13. SUPPLEMENTARY NOTES
    Prostate specific antigen screening for prostate cancer is inexpensive, non-invasive and sensitive, but lacks specificity. The accuracy of confirmatory prostate biopsy is only 52% due to either the absence of tumor or the inability to precisely sample small tumors with the biopsy needles. Thus, there is an urgent need to develop methods to accurately image cancers within the prostate, to rule out cancer in men with false positive PSA elevation and to ensure successful biopsy for those with small cancers. Photoacoustic imaging is an emerging functional imaging technique that can detect and diagnose prostate cancer based on the near-infrared optical absorption of either endogenous tissue constituents or exogenous contrast agents. Although endogenous tissue constituents show promise, in order to implement photoacoustic imaging in the clinic, there is a need for increased tumor cell specificity, sensitivity and depth of imaging. To enhance the application of photoacoustic imaging for the detection of early stage prostate cancer, development of near infrared dyes - labeled RNA aptamer that recognizes the prostate specific cell surface protein - prostate specific membrane antigen is proposed to specifically image prostate-cancer. The design incorporates a high energy tunable laser as the source and an ultrasound linear array to detect the acoustic-lens-focused photoacoustic signals generated from the cancerous lesions within the prostate.

1. INTRODUCTION:

The clinical management of early stage, organ-confined prostate cancer (PrCa) is challenging. The introduction of serum PSA screening in the 1980s lead to a spike in the apparent incidence of PrCa, due to the detection of previously under-diagnosed indolent cancers, which grow slowly and do not affect lifespan\textsuperscript{1}. While PSA screening has declined from its peak, most PrCa is still screen-detected and therefore likely to be indolent, requiring no treatment. Unfortunately, there is no reliable technology to identify the rare aggressive cancers among the mass of indolent screen-detected PrCa, which has lead to frequent over-treatment by surgery or radiation. Much effort has focused on the development of tissue or serum biomarkers to differentiate indolent and aggressive disease, but this has not yet yielded sensitive and specific tools. Consequently, the current clinical paradigm for screen-detected PrCa is active surveillance\textsuperscript{2,3} (AS): monitoring by serum PSA testing and serial prostate biopsies to determine the grade (Gleason score) and extent of tumor.

There is an urgent need for imaging tools for AS, i) to confirm the initial PSA-based diagnosis; ii) to guide biopsies, which are now performed in a blinded manner; and iii) to monitor tumor volume, which is currently not measureable but may represent a biomarker of progression from indolent to aggressive disease. Multi-parametric MRI may fill some of these roles, but it is expensive and technically limited\textsuperscript{4,5}. In contrast, photoacoustic imaging (PAI), is an emerging, noninvasive, functional molecular imaging modality that has not yet entered the clinic, and is likely to be less expensive and more portable than any MRI system. The photoacoustic (PA) signal is an ultrasound wave generated by tissue constituents (hemoglobin (Hb), fat, water, etc.) that absorb short (nanosecond) pulses of laser light in the near infra-red (NIR) spectrum\textsuperscript{6}. PAI can discriminate among such tissue constituents on the basis of optical absorption properties, allowing for PAI spectroscopy, which can detect biological function\textsuperscript{7}. Human PrCa is a viable candidate for PAI since transrectal probes can image the prostate gland \textit{in situ}. Based on ultrasound data from human PrCa patients, we estimate that the distance from the rectal wall to the anterior prostate is \sim 3.5 \text{ cm}, which is within the potential range of depth detection for PAI\textsuperscript{8}. The most common application of PAI spectroscopy in cancer imaging uses the differences in the absorption spectra of Hb and HbO\textsubscript{2} and is therefore capable of detecting tumors based on regions of hypoxia which promote neo-angiogenesis and more aggressive cancers\textsuperscript{9}. However, endogenous tissue constituents such as Hb generate relatively weak photoacoustic signals (due to a small absorptivity factor or extinction coefficient) and lack cancer specificity. Exogenous agents, such as NIR-absorbing dyes linked to tumor-specific binding molecules (such as antibodies) can act as targeted molecular imaging agents (TMIA\textregistered s) to facilitate sensitive and specific detection of the corresponding cancer. For targeting purposes, prostate surface membrane antigen (PSMA) is detected on the surface of nearly every human PrCa, while expression is low to moderate on non-cancer prostate tissue and very low outside the prostate, making it an excellent biomarker for molecular imaging of PrCa\textsuperscript{10}. The initial clinical application of PSMA (ProstaScint) was of limited value because it employed a monoclonal antibody against the cytoplasmic domain of PSMA, detecting only necrotic cells\textsuperscript{11}. Subsequently, improved PSMA binding agents have been developed, including a nuclease-stable RNA aptamer (A10-3.2) that binds very efficiently\textsuperscript{12}. The PSMA also has an unusual extracellular active site encoding glutamate carboxypeptidase activity, allowing for the synthesis of a peptidomimetic inhibitor (YC-27) that has been linked to a NIR dye for successful \textit{in vivo} imaging of PSMA+ mouse xenografts\textsuperscript{13}. Two significant innovations are proposed to enhance
the application of PAI for the detection of early stage PrCa: 1. Use of a NIR dye labeled RNA aptamer that recognizes the prostate specific cell surface protein PSMA to specifically image PrCa and 2. Optimization of multispectral PAI to differentiate small volume, early stage PrCa tumors from surrounding normal prostate tissue.

