a_o-values between a_o and $a_o + da_o$, and f-values between f and f + df:

$$N_{fa} = m(S, a_o, f)\, dS\, da_o\, df \tag{112}$$

The number of cracks N_c in Eq. (104) is equal to the integral of N_{fa} over the area in the a_o - f plane bounded by the curves g = constant and g + dg = constant, where f and a_o satisfy Eq. (103). After equating N_c

to the area there results

$$n(S, g) = B \int_0^\infty m(S, a_o, Bga_o^{-\frac{1}{nq}})\, a_o^{-\frac{1}{nq}}\, da_o \tag{113}$$

As an example, if m is a power law in f,

$$m = m_1(S, a_o)\, f^\alpha \tag{114a}$$

where α is a constant, we find that n(S, g) is given by a power law in g,

$$n(S, g) = B^{1+\alpha}\, g^\alpha \int_0^\infty m_1(S, a_o)\, a_o^{-\frac{1}{nq}(1+\alpha)}\, da_o \tag{114b}$$

By substituting this result into Eq. (108) the function G(g) is found to be the power law in Eq. (111) with $r = -\alpha$ and $g_m = \infty$.

We now examine two special cases of Eq. (110) in order to help bring out the physical significance of this constitutive equation.

<u>Elastic specimen</u>: It is assumed that the creep compliance appearing in Eq. (110) is a constant, D, say; but the compliance in the fracture theory is still the power law, Eq. (93). These assumptions are not inconsistent. This point follows from the fact that the effective time t_α in fracture Eq. (92) is typically several decades smaller than that governing the overall mechanical response of the binder [3]; thus, for example, crack growth may be controlled by viscoelastic processes at the same time the binder response is essentially in its long-time elastic response range.

Equation (110) reduces to

$$\epsilon = D\sigma \left\{ 1 + \int_g^\infty G(g)\, dg \right\}$$

where (115)

$$g = g(\xi) = ||\sigma||_{Mq}^{-1}$$

Equation (115) shows that the microscopic damage is characterized by a single function of the weighted Lebesque norm $||\sigma||_{Mq}$, as in Eq. (110). This result is analogous to that obtained by Farris [2], but the role of stress and strain is reversed.

The power law distribution Eq. (111) reduces this theory to

$$\varepsilon = D\sigma \left\{ 1 + \frac{G_1}{r-1} \left[(||\sigma||_{Mq})^{r-1} - g_m^{1-r} \right] \right\} \tag{116a}$$

when $r \neq 1$, and

$$\varepsilon = D\sigma \left\{ 1 + G_1 \ln[||\sigma||_{Mq}\, g_m] \right\} \tag{116b}$$

when $r = 1$. Solution (116) is valid for only the range $||\sigma||_{Mq} \geq g_m^{-1}$; when $||\sigma||_{Mq} < g_m^{-1}$ failure has not occured and one must set $G_1 = 0$. If $g_m = \infty$, the integral in Eq. (115) converges only if $r > 1$; for this case Eq. (116a) shows that the strain will be approximately homogeneous to degree one in stress if r is close to unity.

<u>Creep of a viscoelastic specimen:</u> We set $\sigma = \sigma_c\, H(\xi)$, where σ_c = constant, and use the viscoelastic theory to predict creep compliance with microcracking, $D_c \equiv \varepsilon/\sigma_c$. For simplicity, isothermal behavior ($a_T = 1$) without rehealing and aging ($M = 1$) is assumed and both power laws Eqs. (93) and (111) will be used with $g_m = \infty$.

From Eq. (107),

$$g' = g(t') = \sigma_c^{-1} (t')^{-\frac{1}{q}} \tag{117}$$

where we have set $\xi' = t'$. Equation (110) yields

$$D_c \equiv \frac{\varepsilon}{\sigma_c} = D_1\, t^n \left[1 + \frac{G_1 B}{q} (\sigma_c)^{r-1}\, t^{\frac{r-1}{q}} \right] \tag{118}$$

where the constant B is a Beta function,

$$B \equiv \int_0^1 (1 - u)^n (u)^{\frac{1}{q}(r-1)-1} du \tag{119}$$

For propellant $n \simeq 0.2$, which implies $q \simeq 12$, and therefore if r is close to unity we see $D_c \sim t^n$ and that D_c is nearly independent of stress. The value $r = 1$ is not admissible since $B = \infty$ for this case.

<u>Generalizations of the constitutive theory with microcracking</u>: The above constitutive theory, Eq. (110), is a special case of the nonlinear theory, Eq. (47), based on thermodynamics. Indeed, we may recover the present theory from Eq. (47) by assuming:

$$Q = \theta \tag{120a}$$

$$\frac{\partial F_s}{\partial \theta} = B(\infty)\, \theta / 9a_G \tag{120b}$$

$$\frac{\partial F_s}{\partial \tilde{J}_2} = J(\infty)/4a_G \tag{120c}$$

$$a_\varepsilon = a_T \tag{120d}$$

$$\frac{1}{a_G} = 1 + \int_{g'}^{\infty} G(g)\, dg \tag{120e}$$

where

$$g' = \left\{ \int_0^{\xi'} M^{\frac{1}{n}} \left| A_1\theta + A_2\sqrt{\tilde{J}_2} \right|^q d\xi \right\}^{-\frac{1}{q}} \tag{120f}$$

and A_1 (or A_2) is an arbitrary constant. However, A_2 (or A_1) must satisfy the following relation in order that the three-dimensional theory reduce to uniaxial Eq. (110):

$$A_2 = \sqrt{\frac{3}{2}}\,(1 - A_1) \tag{120g}$$

Clearly, there is a single damage parameter in this representation which reflects the extent of microcracking; it is weighted Lebesque norm $||A_1\theta + A_2\sqrt{J_2}||_{Mq}$ in Eq. (120f). Moreover, if A_1 and A_2 are positive, pressure ($\theta < 0$) is seen to correctly suppress the amount of crack growth.

It should also be recalled that M reflects the effect of aging and/or rehealing. This function is unity in the absence of these effects, but otherwise is given by

$$M = \frac{D_1}{D_{1r}} \frac{\Gamma_r}{\Gamma} \frac{(\sigma_m I_1)_r^{2n}}{(\sigma_m I_1)^{2n}} \tag{121}$$

where subscript r denotes constant quantities corresponding to a preselected reference state; also, recall that D_1 is the coefficient in creep compliance Eq. (93) and that Γ and $(\sigma_m I_1)$ are fracture properties.

The above theory was developed under the assumption that cracks propagate in the opening mode. However, the equations governing fracture in shearing modes are believed to be analogous to the opening mode case [3] and, therefore, we suggest that Eq. (120) may be valid regardless of the crack mode. However, further study is needed to confirm this point or else to determine if the more general theory, Eq. (47), is valid.

It is important to recognize that the three-dimensional theory based on Eq. (47) along with Eq. (120) is identical to linear theory except stresses are multiplied by a scalar factor, $1/a_G$. Hence, the inverse formulation in which the stress tensor is expressed as a functional of the strain tensor likewise will be identical to linear theory except σ_{ij} is replaced by σ_{ij}/a_G. This latter formulation suffers from the fact that the Lebesque norm is expressed in terms of stress invariants rather than strain invariants; consequently, it generally will not be possible to

obtain an explicit representation for stresses in terms of strains and strain invariants.

Let us now consider how the microcracking model can be combined with nonlinear constitutive equations to obtain a theory which is potentially applicable to a wide range of propellant behavior. First, it should be recalled that Eq. (110) is based on the assumption that cracks are (approximately) arrested after rapid growth. As the applied stress is increased one can expect these previously arrested cracks to again propagate, thereby producing significant vacuole dilatation and eventually gross failure. (It should be added that significant dilatation does not necessarily result from the first growth stage when the binder is relatively soft; e.g., when a crack is cut into a sheet of rubber having high ultimate elongation, and the sheet is stretched in a direction normal to the original crack plane, the crack may open so much that it again becomes a sharp crack with its plane parallel to the loading direction [1]. The net change in dilatation for this process is essentially zero.) If it can be assumed that the subsequent propagation obeys the previously developed model, we suggest that all damage may be characterized by the same function a_G, Eq. (120e), except the distribution function G(g) will depend on strain or stress invariants. Moreover, in the high stress range it probably will be necessary to account for nonlinear stress invariant-dependence in Q and in the derivatives of F_s appearing in Eq. (47). Similarly, strain formulation Eq. (30) may apply in the high strain range after the stress tensor is replaced by σ_{ij}/a_G.

F. Thermodynamic Constitutive Equations with Implicit Pressure Dependence

The strain formulation, Eqs. (5) and (30), and special cases, e.g. Eqs. (19) and (44), are based on the assumption that, except for damage parameters, the nonlinearities are defined by strain (rather than stress) invariants. In principle, one can retain the relatively simple forms of the special cases, but yet account for large superposed pressures. Referring to the thermodynamic theory in [17], it is easily shown that the Eqs. (5) and (30), and resulting special cases, may be applied to deformations superposed on the pressurized state. Namely, one interprets the stresses and strains, σ_{ij} and ε_{ij}, as values which are added to the values existing in a reference pressure state. All material properties may then depend on this pressure as well as strain invariants. In grain analysis, one could select as reference pressure that in the bore, and then account for its time-dependence just as one does for a spacewise uniform, transient temperature.

G. Generalization for Finite Strains

In all preceding three-dimensional equations make the substitutions [12],

$$\begin{aligned} \varepsilon_{ij} &\rightarrow E_{ij} \\ \sigma_{ij} &\rightarrow \frac{\rho_o}{\rho}\,\tau^{ij} \end{aligned} \tag{122}$$

where the deviatoric components of E_{ij} and τ^{ij} are calculated by using the same definitions as for small strain theory and

E_{ij} = Lagrangian (covariant) strain tensor

τ^{ij} = (contravariant) stress tensor referred to convected coordinates and measured per unit area of the deformed body.

ρ_o, ρ = density in the undeformed and deformed states, respectively.

III. EXPERIMENTAL INVESTIGATIONS

A. Test Equipment and Procedures

Poker chip tests: These tests were made on ANB-3335-1 solid propellant samples furnished by Aerojet Solid Propulsion Company (ASPC). As received, the samples were 4.5 by 4.5 by 0.33 inches. The upper and lower surfaces had been machined to attain the 0.33 in. thickness. Therefore, before attempting to bond these samples to the plattens used for loading, all loose oxidizer particles on the surface of the samples had to be removed; two methods were tried. The first method was to spread Duco cement on the surface of the propellant sample and then press a gauze bandage down firmly onto the cement. After the Duco cement dried for eight hours at room temperature, the gauze along with the cement, and hopefully the loose oxidizer particles, were gently peeled back from the surface of the propellant sample. This procedure was based on previous experience by others, in which it was found to lead to very good bonds. Two initial samples cleaned by the above technique and bonded to the steel plattens turned out to fail under low loads, with gross tearing occurring near the bond line where the material was extremely soft (probably due to the Acetone in Duco cement).

