<td>The purpose of this study is to test the efficacy of thrombopoietin (TPO) to heal a segmental bone defect (SBD) in a large animal model, the minipig. The scope of the research comprises the following specific aims (i) to determine the union rate of tibial midshaft defects in minipigs treated with BMP-2, TPO, or saline control; and (ii) to evaluate the safety and side effects of treating tibial midshaft defects in minipigs treated with BMP-2, TPO, or saline control. In the previous research periods we completed surgeries and collection of tissue/data from 27 minipigs which had surgeries with IM nail fixation and 12 minipigs which had surgeries with compression plate fixation. Perhaps the two most significant findings during this period are that we discovered that fixation type (IM nail vs. compression plates) impacts the size requirement for a critical size defect, and that even with a large segmental defect, that is not of critical size, TPO is able to more rapidly allow for bone healing than observed in saline treated controls. We believe with creating a large defect but with using compression plate fixation we can even further improve TPO’s efficacy, which along with finalizing data collection from the previous pig surgeries, will be the main goals in our 1 year no cost extension period (Year 4).</td>

1. INTRODUCTION: The subject of this research is the need for improved treatment of segmental bone defects. The purpose of this study is to test the efficacy of thrombopoietin (TPO) to heal a segmental bone defect (SBD) in a large animal model, the minipig. The scope of the research comprises the following specific aims (i) to determine the union rate of tibial midshaft defects in minipigs treated with BMP-2, TPO, or saline control; and (ii) to evaluate the safety and side effects of treating tibial midshaft defects in minipigs treated with BMP-2, TPO, or saline control.

2. KEYWORDS: Bone healing, bone morphogenetic protein (BMP), thrombopoietin (TPO), therapy, fracture healing, bone regeneration, minipig, pig

3. OVERALL PROJECT SUMMARY:

Task 1 and Milestone 1. Obtain Regulatory Approvals – Completed by Drs. Kacena, Chu, and McKinley (led by Dr. Kacena). Our 3-year IACUC protocol expired 26/09/16 and we obtained IACUC approval for our new protocol (just updated from the previous one with the revised size of the defect as per discussions with Dr. Green Parker, see below for more detail) on 22/09/16. On this same day 22/09/16 we sent the requested documents for ACURO approval. At this time our protocol has undergone administrative review and on 24/10/16 we received an email confirming ACURO approval, but that the final letter will be forth coming.

Task 2. Perform surgeries on minipigs and evaluate bone healing with x-ray.

Task 2a. Fabricate Scaffolds – completed by Dr. Chu.

Task 2b. Perform surgeries on minipigs – 27 minipig surgeries completed – surgeries performed by Drs. Anglen, Chu, and Cheng (plus other approved trainees and vet technicians). Drs. Chu and Anglen optimized the surgical protocol on cadaver minipigs and live pilot minipigs first, tested hardware on tibia curvature etc. Drs. Kacena and Chu ordered all required supplies/equipment/reagents/animals and confirmed schedule. Dr. Kacena has been responsible for management of personnel/trainees for post-operative animal care. The time, effort, and even drugs required (pain management) for post-operative management of minipigs has been substantially larger than was anticipated. The veterinarian was in charge or deciding our post-operative pain management protocol. These studies required significantly more time, effort, and budget than we anticipated. We obtained significant internal funding and cost shared significant effort to accomplish the surgeries and post-operative care to date (we enlisted in the assistance of 6 medical students, 2 additional orthopaedic surgeons (Drs. Todd McKinley and Karl Shively), a graduate student, and a postdoctoral fellow (the latter has been averaging 60-90 hours/week since the surgeries have begun) in addition to our original team of 4 (Drs. Kacena, Chu, Anglen, and Cheng) and everyone is well over their anticipated % effort). We have not increased the salary associated with the effort or added salary for any of the additional personnel at this time.