3. ACCOMPLISHMENTS:

What were the major goals of the project?

1. Identify and synthesis of the near-infrared dyes and perform photoacoustic experiments in-vitro.
2. Conjugation of the tested near-infrared dyes with prostate cancer cell lines and perform photoacoustic imaging experiments.
3. Determination of the sensitivity of the acoustic lens based photoacoustic imaging system in classifying the positive prostate cancer cells from negative prostate cancer cells.

What was accomplished under these goals?

- Identification of IRDye800CW as an exogenous contrast agent for PAI.
- Demonstration of increased sensitivity of IRDye800CW versus other labels using our acoustic lens based PAI device.
- PAI discrimination of PrCa cells expressing PSMA (C4-2) versus non-expressing prostate cancer cells (PC3) using IRDye800 conjugated with A10.3 aptamer bonded to PSMA.
- PAI discrimination of PrCa cells expressing PSMA (C4-2) versus non-expressing prostate cancer cells (PC3) using IRDye800 conjugated with YC-27, a peptidomimetic urea inhibitor bonded to PSMA.

PROJECT SUMMARY:

*Limitations of endogenous contrast agents for prostate cancer diagnosis.* While pre-clinical testing of prostate resection slices indicates that Photoacoustic Imaging (PAI) has higher sensitivity and specificity than TRUS, imaging depth is limited, and chromophores such as de-oxyhemoglobin (dHb) and oxyhemoglobin (HbO₂) have two limitations: i) their small absorptivity factor (extinction coefficient) leads to weak PA signals, limiting the depth of tumor detection as well as the minimal detectable tumor size; and ii) endogenous molecules have little specificity for cancer. In order to improve depth penetration and image quality, exogenous chromophores can be

![Fig. 1. Biological imaging near-infrared window.](image)
employed to enhance sensitivity relative to endogenous agents. This approach has been demonstrated in the use of a near infrared fluorescent (NIRF) dye, IR800CW conjugated to a peptide that targets the neutropilin-1 receptor for the PAI of breast cancer. Excitation of cells can be optimized by use of a laser tuned to the maximum wavelength of NIR dyes with absorptivity factors two to three orders of magnitude greater than those of endogenous agents. Unlike fluorescence imaging with light as the input and backscattered radiation as the output, PA imaging uses light as the input source for excitation but detection and image formation use ultrasound waves generated by the tissue. Since ultrasonic waves scatter much less than light in the tissue, PAI can produce higher resolution imaging deep in tissue, compared to fluorescent detection. For greater tissue depth penetration and sensitivity, PAI utilizes dyes that absorb in the ‘biological NIR window’ between 700-900 nm. The optimal NIR window is designed to circumvent the strong absorbance of Hb, HbO$_2$ and H$_2$O as shown in Fig. 1. NIR dyes related to ICG including Cy7, Alexa750 and IR800CW are ideal and offer a dramatic increase in sensitivity.

**Identification of IRDye800CW as an exogenous contrast agent for PAI.** To quantify the PA signal generated with tunable laser excitation in the 700-1000 nm range of endogenous or exogenous dye components, algorithms have been developed to deconvolute the individual chromophore PA images. Five dyes (IRDye800CW, AlexaFluor750, Cy7-NHS-ester, Cy7-sulfo and Dylight800) were tested using our acoustic lens based device at 100 micromolar (µM) concentration. A water bath setup (Fig. 2) was used to determine the photoacoustic spectra of these five dyes. Each contrast agent was interrogated in the NIR region in a five step-interval range and PA signals recorded using our PAI probe. These recorded PA signals were further processed to find the absorption maxima for each exogenous contrast agent across the NIR region. The PA absorption spectra of each dye have been plotted as shown in the Fig. 3. As expected from the reported peak intensities (lambda max) in the ultraviolet-visible spectra, the Alexafluor 750 has a peak PA signal when irradiated at 750 nm, Cy7-NHS-ester at 760 nm, Cy7-sulfo at 755 nm, Dylight800 at 785 nm and the dye IR800CW has a peak signal at 775 nm. When the targeted molecular imaging agents (TMIAs) are injected into the blood stream and PA imaging is conducted during wash out period, the
image signal will be the linear sum of signal from all the underlying dominant chromophores (dHb, HbO₂ and NIR dye). It is important to create separate images of individual chromophores to obtain the signature related to only the specific biomarker. This task requires input data from the PA signal spectrum of endogenous or exogenous dye components and algorithms have been developed to de-convolve the individual chromophore images to determine i) their PA yield (PA signal per micro molar solution), and ii) their spectra shape. Among the five contrast agents/dyes we investigated, IRDye800CW was chosen based on photoacoustic spectrum analysis as determined by the highest intensity achieved relative to the other agents and because the peak absorption is well separated from endogenous tissue constituents, as shown in Figure 3. The initial aim of the project was to use CY7 as the photoacoustic contrast dye. When we started testing, however, we obtained weak photoacoustic intensity with CY7 and needed to search for an alternative dye for a stronger photoacoustic signal. We therefore tested five dyes by both visible absorption spectra and photoacoustic spectroscopy. The un-normalized spectra of the tested five dyes are shown in Fig. 4. The dye showing superior absorption at equimolar concentrations after exposure to room light for three hours was IR800CW followed by Alexa 750 with considerable less absorption by Cy7, sulfo-Cy7 and Dylite. In subsequent results, IR800CW also displayed the best solution stability. Consistent with this data, the IRDye800CW showed better sensitivity and higher photoacoustic signal versus CY7 (Fig. 3). As a result, IRDye800CW was chosen as a replacement for CY7 in subsequent studies as it was shown to provide optimal signal contrast and better stability in handling and the laser compared to the CY7. In addition, IRDye800CW displays distinctive photoacoustic peak absorption at 775 nm which enables better differentiation from endogenous chromophores.