The second method used to remove the loose oxidizer particles was to press down strips of three-inch wide surgical adhesive tape across the surface of the propellant and then peal back gently. All samples used in the mechanical property tests were prepared in this way.

Steel plattens 0.25 in. thick and 4.00 inches in diameter were sand

blasted by a medium grit in order to prepare them for bonding to the sample. The surfaces were then cleaned using Acetone.

Uralane 8615 epoxy compound, a two-part epoxy mixed in approximately equal parts by weight and obtained from Furane Plastics, Los Angeles, California, was used to bond the propellant samples to the plattens. This epoxy is a black material which has a pot life of approximately twenty minutes once the two components are mixed and a complete curing time of about twenty-four hours. The mixed epoxy was placed on both propellant surfaces and spread as thinly as possible to eliminate bubbles. Two steel plattens were fixed in a lathe using centered pull rods which had been screwed into each plate. A poker chip specimen was completed and made ready for curing by placing the propellant coated with epoxy between the two plattens and then mechanically forcing the plattens against the samples. Since the samples would slide out if left alone, several pieces of tape were used to hold the sample centered on the plattens. The bonded sample was allowed to cure for twenty-four hours in this position at room temperature.

The specimen was then turned in a lathe at a very slow speed and excess propellant was trimmed off even with the steel plattens. Completed poker chip specimens were stored in a dry refrigerator maintained at 74°F and containing a desicant to maintain low humidity.

Just before a test, a teflon coated thermocouple girth wire was placed around the outside of the specimen midway between the two plattens, as shown in Fig. 4. One end of the girth wire was stripped and two closely spaced dots of solder were placed on this end of the wire; by

Figure 4. Poker-Chip Specimen Showing Girth Wire, LVDT's, and Micrometers.

inserting a horseshoe-shaped 1/4 in. long x 36 gage wire holder in between these closely spaced solder dots and into the propellant, the girth wire was secured at one end. This wire extended from the tiedown point completely around the circumference of the specimen and came off tangent to the tie-down point to then connect to a lever arm. Horseshoe-shaped portions of bare 36 gage wire were stuck into the propellant over the girth wire at intervals of approximately 0.4 inches, to hold it in position along the mid-plane between the two plattens.

An aluminum plate approximately 1/4 in. thick by 6.5 in. diameter was mounted on top of the upper platten and fastened securely with a nut on the pull rod. This upper plate was designed to accommodate three vertical micrometers at 120 degree spacings. Another aluminum plate of the same size and an S-shaped bracket were mounted securely on the lower side of the lower platten by tightening the nut on the lower pull rod. This lower aluminum plate was designed to accommodate three linear variable differential transformers (LVDT's) aligned with shafts from the three vertical micrometers on the upper plate. These vertical micrometers had a total travel of 0.05 in. which allowed us to make very fine in-place calibrations.

For tension tests the upper pull rod was attached to a universal joint which was in turn attached to a single lever arm loading frame, (see Fig. 5). The lower pull rod was attached to a universal joint which was in turn attached to a slip joint which engages only when the lever arm is loaded. An LVDT was attached to the S-shaped bracket that extends from beneath the lower platten to be in line with the girth wire. The other end

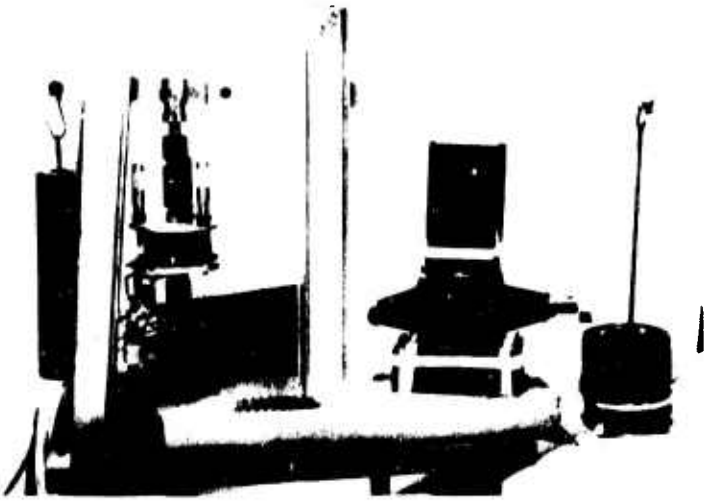

Figure 5. Poker-Chip Assembly used for Tensile tests.

of the LVDT was attached to a Chavetz micrometer which had a total travel of 1.0 in. A modified 4 - 4 1/2 in. hose clamp was attached to the lower platten to support a small L-shaped lever arm. The vertical arm of the lever was connected to the girth wire, while the horizontal arm was connected to a vertical wire extending to a slug within the LVDT mounted on the lower S-shaped bracket. The horizontal girth motion was thus transferred into a vertical motion and magnified by approximately four. With the Chavetz micrometer it was possible to attain an inplace calibration for the girth measurement. To insure that there was no sticking associated with the girth wire or LVDT's, a pulsing vibrator was attached to the frame of the test mechanism.

The three vertical LVDT's spaced 120 degrees apart around the sample were used to measure plate separation and to determine if there was bending in the sample. By averaging the three readings we obtained an overall average strain which, together with the girth measurement, enabled the determination of dilatation. Signals from all four LVDT's were fed into an amplification system that allowed us to obtain high gain settings and to maintain a linear output signal as a function of displacement for a given range.

For testing, the system was loaded to provide 10, 20, 35, and 50 psi average axial stress to the poker chip specimen. Testing was performed at a temperature of 74°F and at a relative humidity of between 34 and 40 percent. All tests were creep and recovery tests with cycles of five minutes creep, ten minutes recovery, and 15 minutes wait between cycles. There were one or two one-minute initial loadings at each load range before the

actual test to insure that the data readings would remain on scale and that the readings were still linear. Five to seven creep and recovery cycles were run for each load range, and only one load range was run per day. Compression tests were also run on poker chip specimens. The only difference in the compression test assembly was that instead of having the upper and lower universal joints attached to the upper and lower pull rods, respectively, heavy steel frames replaced the pull rods; one frame was used to attach the lower platten to the upper universal joint, and another frame connected the upper platten to the lower universal joint.

Strip-biaxial tests: Tests were performed on ANB-3066 and ANB-3335-1 solid propellant obtained from Aerojet Solid Propulsion Company. The biaxial dilatometer used for these tests was obtained from Hill Air Force Base on a loan basis and as received was in unworkable condition as originally manufactured by the CETEC Corporation. The unit was completely dissassembled, and after extensive modification was put into working condition. The dilatometer, shown in Fig. 6, was designed to measure dilatation by two different methods. The first method relied upon direct LVDT measurements of decrease in cross-sectional thickness. The LVDT system consisted of spring loaded probes that slide on the surface of the specimen's sides. Unfortunately the probes were not only insensitive to the small thickness changes but also damaged the surface of the propellant at the point of contact. As a result the LVDT probes were removed entirely, and we relied upon the second method of dilatation measurement. This method was based on state-of-the-art gas dilatometric techniques such as those employed by Farris [11].

The biaxial dilatometer consists of two chambers, a specimen chamber and reference chamber, which are completely separate from each other. The

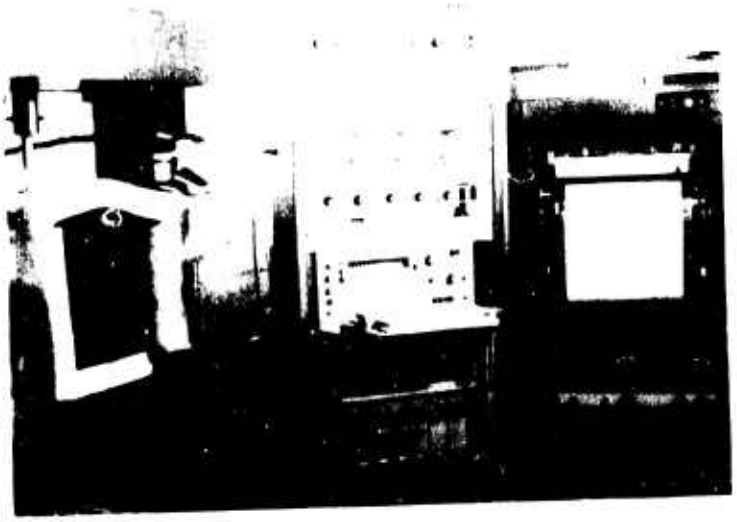

Figure 6. Biaxial Dilatometer Mounted in Instron Test Machine.

dilatometer was configured so that both chambers could be pressurized up to 1000 psi and equalized to the same pressure. Once all the leaks around the dilatometer, plumbing connections, door, shaft, and calibration micrometer were sealed at high pressure, the system was functional. The dilatometer was mounted in an Instron, and an extensometer was mounted to the shaft of the dilatometer to measure sample extension. Unlike other dilatometers which have a compensating shaft that extends from the reference chamber, the dilatometer used in these tests was not equipped with this reference chamber shaft; specimen chamber shaft movement was compensated electronically by coupling the shaft extension with the pressure change due to shaft movement alone.

Before each test, the unit was calibrated for volume change by inserting a precision micrometer shaft into the specimen chamber in increments to simulate a volume change of .00707 in^3 (for the samples used in our tests this corresponds to a volume change of about 0.5 percent). It was possible to resolve volume changes on the order of .01 to .02 percent over a relatively long period, provided the temperature remained constant. To insure constant test conditions, the tests were run in large walk-in chambers which were held to a constant temperature and humidity. The dilatometer and associated plumbing were wrapped thoroughly with insulation material (see Fig. 6) to prevent changes due to the body-heat of people in the room who are running the tests.

The propellant samples furnished by Aerojet were saw-cut into specimens with dimensions of 7.0 by 1.63 by 0.38 inches. Using a circular cutter, each end of each specimen was trimmed to remove the material included within a circular arc with an approximately one-inch radius connecting the two corners

at each end of the specimen, as shown in Fig. 7. The samples were then bonded to aluminum plates using the 8615 epoxy described in the poker-chip section above. The aluminum plates were prepared by first sand blasting the surface to be bonded and then placing masking tape around the plates so that the tape extended approximately 0.25 inches above the surface of the plates. The epoxy was then poured into the cups made by the masking tape to about half full. One 7.0 by 0.38 inch edge of the sample was pushed into the epoxy and against the aluminum plate. Care was taken to create a fillet around the sample as it emerged from the epoxy in order to provide for gripping and a gradual load transfer from the grips. A spacer was placed on each side of the samples to hold the propellant at the center of the aluminum plate while the epoxy cured for twenty-four hours. This process was then repeated for the opposite edge of the sample. After curing, the bonded samples were stored for at least twenty-four hours before testing in constant temperature and humidity walk-in chambers.