**Fig. 3.** PA spectra of five contrast agents. IRdye800CW (blue); AlexaFluor750 (red); Cy7-NHS-ester (green); Cy7-sulfo (orange); Dylight800 (purple).

**Fig. 4.** Optical absorption spectra of five contrast agents. IRdye800CW (blue); AlexaFluor750 (purple); Cy7-NHS-ester (red); Cy7-sulfo (orange); Dylight800 (green).
**Sensitivity of IRDye800CW using our PAI device.** The IRDye800CW was diluted from 50 µM to 90 nM concentrations and photoacoustic signal measured to obtain the sensitivity of the IRDye800CW. Each red square in the plot represents the corresponding IRDye800CW concentration on the x axis and its PA signal intensity on the y axis. PA signal from the dimethyl sulphoxide and de-ionized water has been subtracted from each recorded value and PA signal from the dye alone has been plotted. Using our current PAI system, 90 nanomolar (nM) was determined to be the threshold for signal above noise (Fig. 5).

**PAI of PrCa cells using IRDye800 conjugated with TMIA bonded to PSMA.** Among the five contrast agents/dyes we investigated, IRDye800CW was chosen because it produced the highest PA intensity relative to the other agents and because the peak absorption is well separated from endogenous tissue constituents (Fig. 3). IRdye800CW was serially diluted in DMSO and water. The resultant PA signal intensity above diluent signal correlates well with concentration ($r^2 = 0.979$, Fig. 5). Using our PAI apparatus, 0.8 µM IRDye800CW is the threshold for detecting signal above noise of the NIR dyes tested.

A TMIA was synthesized by labeling the PSMA specific 10.3.2 aptamer with IRDye800CW (GeneLink). Cells expressing (C4-2) or lacking (PC3) PSMA were incubated in a 4 µM solution of the TMIA in PBS, washed thrice in PBS by centrifugation and resuspension, and

**Fig. 5. Sensitivity of IRDye800CW using our PAI device.** IRDye800 concentration varied from 90 nM to 50 µM. Each red square represents the corresponding IRDye800CW concentration and its PA signal intensity.

**Fig. 6.** Specific labeling by TMIA for PAI. PSMA- PC3 (red) and PSMA+ C4-2 (blue) prostate cancer cells were labeled with A10-3.2-IRDye800CW and scanned from 700 nm to 900 nm wavelength laser light in the setup depicted in Fig. 2.
examined in our PAI system. The spectra of the photoacoustic signal from C4-2 cells and PC3 cells shows a peak of maximal PA signal difference at 785 nm. The 20 nm difference between the peak absorbance of the IRdye800CW at 765 nm and this 785 nm peak suggests that conjugation of the IRDye800CW to the aptamer to constitute the TMIA, and/or binding of TMIA to the PSMA molecules on the prostate cell surface, affected the wavelength of absorbance producing peak PA signal (Fig. 6).

Quantitative characterization of this TMIA shows specific and uniform binding to PSMA expressing prostate cancer cells. Four samples of ten million PC3 or C4-2 cells were labeled as above and optically imaged at 770 nm (Fig. 7a) and quantitated (Fig. 7b) using an IVIS spectrum (PerkinElmer). TMIA labeling was uniform (CV = 5.5% for PC3, 6.0% for C4-2), and the signal (C4-2) to noise (PC3) ratio (SNR) was 2.56 +/- 0.08. One of the four samples of these TMIA labeled cell samples was used to tune the PA system alignment, and the remaining three were pipetted into cuvettes and peak PA signal determined at 785 nm excitation from a B-scan (Fig. 7c) and when quantitated the SNR was 2.33 +/- 0.09 (Fig. 7d). The data is reconstructed as C-scan for each cuvette of C4-2 cells (Fig. 7e) and PC3 cells (Fig. 7f). Analyzing the C-scans using an ROI encompassing the cuvette, the SNR was 5.35 +/- 0.04.

**Fig. 7** Enhanced photoacoustic signal from PSMA+ C4-2 prostate cancer cells labeled with A10-3.2-IRdye800CW aptamer-dye. Optical imaging of a twelve well plate containing aliquots of PSMA+ C4-2 (right side 4 wells) and PSMA- PC3 (left side 4 wells) cells labeled with aptamer-dye, (or buffer in middle wells). Fluorescent signal intensity was captured via IVIS (a) and relative intensity plotted (b). The cells were sequentially loaded into the PAI instrument cuvette (Fig 2) and PA signal was captured at 785 nm, by scanning along the long axis of the cuvette (B-scan) (c) and peak PA signal was plotted, p = 0.0174 (d). C-scan images of cuvettes containing C4-2 (e) and PC3 (f).
An alternate targeting moiety, YC-27, comprising a peptidomimetic urea inhibitor, DCL, conjugated to IRDye800CW (Licor), was similarly evaluated. The 20 nm shift in the wavelength of absorbance producing peak PA signal was also apparent (DNS). The YC-27 TMIA also shows specific and uniform binding to PSMA expressing prostate cancer cells as assessed by optically imaging at 770 nm (Fig. 8a and 8b). YC-27 TMIA labeling was higher than for the aptamer TMIA (CV = 17% for PC3, 9.9% for C4-2), but the SNR was much greater, 24.7 +/- 1.22, minimizing the impact of the slight increase in labeling variability. Peak PA signal was determined from a B-scan for each cell type after labeling with the YC-27 TMIA (Fig. 8c) and when quantitated the SNR was 1.86 +/- 0.24 (Fig. 8d). The data is reconstructed as C-scan for each cuvette of C4-2 cells (Fig. 8e) and PC3 cells (Fig. 8f). Analyzing the C-scans using an ROI encompassing the cuvette, the SNR was 5.91 +/- 0.81.