A bonded sample was fastened to loading rails and loaded into the dilatometer specimen chamber as shown in Fig. 8. The door was then put in place and bolted down.

If the test was to be run under pressure, the valve connecting the reference and specimen chambers was opened and the system was pressurized to the desired pressure. The valve was then closed to isolate the chambers again while the system stabilized for one to two hours. Just before running the actual test, the two chambers were equalized by opening the connecting valve and then closed to isolate them again. Also, as described above, the unit was calibrated for volume change. In addition, the internal load cell located within the dilatometer was calibrated.

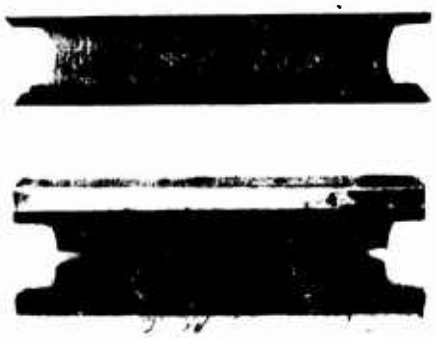

Figure 7. Unfailed and Failed Strip-biaxial Specimen End-Bonded to Aluminum.

Figure 8. Strip-biaxial Specimen Partly Inserted in Dilatometer.

Several types of tests were run including constant strain rate to failure, ramp-relaxation, and cyclic loading and unloading before loading to failure. Sample displacement, volume change, and load were recorded on a light sensitive oscillograph recorder.

Uniaxial tests: These tests were run on AND-3066 and ANB-3335-1 Aerojet propellant using the same biaxial dilatometer used for the strip-biaxial tests. The uniaxial samples were made from the 7.0 by 1.63 by 0.38 inch strip-biaxial specimens. Instead of cutting circular arcs of material away from the ends as was done for the biaxial samples, the rectangular samples were cut completely through to within 0.2 inches of each edge at intervals of 0.37 inches along the length of the sample. The samples were then bonded to the aluminum plates as described for biaxial specimens. This procedure provides nineteen uniaxial samples to be tested at one time, which are shown in Fig. 9.

B. Experimental Data and Comparison with Analysis

Poker-chip tests: Figures 10-13 show compliances and dilatation obtained from tension tests performed on samples Nos. 1 and 2, while Figs. 14-17 show these quantities for compression of sample No. 2. The creep and recovery compliances are defined as follows:

$$D_{pc} \equiv \frac{\varepsilon}{\sigma} \tag{123a}$$

$$D_{pc}^{(r)} \equiv \frac{\varepsilon_r}{\sigma} \tag{123b}$$

where σ is the total axial load divided by platen area, ε is the strain (based on platen separation) during the creep portion of one loading cycle,

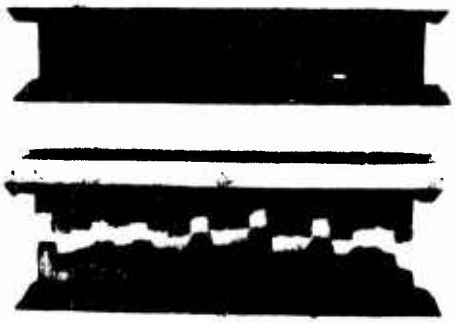

Figure 9. Unfailed and Failed Uniaxial Specimens End-bonded to Aluminum Plates.

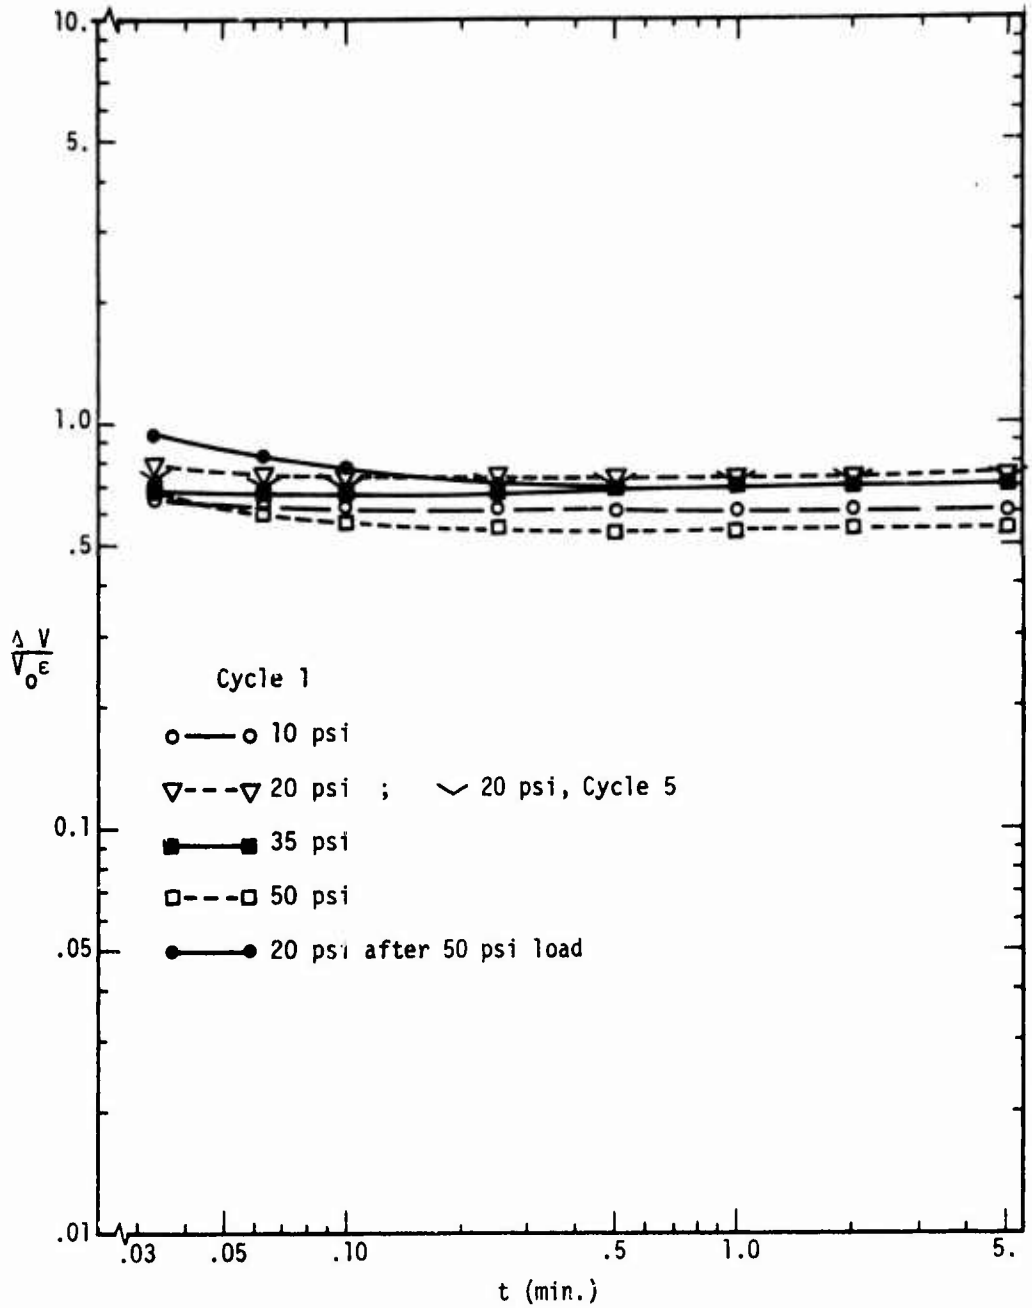

Figure 16. Poker Chip Dilatation in Creep-Compression.

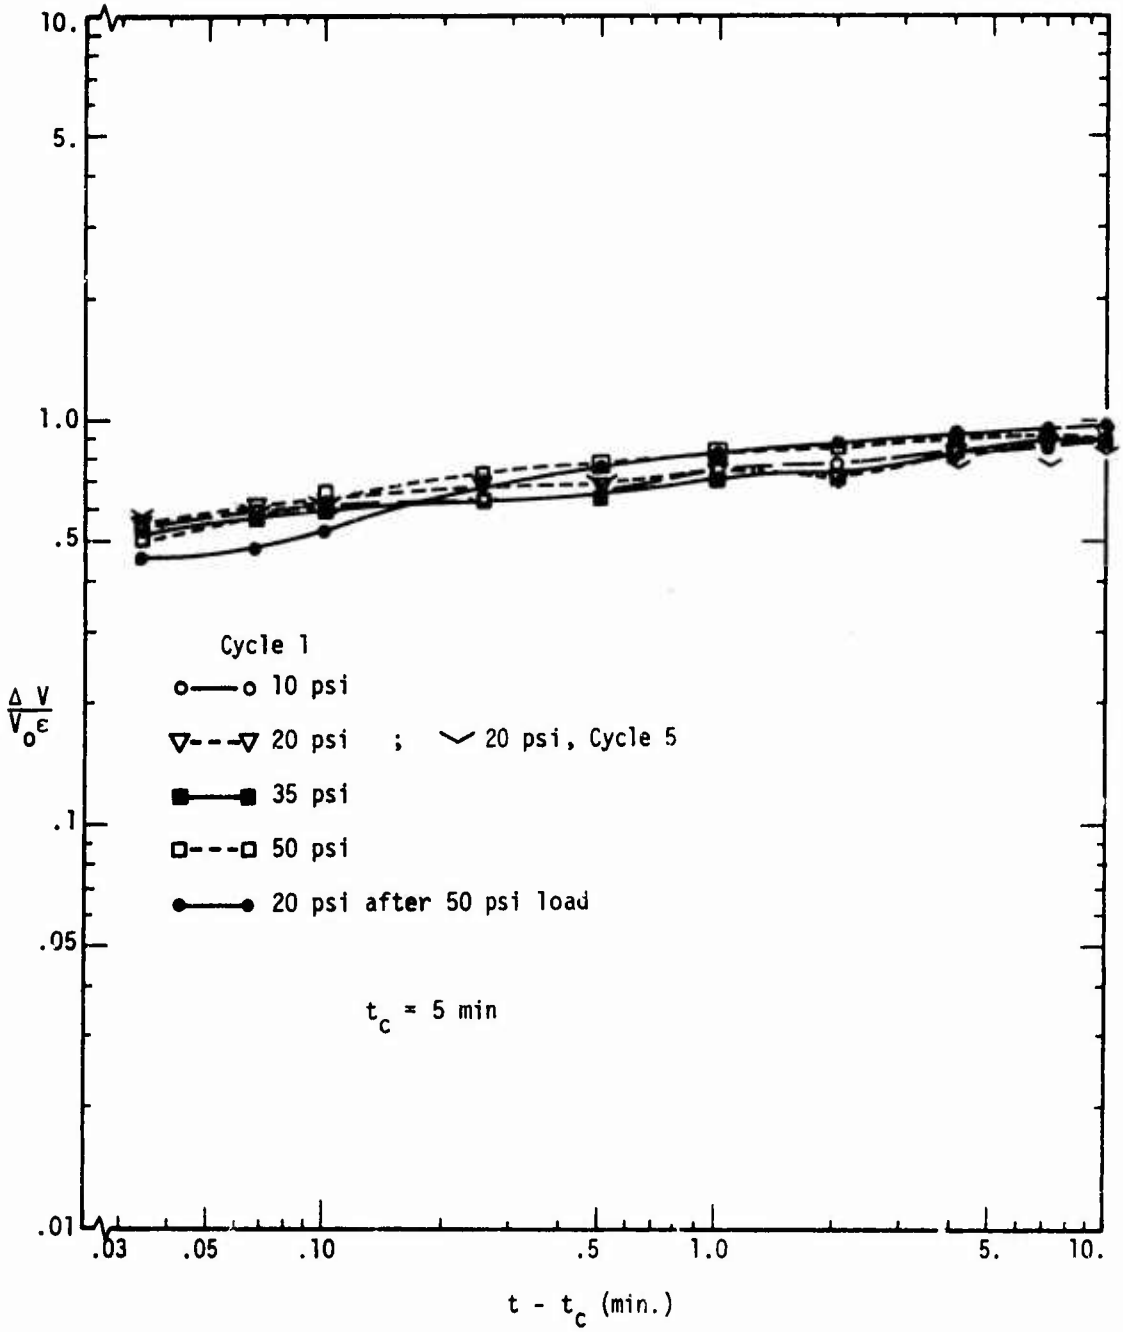

Figure 17. Poker Chip Dilatation in Recovery-Compression.

and ε_r is the recovery strain (which is the strain following load removal). The cycle numbers shown on the graphs represent a loading and unloading sequence, with cycle No. 1 defining the first sequence after the specimen had been loaded once or twice for calibration purposes. Therefore some damage had already been incurred, even before the data labeled cycle No. 1 was obtained. Note, however, that in most cases for each stress level no further significant increase in damage (as measured by changes in compliance and dilatation) appears to have occurred as the sample was cycled.

The dilatation shown in these figures was found using the same procedure described in [4] for earlier work at TAMU; specifically, the following equation was used:

$$\frac{\Delta V}{V_o} = \frac{V_{pl} - V_{para}}{V_o} \tag{124}$$

where

$V_{pl} \equiv$ volume displaced by moving platen

$V_{para} \equiv$ volume swept out by revolving the parabolic area at the periphery around the loading axis.

As an aid in interpreting the compliance and dilatation data, we show in Fig. 18 a graph that enables various property ratios to be deduced from the experimental data. This graph was obtained from a linear quasi-elastic analysis of a compressible poker-chip using the equations in [4]; a condensed version of this graph also appeared in [4]. The following definitions apply:

$E_{pc} \equiv D_{pc}^{-1} \approx$ effective relaxation modulus of poker chip

$D_u =$ creep compliance under uniaxial loading

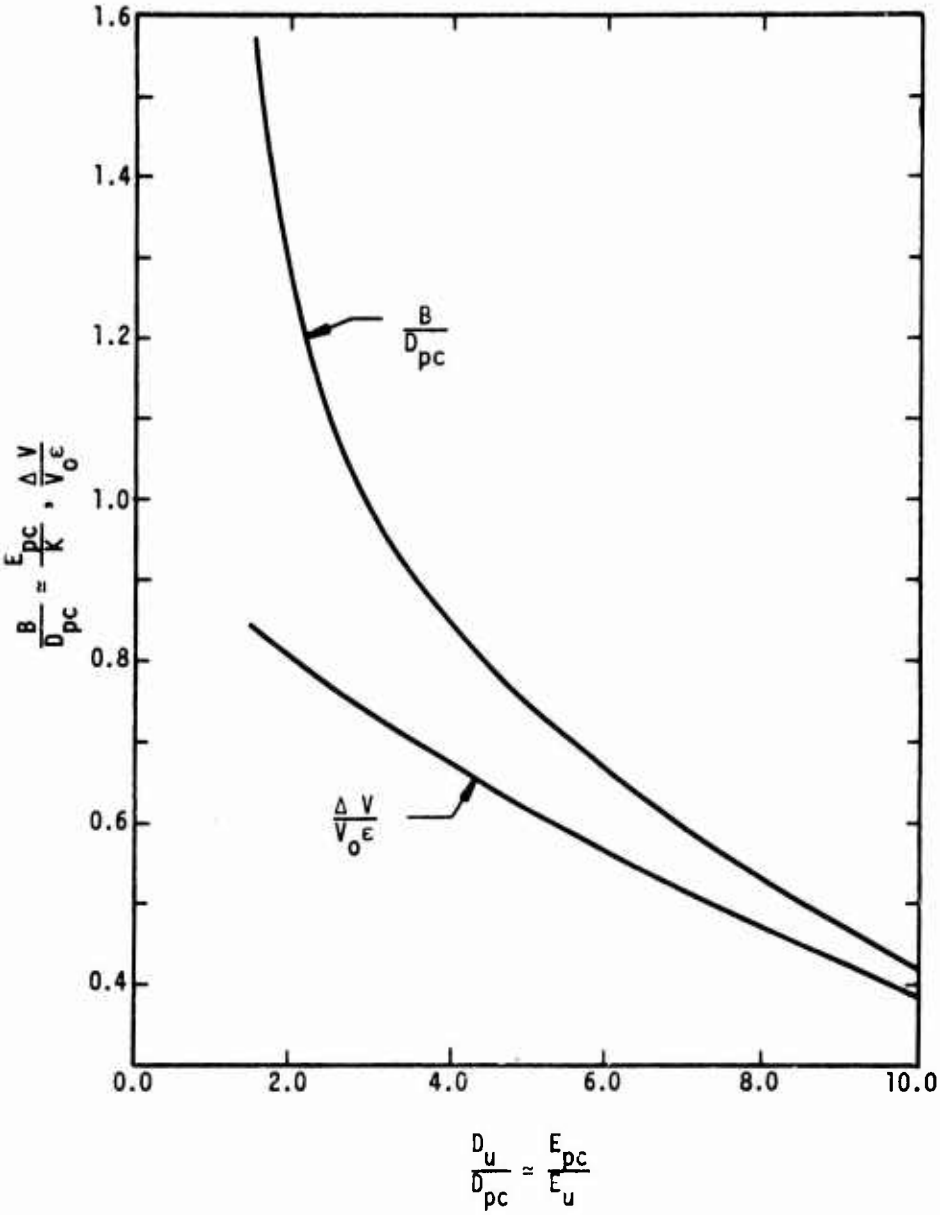

Figure 18. Property Ratios for Poker Chip (Dia/Thickness = 12).

B = bulk creep compliance

K = bulk relaxation modulus ($\simeq B^{-1}$)

E_u = relaxation modulus under uniaxial loading ($\simeq D_u^{-1}$)

In order to illustrate the use of this graph let us consider some of the data in Figs. 10-17. The ratio $\Delta V/V_o\varepsilon$ is reasonably constant in Fig. 12 and, for sample No. 2, has the approximate value of 0.7. Reading across and down from the $\Delta V/V_o\varepsilon$ curve in Fig. 18 we find $D_u/D_{pc} \simeq E_{pc}/E_u = 3.5$. Reading up to the B/D_{pc} curve and over to the ordinate we find $B/D_{pc} \simeq E_{pc}/K \simeq 0.9$.

From the compliance curve in Fig. 10 one can obtain D_{pc} at any time, and therefore calculate the remaining properties in these ratios. For example, at $t = 0.1$ min, $D_{pc}^{-1} \simeq 3000$ psi, and therefore $K \simeq 3300$ psi. This extremely low value predicted for bulk modulus (which is typical of the values obtained from the other data) is probably in error because of non-linear effects. However, it is believed that its order of magnitude is not unreasonable since the specimen probably has a significant void fraction as a result of prior loadings.

An observation of interest is that if $\Delta V/V_o\varepsilon$ is independent of time, as it is in Fig. 12 and in Fig. 16 except at short times, linear theory can be used to show that Poisson's ratio is constant. Now, a composite material consisting of a relatively incompressible viscoelastic binder together with voids and rigid particles can be shown to have a constant Poisson's ratio; this result is easily established by means of the linearity assumption plus dimensional analysis. This latter observation is, of course, consistent with the hypothesis that the poker chip specimens, as tested, contained a

large initial void fraction due to previously induced damage.

A partial check on the microcrack theory in Section II-E is provided by a comparison of creep and recovery data. First of all, consider the following isothermal constitutive equation relating average axial stress applied to the poker-chip, σ, and the axial strain, ε:

$$\varepsilon = \int_0^t D_p(t - t') \frac{d\,P(\sigma)}{dt'} dt' \tag{125}$$

where $P = P(\sigma)$ is a nonlinear function of stress. Also D_p is the <u>linear</u> viscoelastic poker-chip creep compliance. The creep and recovery compliances are predicted to be, respectively,

$$D_{pc}(t) = \frac{P}{\sigma} D_p(t) \tag{126a}$$

$$D_{pc}^{(r)} = \frac{P}{\sigma} [D_p(t) - D_p(t - t_c)] \tag{126b}$$

where t_c is the time at which the load is removed. Combining Eqs. (126a) and (126b) we find

$$D_{pc}^{(r)} = D_{pc}(t) - D_{pc}(t - t_c) \tag{127}$$

Since Eq. (125) with $P = \sigma$ is an exact equation for linear materials, we conclude that the recovery compliance for this special nonlinear theory is related to creep compliance in the same way as in linear theory. Equation (127) has been used to construct the theoretical recovery curves shown in Figs. 11 and 15. Considering the scatter in experimental data, predictions for the tension test are quite good. However, the theory is seen to underpredict recovery compliance in compression; the difference is believed to be due, at least in part, to rubbing between flaw faces which would impede recovery from a compressed state. In both tension and compression

the creep compliance varies appreciably with stress level.

Now, refer to the theory with microcracking. Rigorously, a nonlinear stress analysis of the poker-chip is required to interpret the data because the stresses are not spacewise uniform. However, we will argue that Eq. (110) is approximately valid for the tension tests after replacing D by D_p, if the underlying three-dimensional theory, Eqs. (47) and (120), are themselves correct.