**Fig. 8** Enhanced photoacoustic signal from PSMA+ C4-2 prostate cancer cells labeled with YC27-IRdye800CW urea-dye. Optical imaging of a twelve well plate containing aliquots of PSMA+ C4-2 (right side 4 wells) and PSMA- PC3 (left side 4 wells) cells labeled with urea-dye, (or buffer in middle wells). Fluorescent signal intensity was captured via IVIS (a) and relative intensity plotted (b). The cells were sequentally loaded into the PAI instrument cuvette (Fig 2) and PA signal was captured at 785 nm, by scanning along the long axis of the cuvette (B-scan) (c) and peak PA signal was plotted, p = 0.0246 (d). C-scan images of cuvettes containing C4-2 (e) and PC3 (f) are shown.

**CONCLUSION:** TMIAs optimized for PAI, in combination with an acoustic lens, allowed us to discriminate between prostate cancer cells lines that either express PSMA or do not express PSMA. Both the A10 aptamer and the PSMA inhibitor in YC-27 specifically bind PSMA-expressing cells and can be successfully delivered *in vivo*, i.p. or intra-tumorally. While the aptamer TMIA showed good SNR for PAI, it is expensive to synthesize and less stable than the inhibitor. Conjugation of modified
chromophores to the inhibitor DCL is more tractable and thus represents an immediately available approach for use in developing “louder” targeted agents to detect PrCa by PAI.

With successful completion of this research, we will have a device and an accompanying molecular imaging reagent that can be readily moved into human clinical trials. We believe that this work will ultimately yield a real-time, safe and effective imaging device that has a potential to aid in the diagnosis of early stage prostate cancer and reduce patient anxiety (due to the need for biopsy and repeat biopsy) and also reduce the amount of over-treatment of prostate cancer.

What opportunities for training and professional development has the project provided? Nothing to Report.

How were the results disseminated to communities of interest? Journal publications and presentations at scientific conferences.

What do you plan to do during the next reporting period to accomplish the goals? Nothing to Report.

4. Impact:

What was the impact on the development of the principal discipline(s) of the project? The use of photoacoustic imaging (PAI) technology in conjunction with two molecular imaging agents that specifically target the prostate-specific membrane antigen (PSMA) expressed on the tumor cell surface of most prostate cancers. We demonstrated successful imaging of phantoms containing cancer cells labeled with either of two different PSMA-targeting agents, the ribonucleic acid aptamer A10-3.2 and a urea-based peptidomimetic inhibitor, each linked to the near-infrared dye IRDye800CW. By specifically targeting cells with these agents linked to a dye chosen for optimal signal, we are able to discriminate prostate cancer cells that express PSMA.

Major accomplishments and innovations:
- Identification of IRDye800CW as an exogenous contrast agent for PAI.
- Demonstration of increased sensitivity of IRDye800CW versus other labels using our acoustic lens based PAI device.
- PAI discrimination of PrCa cells expressing PSMA (C4-2) versus non-expressing prostate cancer cells (PC3) using IRDye800 conjugated with A10.3 aptamer bonded to PSMA.
PAI discrimination of PrCa cells expressing PSMA (C4-2) versus non-expressing prostate cancer cells (PC3) using IRDye800 conjugated with YC-27, a peptidomimetic urea inhibitor bonded to PSMA.

What was the impact on other disciplines? Nothing to Report.
What was the impact on technology transfer? Nothing to Report.
What was the impact on society beyond science and technology? Nothing to Report.

5. Changes/Problems:

Actual or anticipated problems or delays and actions or plans to resolve them. Nothing to Report.

Changes that had a significant impact on expenditures: Nothing to Report.

Significant changes in use or care of human subjects, vertebrate animals, biohazards, and/or select agents. Nothing to Report.

Other Products:
- Identification of IRDye800CW as an exogenous contrast agent for photoacoustic imaging (PAI).
- Demonstration of increased sensitivity of IRDye800CW versus other labels using our acoustic lens based PAI device.
- PAI discrimination of PrCa cells expressing prostate-specific membrane antigen (C4-2) versus non-expressing prostate cancer cells (PC3) using IRDye800 conjugated with A10.3 aptamer bonded to prostate-specific membrane antigen (PSMA).
- PAI discrimination of PrCa cells expressing PSMA (C4-2) versus non-expressing prostate cancer cells (PC3) using IRDye800 conjugated with YC-27, a peptidomimetic urea inhibitor bonded to PSMA.

7. PARTICIPANTS & OTHER COLLABORATING ORGANIZATIONS.

What individuals have worked on the project?