Considering linear theory first, if Poisson's ratio, ν, is constant and the material is linear, the stresses throughout the poker-chip can be shown to be timewise constant during creep and zero during recovery. In tension tests, the thickness-averaged normal stresses are approximately equal and distributed parabolically across the radius (with the maximum occurring at the center), while the thickness-averaged shear stress increases linearly with radius from the center [18]. With this observation in mind, and assuming the stresses in a nonlinear poker-chip are distributed in the same general way, we suggest that the Lebesque norm of stress invariants in Eq. (120f) may be reasonably uniform. On physical grounds it can be argued that A_1 and A_2 are positive; therefore the variation in θ will tend to cancel that of $\sqrt{J}$ since the former invariant is large when the latter one is small and vice-versa. (This cancellation of effects will not occur with compression since both invariants increase algebraically with radius.) If indeed g', and therefore a_G, are essentially independent of radius, the relation between average stress and axial strain will be essentially the same as for linear theory except σ/a_G will replace stress; this can be shown by referring to the thickness-averaged field equations for the poker-chip [19].

Hence, by making the substitution $P \rightarrow \sigma/a_G$ in Eq. (125), the approximate equation with microcracking is obtained. That this equation successfully predicted recovery from creep would seem to imply a_G is essentially independent of time, although it depends on stress in view of the observed stress-dependence of creep compliance. For the power-law distribution function Eq. (111), we find during creep ($0 < t < t_c$):

$$\frac{1}{a_G} = 1 + C_1(\sigma)^{r-1}(t)^{\frac{r-1}{q}} \tag{128}$$

where C_1 is a constant; during recovery a_G^{-1} is given by Eq. (128) with $t = t_c$. For the data in Fig. 10, $n \approx 1/6$, which implies $q \approx 14$. Moreover, we find the stress-dependence of the creep compliance in Fig. 10 can be predicted by neglecting the unity term in Eq. (128) and setting $r \approx 1.8$. Thus, the time-dependence of a_G is relatively weak compared to that of the creep compliance itself. It is of interest to note in passing that the value $r = 2$ is predicted from an approximate distribution function for strain concentration factors derived by Farris [19] for spherical particles.

Strip-biaxial and uniaxial tests: A large number of constant strain rate tests were conducted at room temperature and at approximately -20°F in order to assess the accuracy of simplified constitutive equations in Sections II-A and II-D.

Although most of the tests were conducted on ANB-3335-1 propellant, a study of ANB 3066 at T = -20°F was made early in the program; typical results for stress and dilatation are shown in Fig. 19. The prediction of dilatation was made by first evaluating the constants a_s and b_s in the

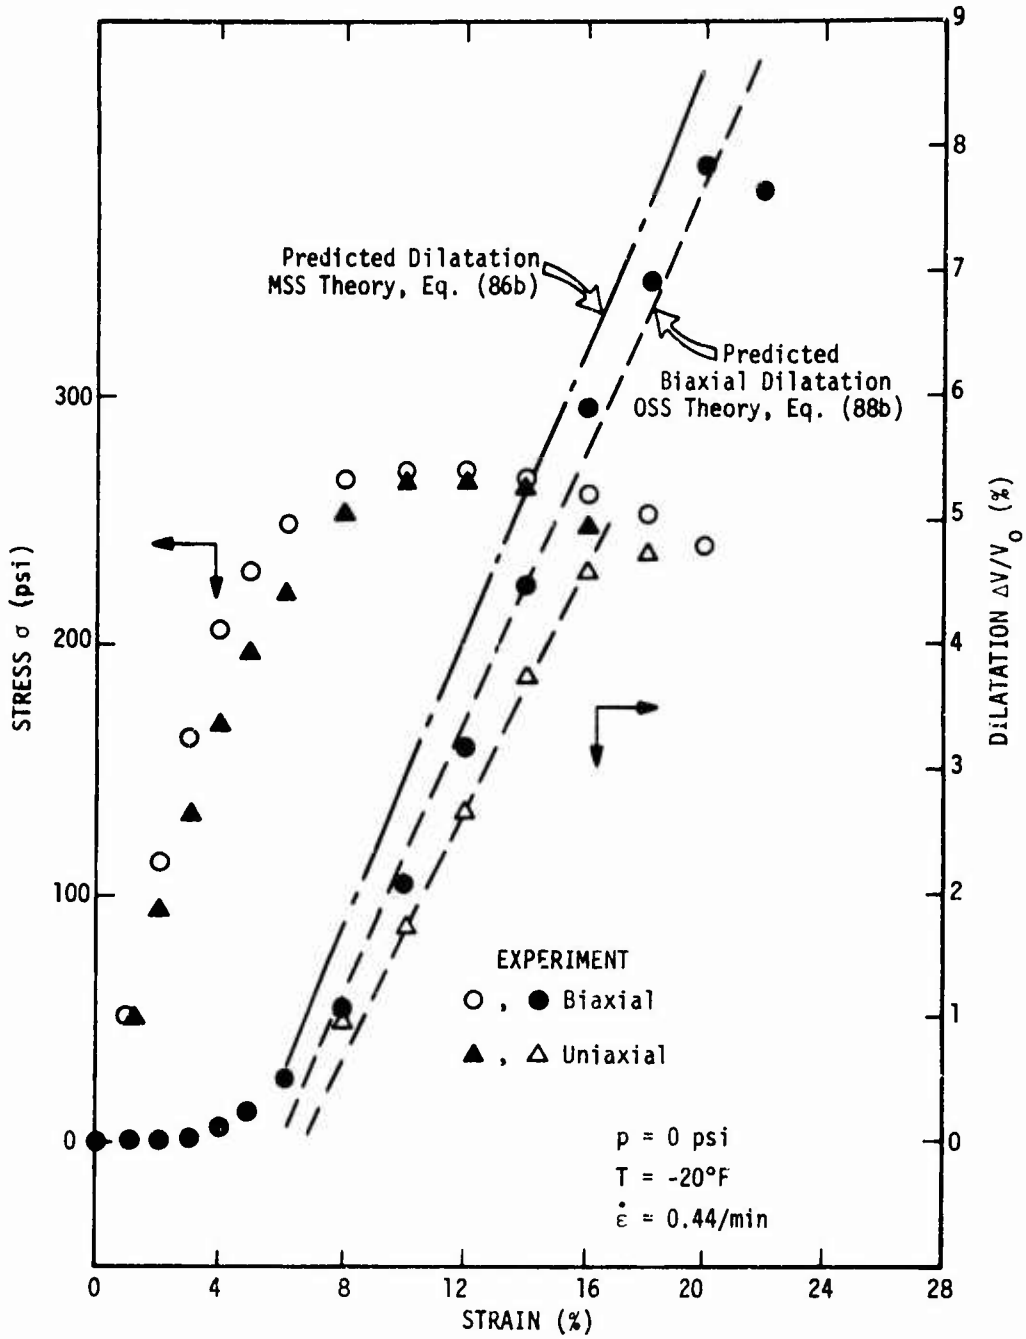

Figure 19. Uniaxial and Strip-Biaxial Data on ANB 3066 Propellant.

MSS theory and a and b in the OSS theory from the uniaxial data. Equations (86b) and (88b) were then used to construct the dilatation for the biaxial test. Obviously, the octahedral strain theory is most accurate for these data. Also, referring to Eq. (32), we find if $\beta \approx 2$ the stress can be predicted reasonably well.

Similar results were found for ANB 3335-1, as shown in Fig. 20. Again the OSS theory is seen to be better than the MSS theory. Also, for this case $\beta \approx 2$. Typical room temperature data on this propellant are given in Fig. 21, for which $\beta \approx 2.5$. The biaxial dilatation data now fall between the OSS and MSS theories. A study of the data obtained on several other specimens revealed that the OSS prediction was generally best, although some of the results were similar to that shown in Fig. 21. In most of these latter cases some of the uniaxial specimens cut from a single strip appeared to fail prematurely, which would account for the OSS prediction being low compared to the biaxial dilatation data.

In order to check the hypothesis that $\tilde{I}_3$ is absent from the dilatational constitutive Eq. (10) (or Eq. (61)), it is not, of course, necessary to use a piecewise linear representation of dilatation. If the term $\theta/3K_e$ is negligible in these equations, then a plot of the actual uniaxial and biaxial data on a graph of I_T vs. $\sqrt{\tilde{I}_2}$ will form a single curve if $\tilde{I}_3$ does not enter the constitutive equation. Figures 22-25 show such plots for 0 psi and 200 psi. Although there is some spread, the theory seems to be quite adequate for correlating the dilatation in the biaxial and uniaxial modes; most of the spread is believed due to premature failure of some uniaxial samples.

It should be added that in view of the relatively large strains involved, we have used invariants based on Lagrangian strains in Figs. 22-25; see

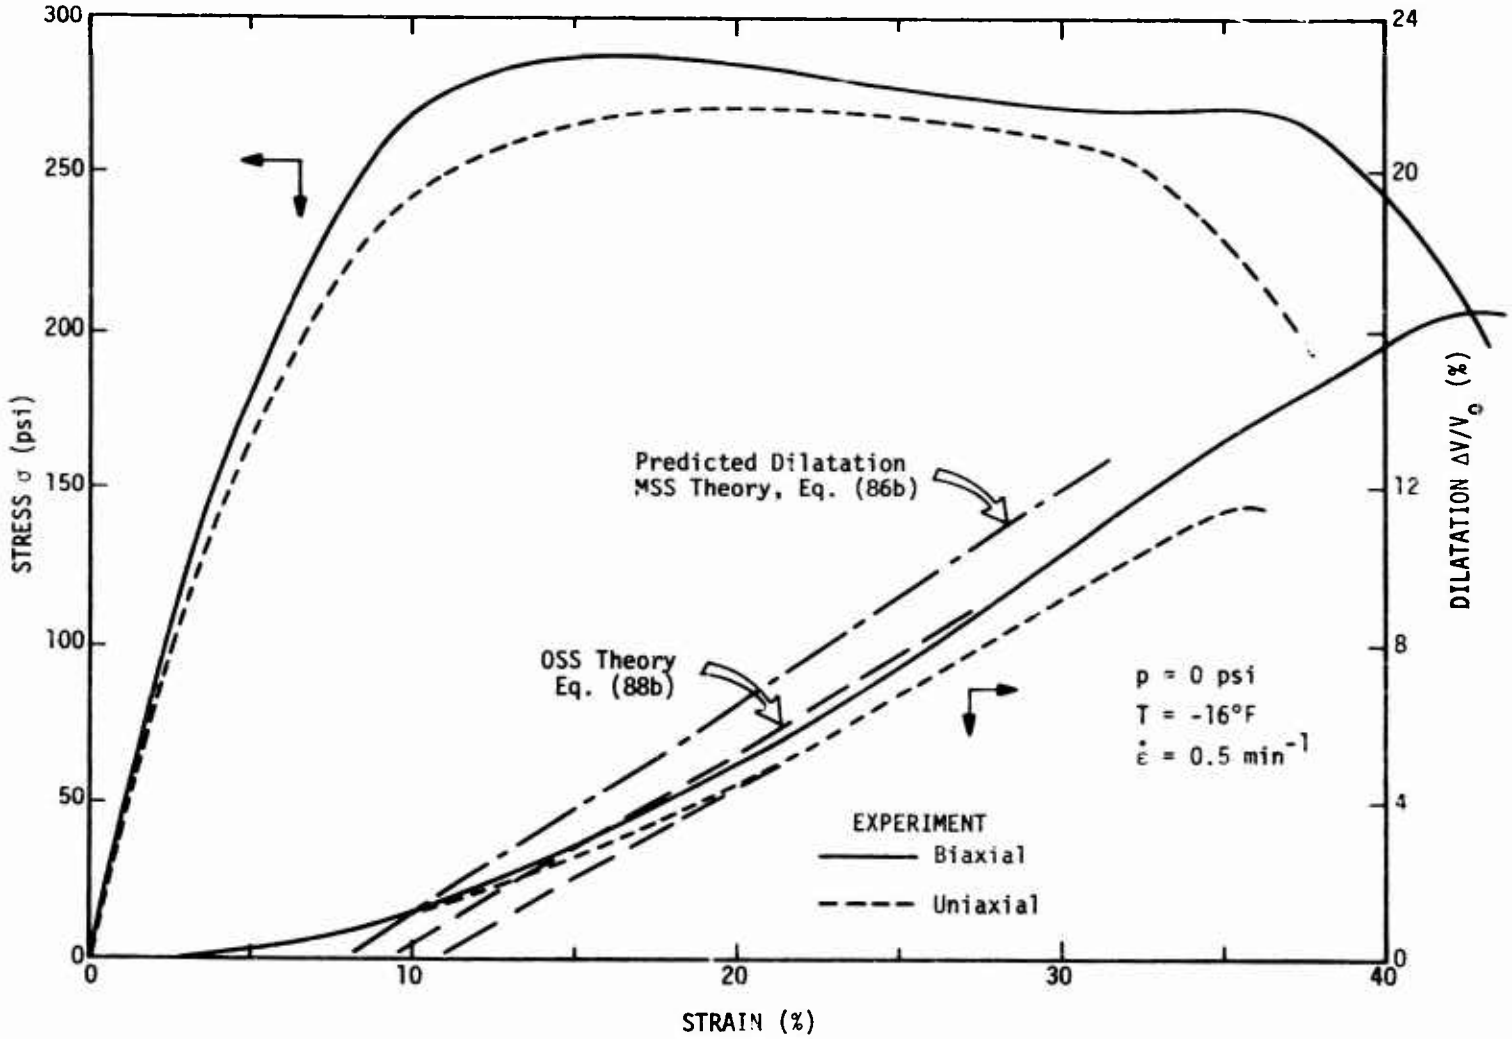

Figure 20. Uniaxial and Strip-Biaxial Data on ANB 3335-1 Propellant.

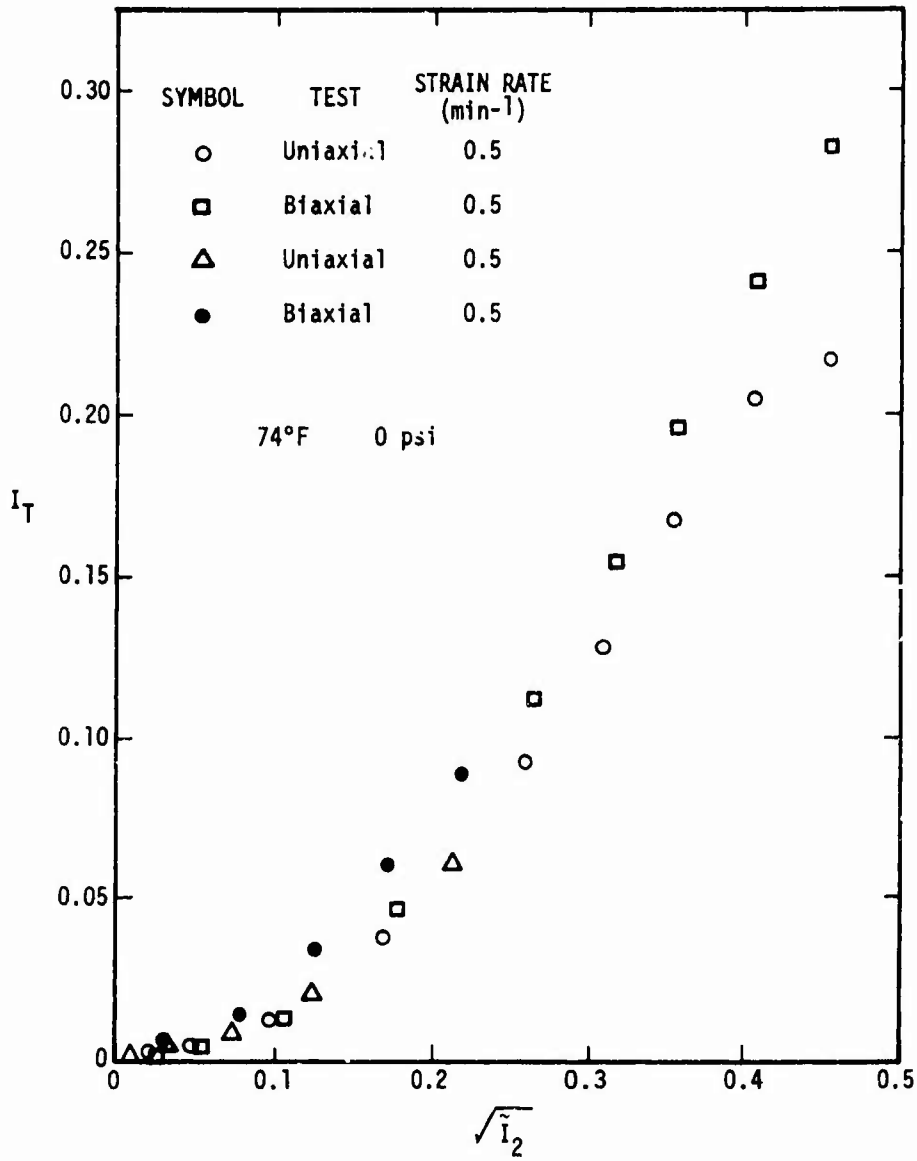

Figure 24. Relation Between First and Second Strain Invariants for ANB 3335-1 Propellant

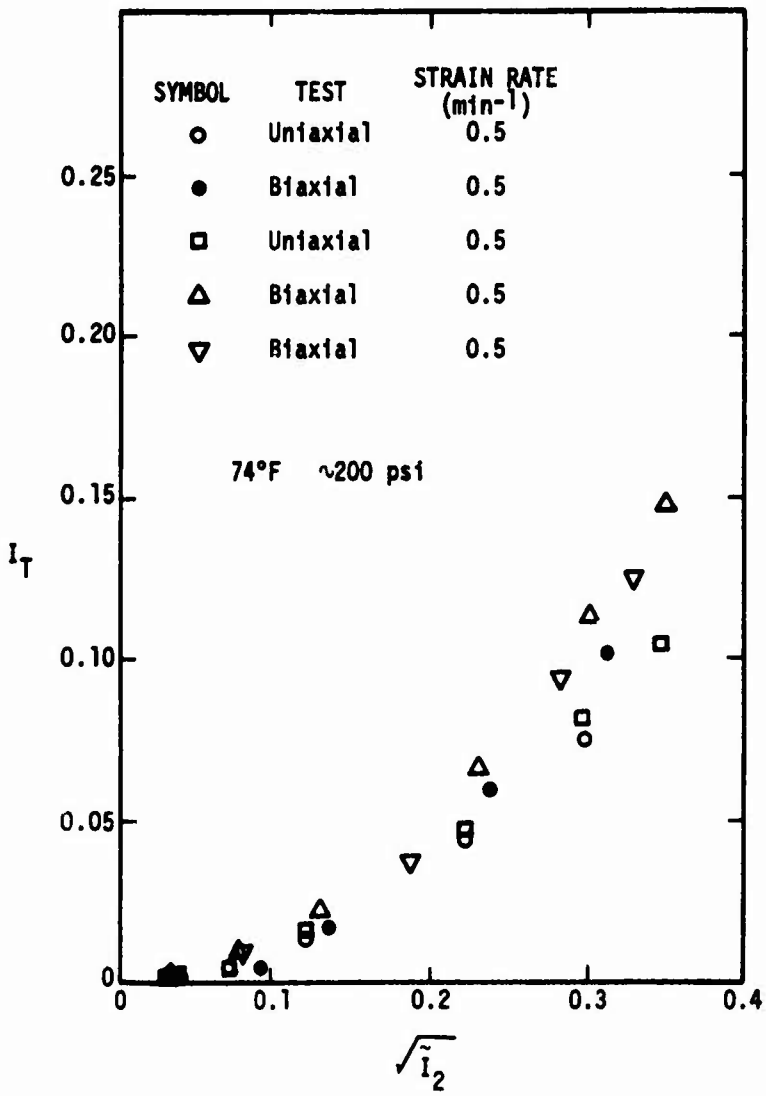

Figure 25. Relation Between First and Second Strain Invariants for ANB 3335-1 Propellant.

Section II-G. In particular, with primes denoting deviatoric strains,

$$I_T \equiv E_{ii} - 3\alpha\Delta T \tag{129a}$$

$$\tilde{I}_2 \equiv E_{ij}' E_{ij}' \tag{129b}$$

Note that the invariant defined by Eq. (129a) is not equal to the dilatation, except for small strains.

Finally, it is of interest to compare the value of the modulus ratio in Eq. (23) found from the uniaxial and biaxial stress-strain data with that obtained from the poker chip tests. For the former tests at 74°F we have found that the relation $\beta/a \approx 5$ holds. Thus,

$$\frac{K_e}{G_e} \approx 5\sqrt{6} \approx 12 \tag{130}$$

Referring to Fig. 18, it is found that this result predicts the dilatation-strain ratio

$$\frac{\Delta V}{V_o \epsilon} \approx 0.69 \tag{131}$$

where the standard linear elastic relation

$$G_e = \frac{3K_e E_u}{9K_e - E_u} \tag{132}$$

has been used; also, corresponding to the notation in Fig. 18, $K_e \equiv K$. The ratio in Eq. (131) is of the correct order of magnitude, based on the poker chip data in Fig. 12.

IV. CONCLUSIONS

Emphasis in this study has been on (i) establishing a simple constitutive theory for propellant at large values of vacuole dilatation, and (ii) the use of viscoelastic fracture mechanics as a means of relating overall mechanical response to fundamental parameters that define the extent of microstructural damage.