Name: Vikram Dogra, M.D.
Role: Principal Investigator

Nearest person month worked: 1

Contribution to Project: Dr. Dogra is Professor of Radiology, Urology and Biomedical Engineering at University of Rochester. He has over 30 years of experience in diagnostic and clinical research with several imaging modalities such as Ultrasound, Magnetic resonance imaging and Computed tomography. His research laboratory at University of Rochester primarily focuses on Photoacoustic imaging. His special skills include organizational capacity, leadership, and in-depth clinical knowledge in applications of ultrasound and problems faced in the detection of cancer. He directly oversaw all of the work performed in the project and guided the entire team towards achieving the objectives.

Name: John Krolewski, M.D., Ph.D.
Role: Co-Investigator

Nearest person month worked: 1

Contribution to Project: Dr. Krolewski is a Professor of Pathology and Laboratory Medicine and has been investigating mechanisms of cell death and cytokine signaling in the prostate for over 20 years. He directed the cell studies involved in this project.

Name: Kent Nastiuk, Ph.D.

Role: Co-Investigator

Nearest person month worked: 2

Contribution to Project: Dr. Nastiuk is an Associate Professor of Pathology and Laboratory Medicine. He has carried out much of the generation of biological models for this project. He has over 15 years of experience investigating signaling in the prostate, and is well versed in both cell culture and animal models for prostate cancer growth.

Name: Bhargava Chinni, MS

Role: Research Associate

Nearest person month worked: 7

Contribution to Project: Bhargava has performed all the photoacoustic experiments in this project and studied the spectrums of the near-infrared contrast agents, imaging, data acquisition, image processing tasks and data analysis under Dr. Rao’s supervision. He has worked on Photoacoustic Imaging over 5 years with Dr. Dogra and Dr. Rao. He has performed several in-vitro photoacoustic experiments in Dr. Dogra’s laboratory at University of Rochester.

Name: Navalgund Rao, PhD

Role: Consultant

Nearest person month worked: 1

Contribution to Project: Dr. Rao is a Research Professor at Rochester Institute of Technology in the Center for Imaging Sciences department. He has over 30 years of expertise in the field of ultrasound imaging. Dr. Rao oversaw all the photoacoustic imaging experimental work and image analysis tasks performed in this project.

Name: Hans Schmitthenner, PhD

Role: Consultant

Nearest person month worked: 1

Contribution to Project: Dr. Schmitthenner is a Research Scientist at Rochester Institute of Technology. He oversaw the synthesis of the contrast agents investigated in this project.
Name: Shalini Singh, PhD
Role: Post Doc
Nearest person month worked: 3

Contribution to Project: Dr. Singh has performed all the IVIS experiments in this project at University of Rochester. Dr. Nastiuk and Dr. Krolewski has guided Dr. Singh in performing the conjugation of prostate cancer cell lines with the contrast agents and perform fluorescence experiments using IVIS machine.

Has there been a change in the active other support of the PD/PI(s) or senior/key personnel since the last reporting period? Nothing to Report.

What other organizations were involved as partners? Nothing to Report.

8. SPECIAL REPORTING REQUIREMENTS: None

9. APPENDICES:

Quantitative volume determination of normal, neoplastic and hyperplastic mouse prostate using ultrasound imaging: Genetically engineered mouse models are essential to the investigation of the molecular mechanisms underlying human prostate pathology and the effects of therapy on the diseased prostate. Serial in vivo volumetric imaging expands the scope and accuracy of experimental investigations of models of normal prostate physiology, benign prostatic hyperplasia and prostate cancer, which are otherwise limited by the anatomy of the mouse prostate. Moreover, accurate imaging of hyperplastic and tumorigenic prostates is now recognized as essential to rigorous pre-clinical trials of new therapies. Bioluminescent imaging has been widely used to determine prostate tumor size, but is semi-quantitative at best. Magnetic resonance imaging can determine prostate volume very accurately, but is expensive and has low throughput. We therefore sought to develop and implement a high throughput, low cost, and accurate serial imaging protocol for the mouse prostate.

Detecting the sound of light to classify cancer from benign: Prostate specific antigen screening for prostate cancer is inexpensive, non-invasive and sensitive, but lacks specificity. The accuracy of confirmatory prostate biopsy is only 52% due to either the absence of tumor or the inability to precisely sample small tumors with the biopsy needles. Thus, there is an urgent need to develop methods to accurately image cancers within the prostate, to rule out cancer in men with false positive PSA elevation and to ensure successful biopsy for those with small cancers. Photoacoustic imaging is an emerging functional imaging technique that can detect and diagnose prostate cancer based on the near-infrared optical absorption of either endogenous tissue constituents or exogenous contrast agents. Although endogenous tissue constituents show promise, in order to implement photoacoustic imaging in the clinic, there is a need for increased tumor cell specificity, sensitivity and depth of imaging. To enhance the
application of photoacoustic imaging for the detection of early stage prostate cancer, development of near infrared dyes - labeled RNA aptamer that recognizes the prostate specific cell surface protein - prostate specific membrane antigen is proposed to specifically image prostate-cancer. The design incorporates a high energy tunable laser as the source and an ultrasound linear array to detect the acoustic-lens-focused photoacoustic signals generated from the cancerous lesions within the prostate.