Under item (i) we have found the dilatation of strip-biaxial specimens and uniaxial specimens to be essentially equal when referred to equal values of the octahedral shear strain. An implication of this result is that the third deviatoric strain invariant probably can be omitted from the nonlinear constitutive theory without introducing appreciable error. It is shown that dilatation measured on thin simple shear specimens would provide another check of this conclusion; however shear data were not obtained in this study.

In the area (ii) we developed a constitutive theory which is identical to linear viscoelasticity except the stress tensor is multiplied by a scalar function that reflects microstructural damage. This function depends on a weighted Lebesque norm involving stress invariants (rather than strain invariants) and is expressed in terms of temperature-reduced time; the weighting function in the norm reflects one effect of aging and rehealing, if any. The fracture mechanics theory was developed during the latter portion of the program and therefore only a limited check of the theory is given.

ACKNOWLEDGMENT

The author is indebted to Messrs. L. E. Lewis and R. T. Shankle who conducted most of the tests, and to Mr. J. B. Hattox who assisted during the latter phases of the study and prepared Section III-A. Mr. Scott W. Beckwith provided guidance on the experimental program during the course of the investigation, and his help is gratefully acknowledged.

APPENDIX B

PREPROCESSOR CODE NL001

1.0 INTRODUCTION

NL001 is a preprocessor for the nonlinear viscoelastic characterization code NL002. It takes the raw test data, consisting of a temperature, strain rate, time step increment, stress and dilatation, and then calculate the following data:

1. Principal strains, shear strain and true stress
2. Strain rates
3. Strain invariants
4. Dilatation, corrected for pressure and temperature
5. Octahedral strain
6. The 10th, 20th, 30th, 40th, 50th, 60th and infinite Lebesque norms

All these data are generated for the same time points as the original data. The generated and raw test data are then assigned a user prescribed identification and written out onto a tape as a single element. This process is then repeated once for each test, with each test being limited to 100 input data points. There is, however, no limit to the number of tests which may be processed in a single run.

Reproduced from best available copy.

2.0 PROGRAM INSTRUCTIONS

The purpose of this section is to list the basic variables of the NL001 code and provide a set of input instructions for running the program.

2.1 BASIC VARIABLES

Following is a list of the basic program variables of NL001. Each variable is described briefly and labeled as either an input or calculated output variable. All input is also saved as output. Any variable which is not either input or output is merely a working variable used internally, usually for intermediate calculations.

A1, A2	Working variables
BETA	Volumetric expansion coefficient - input
BULK	Bulk modulus - input
C1, C2	Arbitrarily small constants - fixed in program by user. Presently 1.0E-6.
DIL	Dilatation an input - corrected for temperature and pressure for output
DR1, DR2, DR12	Normal and shear calculated strain rates - output
DT	Time step in minutes - input
EOCT	Octahedral strain - output
EPS	Epsilon tester working variable
E_{11}, E_{22}, E_{33}	Normal strains - output
E_{12}	Shear strain - output
INV1	First strain invariant = $E_{11} + E_{22} + E_{33}$ - output
INV2	Second strain invariant = $E_{11} E_{22} + E_{22} E_{33} + E_{33} E_{11}$ - output

INV3	Third strain invariant = E_{11} E_{22} E_{33} - output
KODE	Input control variable: = 1 if a uniaxial test, = 2 if a biaxial test, = 3 if a shear test
KTEMP	Input control variable: = 1 if a constant temperature test = 2 if a variable temperature test
LAST	Input delimiter flagging last input data point. Set blank or zero if not last data point - nonzero if last data point.
MATID	Material identification - input
NAME	Test identification - input
NDP	Number of data points of a specific test
NØRMF	Infinite Lebesque norm - output
NORMi	ith Lebesque norm - output
PRES	Test pressure - input
RATE	Strain rate, observed - input
SP	Working variable
STRESS	Observed stress-input
STRUE	True stress - output
T	Time in minutes - output
TEMP	Test temperature - input

2.2 INPUT INSTRUCTIONS

The following series of cards are read once for each test processed through NL001. The last card of the input deck is always a blank, however there is no blank card between tests. The required input variables for each card appear below with their formats shown in parentheses.

Card 1 (A6, E14.4, 2I5, 5a4, 2E15.6) NAME, PRES, KTEMP, KØDE, MATID, BULK, BETA

Card(s) 2 (5E10.3, I5) TEMP(J), RATE(J), DT(J), STRESS(J), DIL(J), LAST

Here J indicates the Jth data point of this test. Card 2 is repeated once for each data point.

Cards 1 and 2 are repeated once for each test processed.

Card 3 - A blank card indicating that last test has been processed.

2.3 SAMPLE INPUT SHEET

Shown below is a sample input sheet for NL001. It contains the input data for two uniaxial constant temperature tests. The first, U00100 is at ambient pressure while U10105 is run at 100 psig.

2.4 PROGRAM LISTING

The listing of NL001 appears below. Note that it is written specifically for the UNIVAC 1108 computer. Use of this program on any other computer would require substitution of the appropriate statements for the MAKELT and SQUEEZ subroutines.

APPENDIX C

POST PROCESSOR CODE

1.0 INTRODUCTION

POST is a postprocessor for the NL001 code. It takes the output of NL001 off the NL001 output tape, and prints selected output in a report format. There is a minimum of two pages of output for each test reported. The first two columns of each page are the data point numbers and time in seconds. Page 1 then contains the three strain invariants, the dilatation $\Delta V/V_0$, corrected for any temperature and pressure effects, and the octahedral strain. Page 2 displays the temperature, calculated strains, and the true stress. In addition to the above, each page has a heading giving material type, bulk modulus and volumetric expansion coefficient, the test type, initial strain rate, pressure, and whether it is a constant or variable temperature test.

The only card input to POST is the last card, a blank, signifying the end of the data. All other input is read directly from the NL001 output data tape.

2.0 PROGRAM INSTRUCTIONS

The purpose of this section is to list the basic variables of the POST code and provide a set of instructions for running the program.

2.1 BASIC VARIABLES

Following is a list of the basic program variables of POST. The names and meaning of variables is compatible with the NL001 code.

BETA	Volumetric expansion coefficient
BULK	Bulk modulus
DUM	Dummy variable
EDØTO	Initial strain rate
ITEMP	Alphanumeric constant/variable temperature header
ITYPE	Alphanumeric uniaxial/biaxial/shear test type header
KØDE	Test type control variable
KTEMP	Temperature control variable
LAST	Last data point delimiter
MATID	Material identification
NAME	Test element identification
NDP	Number of data points in a specific test
PRES	Test pressure, psig
X	An array used to store the various output quantities

2.2 INPUT INSTRUCTIONS

There is no card input for PØST. All input is read from the NL001 data output tape, element by element. The user merely inserts an "ADD" card for each element of the tape he wishes processed by POST. After the last "ADD" card, the user inserts a blank card to terminate execution.

2.3 SAMPLE INPUT SHEET AND OUTPUT

Shown below is a typical input sheet for POST showing the UNIVAC 1108 "ADD" cards and the last (blank) card. In the example shown, two tests are processed U00100 and U10105. Following the sample input sheet is the actual output generated by POST.

2.4 The listing of POST appears below. Note that it is machine independent, except that it expects the input to be in a specific format. This format is exactly that used by the NL001 code.

JOB NUMBER	REPORT TITLE	DATE
	Sample input - Post	

```
" XQT PØST
" ADD U00100
" ADD U10105
        ( BLANK CARD )
```

S 0140-10 (REV 7/68)

PLEASE PRINT CLEARLY - USE BLACK PENCIL

APPENDIX D

CHARACTERIZATION CODE NL002

1.0 INTRODUCTION

The computer code NL002 is a nonlinear thermoviscoelastic characterization code that accepts pressurized uniaxial, biaxial and shear data from code NL001. Dozens of experiments of this type having arbitrary deformation-temperature time histories can be simultaneously fit to constitutive equations using NL002 which performs both a distortional and bulk characterization as described in the text of this report.

2.0 PROGRAM INSTRUCTIONS

The purpose of this section is to present the basic program variables, their definitions and use in the NL002 code, a sample problem and a listing of the program following the sample problem input sheet.

2.1 BASIC VARIABLES

A	Coefficient in $_e$ A*DIL/EOCT which is a modulus multiplier
AT	Shift function - input
AVGAT	Interpolated value of shift function at a specific arbitrary point
B	Coefficient of t in power law term $(1 + Bt)^P$ - input
BB	Solution vector in regression analysis
BCAL	Calculated value of dilatational stress
BETA	Thermal volumetric expansion coefficient - input
BO	Regression coefficients for bulk term - calculated
BULK	Bulk modulus - input
CO	Regression coefficients for shear term - calculated
D	Slope of shift function vs temperature curve - calculated
DEV	Local percent error

DEV1	Final local error on σ_{11}
DEV2	Final local error on σ_{22}
DI	Working variable
DIL	Corrected dilatation $\Delta V/V_o$ - input
DR1	Calculated strain rate $\dot{E}_{11}$ - input
DR2	Calculated strain rate $\dot{E}_{22}$ - input
DR12	Calculated strain rate $\dot{E}_{12}$ - input
DT	Time step - input
DTR	Reduced time step - calculated
EØCT	Octahedral strain - input
E11, E22, E33	Principal strains - input
E12	Shear strain - input
F	A coefficient defined as $F = e^{[A*DIL/E_{OCT}]}$
G	A coefficient defined as $G = (1 - \frac{E_{OCT}}{NORMF})$
IFF	F coefficient flag; set IFF(I) = 1 to multiply Ith term in regression by the coefficient F
IFG	G coefficient flag; set IFG(I) = 1 to multiply Ith power law term by the coefficient G
IFN	Norm selector; selects up to six norm terms, 10th, 20th, 30th, 40th, 50th, or 60th depending upon whether or not IFN(I) is 1, 2, 3, 4, 5, or 6 respectively.
INT1, INT2, INT12	Hereditary integral terms - calculated
INV1, INV2, INV3	First, second, and third strain invariants respectively - input

IPG	Page counter
KØDE	Test type indicator - input
KTEMP	Constant or variable temperature test indicator - input
LAST	Input data delimiter
LINE	Output line counter
MATID	Material identification - input
NAME	Run title printed at top of each page
NAT	Number of values of shift function vs temperature
NBULKS	Number of terms in series for bulk term regression presently fixed at 14
NDP	
NORM	The Lebesque norms of E_{OCT} - input
NORMF	Infinite norm of E_{OCT} - input
NORMS	Number of norm terms in series for shear term regression - limited to a maximum of 6
NPL	Number of power law terms of the form $(HBt)^P$
NTERMS	Number of terms in series for shear term regression - limited to a maximum of 14.
NTEST	Test number in this run
NTØT	Total number of data points processed in this run, i.e., ΣNDP
N1	First data point used in regression analysis
P	Exponent in power law term $(HBt)^P$
PRES	Test pressure, psig
R	Primary matrix of regression analysis
RATE	Observed strain rate - input

RESID	
RESID1	Interim variable used in calculating standard deviations
RESID2	
SCAL	Calculated value of stress in shear regression
STD	Standard deviation
STRESS	Observed stress
STRN	Interim strain storage variable
STRUE	True stress
SUM	
SUM1	Interim variables used in calculating average error and standard deviation
SUM2	
S1, S2	True stress, STRUE = S1-S2
S1CAL	Calculated values of S1 and S2
S2CAL	
T	Time in minutes
TEMP	Test temperature
TITLE	Test identification - input
TR	Reduced time - calculated
TSHFT	Temperature at which shift function is input
XBAR	Average error
XF, XF1, XF2	Terms in series used for regression analysis
XN	Power to which norm term is raised
XP, XQ	Working variables
Z	Exponent of G coefficient

2.2 PROGRAM INPUT

This section lists the required input for NL002 on a card by card basis. The format for each card is shown in parentheses.