**Modular Synthesis of Targeted Near Infrared Agents for Photoacoustic Imaging of Cancer:** Photoacoustic imaging (PAI) is a sensitive, non-invasive means of detecting cancer and is poised to become a transformative method for early screening, targeted biopsies and monitoring disease progression. A key innovation needed in PAI is the design of ‘high-gain’ imaging agents which can readily be prepared and conjugated to groups which target biomarkers in diseased cells. The current technology relies on using endogenous dyes such as deoxyhemoglobin or oxy-hemoglobin. The goal is to provide a versatile and broadly applicable synthesis of peptide-based agents combining high-gain NIR dyes that may be conjugated to a PSMA inhibitor for the early detection of prostate cancer by PAI. There is a precedent for the use of a targeted exogenous NIR dye, IR800CW, conjugated to a peptide specific for neutropilin yielding a photoacoustic signal.

**PSMA-targeted Near Infrared Dye Imaging Agents for Photoacoustic Imaging of Prostate Cancer:** Photoacoustic imaging (PAI) is an emerging noninvasive modality poised to enter the clinic. PAI is well-suited for early, specific detection of prostate cancer (PrCr) and to guide biopsies and active surveillance. In most cases the ultrasound signal in PAI is generated by endogenous chromophores such as hemoglobin energized from nanosecond pulses of a near infra-red (NIR) laser. High absorptivity exogenous agents, such as NIR dyes linked to tumor-specific targeting molecules have been shown to enhance the sensitivity in PAI of breast cancer models. However, reports of exogenous NIR dye based targeted molecular imaging agents (TMIAs) for PAI of PrCa and for other cancers are sparse. To meet this need we envisioned a collaboration which combines a new method of evaluating NIR agents by a novel PAI instrument with a new modular synthesis of TMIAs. For targeting purposes, prostate surface membrane antigen (PSMA) expressed in PrCa cells, and with low expression in non-cancer tissue, is an excellent biomarker for imaging PrCa. Two targeting agents have shown high affinity for PSMA, a nuclease-stable RNA aptamer (A10-3.2) and a urea inhibitor (DCL) which has been coupled with NIR dyes to form TMIAs such as YC-27 and to F agents for PET of PrCa. Our goal was to utilize these motifs and compare binding by fluorescence and PA signal of both the aptamer and the urea targeting systems and to confirm the PSMA binding by confocal fluorescence microscopy.
Photoacoustic imaging with an acoustic lens detects prostate cancer cells labeled with PSMA-targeting near-infrared dye-conjugates

Abstract. There is an urgent need for sensitive and specific tools to accurately image early stage, organ-confined human prostate cancers to facilitate active surveillance and reduce unnecessary treatment. Recently, we developed an acoustic lens that enhances the sensitivity of photoacoustic imaging. Here, we report the use of this device in conjunction with two molecular imaging agents that specifically target the prostate-specific membrane antigen (PSMA) expressed on the tumor cell surface of most prostate cancers. We demonstrate successful imaging of phantoms containing cancer cells labeled with either of two different PSMA-targeting agents, the ribonucleic acid aptamer A10-3.2 and a urea-based peptidomimetic inhibitor, each linked to the near-infrared dye IRDye800CW. By specifically targeting cells with these agents linked to a dye chosen for optimal signal, we are able to discriminate prostate cancer cells that express PSMA. © The Authors. 1 Introduction

The clinical management of early stage, organ-confined prostate cancer (PrCa) is challenging. The introduction of serum prostate-specific antigen (PSA) screening in the 1980s led to a spike in the apparent incidence of PrCa, due to the detection of previously underdiagnosed indolent cancers, which grow slowly and do not affect lifespan.1 While PSA screening has declined previously underdiagnosed indolent cancers, which grow slowly and do not affect lifespan. While PSA screening has declined, the current clinical paradigm for screen-detected PrCa is active surveillance2,3 (AS): monitoring by serum PSA testing and serial prostate biopsies to determine the grade (Gleason score) and extent of tumor.

There is an urgent need for imaging tools for AS, (i) to confirm the initial PSA-based diagnosis; (ii) to guide biopsies, which are now performed in a blinded manner; and (iii) to monitor tumor volume, which is currently not measureable but may represent a biomarker of progression from indolent to aggressive disease. Multim parametric magnetic resonance imaging (MRI) may fill some of these roles, but it is expensive and technically limited.4 In contrast, photoacoustic imaging (PAI), an emerging, noninvasive, functional molecular imaging modality that has not yet entered the clinic, is likely to be less expensive and more portable than any MRI system. The photoacoustic (PA) signal is an ultrasound (US) wave generated by tissue constituents [hemoglobin (Hb), fat, water, and so on] following absorption of short (nanosecond) pulses of laser light in the near-infrared (NIR) spectrum.5 PAI can discriminate among such tissue constituents on the basis of optical absorption properties, allowing for PAI spectroscopy, which can detect biological function.6