Card 1	(20A4) NAME
Card 2	(2E10.0) A, Z
Card 3	(7I5) IFG(I), I = 1,7
Card 4	(14I5) IFF(I) I = 1, 14
Card 5	(06I5) IFN(I),I = 1,6
Card 6	(6E10.0) XN(Ie) I = 1,6
Card 7	(15) NPL
Card(s)	(8E10) (P(I)), I = 1 NPL)
Card(s) 9	(2E10.0, I5) TSMFT(I), AT(I), LAST. Where LAST = 0 or blank if another TSMFT vs AT pair follows, and LAST ≠ 0 if this is last pair.
Card(s) 10	"ADD" cards to add elements from NL001 output data tape, as many as desired
Card 11	A blank card to indicate end of data

The above cards are shown on the coding sheet below.

2.3 SAMPLE PROBLEM

Shown below is an input sheet for a simple but typical problem using 13 tests of 77° data, as indicated in the title, Card 1. Card 2 sets A = Z = 1.0. Card 3 indicates that all power law terms are multiplied by G. Card 4 indicates that <u>all</u> terms in the shear term series are to be multiplied by F. Card 5 says to take 6 norm terms, but to use the 10th norm for each

term. Card 6 gives the power to which each norm term indicated on Card 5 is raised. Card 7 indicates how many power law terms to keep; here 3. Card 8 shows that these 3 power law terms of the for $(1 + Bt)^{)}$ are $(1 + t)$, $(1 + 2t)^2$, and $(1 + 3t)^3$. Card 9 shows a constant shift function vs temperature curve. Cards 10 are the elements from the NL001 data output tape for the tests of interest. Card 11 is a blank card which indicate the ned of a run.

2.4 PROGRAM LISTING

A complete source listing follows the data input sheet for the above problem.

APPENDIX E

CHARACTERIZATION CODE NL003

1.0 INTRODUCTION

The computer code NL003 is identical in input and operation as NL002 and performs the identical distortional characterization. NL003 differs from NL002 in the bulk characterization. In this code the dilatation is expressed in terms of the mean pressure and the octahedral shear strain as discussed in the text of this report.

Since the code operation is identical only a sample problem and the listing is provided in this appendix.

APPENDIX F

SUBPROGRAMS

1.0 INTRODUCTION

This appendix lists the additional subprograms called for in codes NL001, NL002, NL003, POST, and LINVIS. These routines are used for page counting, headings and matrix inversion and are common to these codes. Since these subroutines need no input from the user only the listings are presented.

APPENDIX G

COMPUTERIZED CHARACTERIZATION PROCEDURES FOR LINEAR VISCOELASTIC MATERIALS USING ARBITRARY DEFORMATION HISTORIES

By

Richard J. Farris

1.0 INTRODUCTION

The purpose of this appendix is to provide an improved means of linear viscoelastic characterization. The computer code presented in this appendix was the first code developed on this contract and formed the basis for the nonlinear characterization codes. The code calculates the best fit distortional stress-strain relation for mixed uniaxial, biaxial and shear tests having complex deformation histories including transient temperature histories. The representation used is

$$\sigma^{(D)}(t) = \int_0^t G(t'-\xi')\dot{\varepsilon}^{(D)}(\xi)d\xi \tag{1}$$

where $\sigma^{(D)}$ = distortional stress

$\varepsilon^{(D)}$ = distortional strain

Thermal effects are included in that the distortional strain depends upon thermal dilatation and the reduced time, $t'-\xi'$, depends upon temperature in the usual manner

$$t'-\xi' = \int_\xi^t d\tau/A_T(\tau) \tag{2}$$

The kernel function G(t) can be represented as either a Prony series or as a power law series depending upon users preference.

In the Prony series representation the kernel function becomes

$$G(t) = A_1 + \sum_{i=2}^{M} A_i e^{-\beta_i t} \tag{3}$$

and in the power law representation the kernel function is

$$G(t) = A_1 + \sum_{i=2}^{M} A_2(1 + \beta_i t)^{N_i} \tag{4}$$

The code requires as input parameters the time-temperature shift function and a family of exponents β_i, $i \leq 15$, for the Prony series representation. The code then computes the best fit linear coefficients A_i based on a relative regression analysis as discussed in the text of this report. Once having determined the coefficients the program can be used to calculate the response to any history of interest.

There are many advantages to this type of characterization method some of which are given below.

- All of the data obtained on a material can be used in the characterization.
- The method can provide the best approximation to any complex history.
- Provides the best fit to all of the data not just a relaxation test.
- Provides direct comparisons between observed and predicted data.
- The method is much more accurate than usual methods and provides statistical information regarding accuracy and variability.
- Eliminates the need for special tests and test equipment, such as stress-relaxometers, since characterization can be carried out from any experiment.
- It provides a practical method for linear and nonlinear viscoelastic characterization.

As an example of the application of the method the following figures are included. Figure 1 demonstrates the excellent results obtained when a five term Prony series is fit to a ramp loaded stress-relaxation experiment for a composite propellant. From this experiment, one might get the misleading impression that linear viscoelasticity was a good approximation to propellant response. Figure 2 shows the linear viscoelastic analytical continuation (based on the fit from Figure 1) compared to the experimental results when straining is again commenced. Obviously the material is not linearly viscoelastic. The remaining figures illustrate the excellent fit obtained in Solethane 113, an unfilled rubber, on a series of experiments using complex histories at temperatures from -65°F to +150°F. The last figure shows a comparison of predicted transient thermoviscoelastic stress response for Solethane 113 with experimental results. The Solethane characterization was carried out using 15 Prony series terms and the predictions were within $\pm$ 10% for one standard deviation demonstrating that linear viscoelasticity is an excellent approximation to the behavior of this unfilled polymer.

2.0 PROGRAM INSTRUCTIONS

This section presents a description of the basic variables of the LINVIS linear viscoelastic characterization code. It includes a data sheet showing the input variables and formats, a sample problem and a listing of the program.

2.1 BASIC VARIABLES

AT	Vector of shift function - input
AVGAT	Average value of AT - calculated
B	Constant in the power series term $(1 + Bt)^{NN}$ or the exponent in the prony series term e^{-Bt} - input
BB	Column vector in regression equation
BETA	Volumetric expansion coefficient - input
CO	Regression coefficients - calculated
D	Slope of shift function - calculated
DEV	Percent error between calculated and observed stress
DEVRAT	Deviation strain rate - calculated
DT	Time increment - input
E1, E2	Principal normal strains - calculated
F	Working variable
G	Inverse matrix
I2	Set to 1 to include a linear elastic term in the series characterization otherwise leave blank or zero - input
I3	Number of power or prony series terms - input
I4	I2 + I3 - calculated

I6	Equal to NTEMP - Calculated
INV1	First strain invariant - input
JL	Total number of input data points - calculated
KFL	Number of input data points in a particular test - calculated
KODE	Test type: = 0 for uniaxial; = 1 for shear; = 2 for biaxial stop - input
LLL	Characterization type: = 0 for power series; = 1 for prony series - input
NN	Exponent in the power series term $(1 + Bt)^{NN}$ - input
NEXP	Number of data points for this test - input
NTEMP	Number of shift function vs temperature pairs - input, 20 max.
NTESTS	Number of tests for this run - input
RATE	Incremental strain rate - input
SIG1	Working array to store all stress input
STD	Standard deviation - calculated
STRN1	Same as SIG1 except for strain - calculated
T	Time - calculated
TEM	Same as SIG1 except for temperature - calculated
TEMP	Temperature at a data point - input
TIME	Output time - calculated
TITLE	80 column alphanumeric identification - input
TR	Reduced time - calculated
TTEMP	Shift function input temperature - input
V	Working matrix
VOLUME	Same as SIG 1 except for INV1 - calculated

X	Dummy array
XBAR	Average error - calculated
XF	Union of the X sets
Y	Observed stress - input
YCAL	Calculated stress - output

2.2 DATA INPUT

The input variable required by LINVIS are shown below, card by card, with the format shown in parentheses.

Card 1 (20A4) TITLE

Card 2 (E10.0) BETA

Card 3 (5I5) I2, I3, LLL, NTESTS, NTEMP

Card(s) 4 (2E10.0) NN, B

Card(s) 5 (2E10.0) TTEMP, AT

Card 6 (2I5) NEXP, KØDE

Card(s) 7 (5E10.0) TEMP, RATE, DT, Y, INV1

Cards 1 through 5 are read only once per run.

Cards 6 and 7 are repeated for each test.

The above cards are shown on the data sheet below.

2.3 Shown below are the sample input sheets for a typical problem. By referring to the master data sheet, above, the input is self explanatory. The output sheets for this sample problem follow the data sheets.

2.4 PROGRAM LISTING

A complete source listing follows the sample problem output.

APPENDIX H

SAMPLES OF EXPERIMENTAL DATA

This appendix lists some of the experimental data obtained on ANB-3335-1 propellant at 0°F. These data are from "pressurized" uniaxial and biaxial experiments. In total over 250 experiments of the type illustrated were performed on this propellant at temperatures from -65°F to +150°F and pressures from atmospheric to 1000 psi. After processing the raw data through the Preprocessor Code NL001, calculated stress-strain-invariant histories are stored on magnetic tape. The experimental data listed in this appendix represents only a partial listing of the calculated information from each experiment. These listings were obtained using the Post Processor Code.

These data are illustrated in this appendix to demonstrate the type of experimental data obtained and used on this contract. Arrangements can be made to obtain a copy of the complete magnetic tape data file for those who are interested in testing theory against real data.

SUMMARY OF TEST NO. U00605

MATERIAL DATA

MATERIAL ID ANR 3335-1
BULK MODULUS = .5000+06
VOLUMETRIC EXPANSION COEFFICIENT = .1000-03

TEST DATA

TYPE ... UNIAXIAL
INITIAL STRAIN RATE = .3300+00
PRESSURE = 0. PSIG
TEMPERATURE IS CONSTANT