Human PrCa is a viable candidate for PAI since transrectal probes can image the prostate gland in situ. Based on US data from human PrCa patients, we estimate that the distance from the rectal wall to the anterior prostate is ~3.5 cm (VD, BC, JJK, KLN, unpublished data), which is within the range of depth detection of PAI for PrCa.7 The most common application of PAI spectroscopy in cancer imaging exploits differences in the absorption spectra of Hb and HbO2 and is therefore capable of detecting tumors based on regions of hypoxia, that promote neoangiogenesis and more aggressive cancers.8 However, endogenous tissue constituents, such as Hb, generate relatively weak photoacoustic signals (due to a small absorptivity factor or extinction coefficient) and lack cancer specificity. Exogenous agents, such as NIR-absorbing dyes or gold particles, linked to tumor-specific binding molecules, such as antibodies, can act as targeted molecular imaging agents (TMIAs) to facilitate sensitive and specific detection of the corresponding cancer. Several TMIAs-targeting PrCa have been reported, but while overexpressed in some PrCa, the targets (GRPR and Her2) are more widely expressed.9 In contrast, PSMA is highly specific and detected on the surface of nearly every human PrCa,
with low to moderate expression on noncancer prostate tissue and very low expression outside the prostate, making it an excellent biomarker for molecular imaging of PrCa. Unfortunately, the FDA-approved application of PSMA detection (ProstaScint) is of limited value because while PSMA is an excellent target, ProstaScint employs a monoclonal antibody against the internal (cytoplasmic) domain of PSMA, and so detects only necrotic cells. Subsequently, improved PSMA-binding agents have been developed, including a nuclease-stable ribonucleic acid aptamer (A10-3.2) that binds very efficiently. PSMA also has an unusual extracellular active site encoding glutamate carboxypeptidase activity, allowing for the synthesis of a urea-based peptidomimetic inhibitor (DCL), that has been linked to a NIR dye for successful in vivo imaging of PSMA+ mouse xenografts and for radiometric imaging of PrCa in patients.

2 Materials and Methods

Figure 1 shows the PAI instrument we employed in this study, similar to the prototype we described previously. Following laser excitation, PA signals from all the absorbers in a small volume of tissue are simultaneously focused on an US detector using an acoustic lens, which corrects for loss of lateral image resolution. The acoustic lens eliminates the need for expensive off-line computer algorithm-based image reconstruction, reducing errors in the final image. This may facilitate more rapid translation to the clinic. Our PA imaging device is comprised of four modules: (i) a fiber-coupled tunable NIR-pulsed laser with wavelengths ranging from 700 to 1000 nm, pulse repetition frequency of 10 Hz, and pulse duration of 5 ns with a surface laser energy intensity of ~20 mJ/cm²; (ii) an unfocused 32-element (1 x 0.7 and pitch of 0.7 mm) linear US sensor array with a central frequency of 5 MHz (range 2 to 8 MHz) and 60% bandwidth; (iii) a spherical acoustic lens with a diameter of 25.4 mm and focal length of 39.8 mm to focus PA signal on the sensors; and (iv) a custom designed 32-channel simultaneous data acquisition unit to amplify (40 to 70 decibels variable gain), digitize (12-bit, 30 MHz), average (8x), and store the received PA signals. To acquire C-scan PA planar images, the device is raster-scanned over the cone shaped (20 mm x 1 to 2 mm) sample cuvette using dual-axis stepper motors, while the laser light is delivered using a trans-illumination setup. Previously we used this system to image phantoms and ex vivo human PrCa specimens.

3 Results

3.1 Identification of Optimal Chromophore for Imaging Agent

In order to improve depth penetration and image quality, exogenous chromophores can be employed as contrast agents as part of a TMIA. Using a laser tuned to the maximum excitation wavelength of the TMIA-chromophore, tumor detection can be greatly enhanced as these exogenous chromophores have absorptivity factors two- to three-orders of magnitude greater than those of endogenous agents such as Hb. For greatest tissue depth penetration and sensitivity, TMIA labeled with chromophores that absorb in the “biological NIR window” between 750 and 900 nm circumvent the natural absorbance of Hb, HbO₂, and H₂O. To identify a suitable NIR dye, optical absorbance of a 100-μM solution of five commercially available dyes IRDye800CW (Licor), Cy7 (synthesized by H.S.), AlexaFluor750, Cyanine7-sulfo, and Dylight800 (ThermoFisher) was first measured to ensure concordance with supplier data after dilution [Fig. 2(a)]. As expected from the reported peak intensities (lambda max), the Alexafluor 750 and Cy7 have a peak optical absorption when irradiated at 750 nm, Cy7-sulfo...
at 755 nm, Dylight800 at 785 nm, and the dye IR800CW at 775 nm. The spectra of the photoacoustic signal of a 100-μM solution of each contrast agent was then determined over the 710- to 1000-nm wavelength range [Fig. 2(b)]. The inset shows the maxima of each PA signal and the corresponding wavelength (indicated beneath) in the 730 to 875 nm window (signal below 730 nm reflects laser output fluctuation). Among the five contrast agents/dyes we investigated, IRDye800CW was chosen because it produced the highest PA intensity relative to the other agents and because the peak absorption is well separated from endogenous tissue constituents [Fig. 2(b)]. IRDye800CW was serially diluted in DMSO and water. The resultant PA signal intensity above diluent signal correlates well with concentration \[ r^2 = 0.979; \text{Fig. 2(c)} \]. Using our PAI apparatus with the acoustic lens in-line, 0.8-μM IRDye800CW is the threshold for detecting signal above noise.

### 3.2 Photoacoustic Signal from Target Expressing Prostate Cells

A TMIA was synthesized by labeling the PSMA-specific 10.3.2 aptamer with IRDye800CW (GeneLink). Cells expressing (C4-2) or lacking (PC3) PSMA were incubated in a 4-μM solution of

![Enhanced photoacoustic signal from PSMA+ C4-2 PrCa cells labeled with A10-3.2-IRDye800CW aptamer-dye. Optical imaging of a multiwell plate containing aliquots of PSMA+ C4-2 (right side four wells) and PSMA- PC3 (left side four wells) cells labeled with aptamer-dye (buffer in middle wells). Fluorescent signal intensity was captured via (a) IVIS and (b) relative intensity plotted, \( p < 0.001 \). Cells from three of each of the wells in (a) were sequentially loaded into the PAI instrument cuvette (Fig. 1) and PA signal (B-scan) was captured at 785 nm from c4-2 (red lines) and PC3 (blue lines), by scanning the elevation (long) axis of the cuvette, elevation position (arbitrary) of the probe and (d) peak PA signal was plotted, \( p = 0.0174 \). C-scan images of cuvettes from (c) containing labeled (e) C4-2 and (f) PC3 cells.](image)
the TMIA in PBS, washed thrice in PBS by centrifugation and resuspension, and examined in our PAI system. The spectra of the photoacoustic signal from C4-2 cells and PC3 cells shows a maximal PA signal difference at 785 nm (Fig. 3). The acoustic lens allows signal detector signal focus from a large incident angle thereby enhancing detection up to fourfold [data not shown (DNS) and Ref. 14]. The 20-nm difference in the wavelength producing peak PA signal between the IRdye800CW alone, at 765 nm, and this 785 nm peak suggests that conjugation of the IRdye800CW to the aptamer to constitute the TMIA, and/or binding of the TMIA to the PSMA molecules on the prostate cell surface, affected the wavelength of absorbance producing the peak PA signal (Fig. 3).

3.3 Quantitative Assessment of Aptamer as Targeting Agent

Quantitative characterization of this TMIA shows specific and uniform binding to PSMA-expressing PrCa cells. Four samples of ten million PC3 or C4-2 cells were labeled as above and imaged at 770 nm [Fig. 4(a)] and fluorescence emission was quantitated [Fig. 4(b)] using an IVIS spectrum (Perkin Elmer). TMIA labeling was uniform (CV = 5.5% for PC3, 6.0% for C4-2) and the signal (C4-2) to noise (PC3) ratio (SNR) was 2.56 ± 0.08. One of the four TMIA-labeled cell samples was used to tune the PA system alignment, and the remaining three were sequentially pipetted into the PA cuvette (Fig. 1) and peak PA signal determined at 785 nm excitation from a B-scan [Fig. 4(c)] for each of the six samples. When quantitated, the SNR was 2.33 ± 0.09 [Fig. 4(d)]. The B-scan data were reconstructed as C-scan depicting each cuvette of C4-2 cells [Fig. 4(e)] and PC3 cells [Fig. 4(f)]. Analyzing the C-scan signal using ROIs encompassing each of the six cuvettes, the PA SNR was 5.35 ± 0.04.

3.4 Quantitative Assessment of Inhibitor as Targeting Agent

An alternate targeting moiety, consisting of the DCL inhibitor conjugated to IRDye800CW (YC-27, Licor) was similarly evaluated as a TMIA. As above, there was a 20-nm shift in the wavelength of absorbance producing peak PA signal, to 785 nm (DNS). The YC-27 TMIA also shows specific and uniform binding to PSMA-expressing PrCa cells as assessed by fluorescence imaging at 770 nm [Figs. 5(a) and 5(b)]. Variability of YC-27 TMIA labeling was somewhat higher than for the aptamer TMIA (CV = 17% for PC3, 9.9% for C4-2), but the fluorescent SNR was much larger, 24.7 ± 1.22 (versus 2.56 for the aptamer). Peak PA signal from a B-scan for each cell type after labeling with the YC-27 TMIA [Fig. 5(c)] produced an enhanced photoacoustic signal from PSMA+ C4-2 PrCa cells labeled with YC27 TMIA. Optical imaging of a multiwell plate containing aliquots of PSMA+ C4-2 (right side four wells) and PSMA-PC3 (left side four wells) cells labeled with urea-dye (buffer in middle wells). Fluorescent signal intensity was captured via (a) IVIS and (b) relative intensity plotted, \( p < 0.001 \). (c) Cells from three of each of the wells in (a) were sequentially loaded into the PAI instrument cuvette (Fig. 1) and PA signal (B-scan) was captured at 785 nm from c4-2 (red lines) and PC3 (blue lines), by scanning the elevation (long) axis of the cuvette, elevation position (arbitrary) of the probe and (d) peak PA signal was plotted, \( p = 0.0246 \). C-scan images of cuvettes containing C4-2 (e) and PC3 (f).
SNR of $1.86 \pm 0.24$ [Fig. 5(d)]. Figures 5(e) and 5(f) are C-scans depicting each cuvette of C4-2 cells and PC3 cells, respectively. Analyzing the C-scans using an ROI encompassing each cuvette, the PA SNR was $5.91 \pm 0.81$.

4 Discussion

TMIA-s optimized for PAI, in combination with an acoustic lens, allowed us to discriminate between PrCa cells lines that either express PSMA or do not express PSMA. Both the A10 aptamer and the DCL inhibitor specifically bind PSMA-expressing cells and are compatible i.p. or intratumoral delivery in vivo.\textsuperscript{10,17,18} While the aptamer TMIA showed slightly better SNR for PAI, it is expensive to synthesize and less stable than the inhibitor. The YC-27 is much brighter by fluorescence and conjugation of modified chromophores to the DCL inhibitor is more tractable.\textsuperscript{18} The urea-targeting agent therefore represents a better approach to developing “louder” TMIA-s that will be necessary to overcome the challenges to detecting PrCa by PAI in vivo, intensity of light penetration to deep tissue, and TMIA-chromophore abundance due to target density from small tumors.