We next completed surgeries on 12 minipigs – surgeries performed by Drs. McKinley, Chu, and Zhao (plus other approved trainees and vet technicians). This surgery used compression plates rather than the IM nail system as the IM nail system showed that it was not biomechanically stable over time.

Task 2c. Perform radiographic assessments. X-rays have been obtained for the 27 minipigs with IM nails. Completed by Drs. Anglen, Chu, and Cheng. X-rays have been obtained for the 12 minipigs with compression plates. Completed by Drs. McKinley, Chu, and Zhao.

Task 3. Determine the bone union rate of the minipigs after implant retrieval using uCT and histology.

Task 3a. Retrieve tibiae from minipigs – completed for 27 minipigs with IM nails by Drs. Chu and Cheng (and Dr. Kacena’s medical students, postdoctoral fellows as well as pathologists).

Retrieve tibiae from minipigs – completed for 12 minipigs with compression plates by Drs. Chu and Zhao (and Dr. Kacena’s medical students, postdoctoral fellows as well as pathologists).

Task 4. Determine the biomechanical properties of the newly formed callus.
Task 4a. Retrieve samples – completed for 27 minipigs with IM nails by Drs. Chu and Cheng (and Dr. Kacena’s medical students, postdoctoral fellows as well as pathologists).

Retrieve samples – completed for 12 minipigs with compression plates by Drs. Chu and Zhao (and Dr. Kacena’s medical students, postdoctoral fellows as well as pathologists).

Task 4b. Perform torsion testing – completed for 27 minipigs with IM nails by Dr. Chu. Is being completed for 12 minipigs with compression plates by Drs. Chu and Zhao.

Task 5. Evaluate potential systemic side effects of TPO by studying the blood of the minipigs before and post-surgery.

Task 5a. Collect blood samples. We have completed the collection of the blood samples as per approved IACUC/ACURO protocols. Completed for 27 minipigs with IM nails by Drs. Kacena and Cheng. Completed for 12 minipigs with compression plates by Drs. Kacena and Zhao.

Task 5b. Evaluate platelet numbers. Complete blood counts were completed on all blood samples, data has been collected and is being analyzed. It appears there is no specific trend/changes for any of the minipigs assessed. Completed for 27 minipigs with IM nails by Drs. Kacena and Cheng. Completed for 12 minipigs with compression plates by Drs. Kacena and Zhao.

The remaining tasks/milestones will be achieved during our 1 year NCE period.

The surgical method is detailed in our IACUC/ACURO protocols. Briefly, Prior to surgery, x-rays of the right tibia will be collected to confirm skeletal maturity (epiphyses are closed). Also prior to surgery, PPF/TCP scaffolds of 17 mm in the outer diameter, 10 mm in the inner diameter, and 25 mm in height will be fabricated using the casting method described in our previous publication. (Chu et al 2007) As a carrier for saline, BMP-2, or TPO we have chosen to use an FDA approved type I bovine collagen sponge (Helistat, 7.5 cm x 10.0 cm x 5.0 mm, ½ of a sponge will be used for each pig or 7.5 cm X 5.0 cm X 5.0 mm). Collagen sponges will be treated with BMP-2, TPO, or saline and allowed to sit for 15 minutes prior to implantation.

The animals will be induced and maintained under sodium thiopental and fentanyl dihydrogencitrate for the duration of the procedure. First, a subcutaneous implantable port system will be inserted into each minipig to provide better access for later blood sampling and injections. The animals will be properly draped and surgical site will be prepared using sterile technique. The right hind-limb will be prepared with betadine. A 10 cm incision will be made in the proximal diaphysis of the tibia using an anteromedial approach. The exposure will be carried down between the tibia and the TA muscle and the tibia will be circumferentially exposed through muscle elevation. The tibia will be marked for length and orientation to ensure rotational accuracy. Two parallel, transverse osteotomies will be made 25 mm apart with a reciprocating saw (Stryker, Kalamazoo, MI). Please note that in our revised IACUC protocol based on our observations noted below we recommended a 40mm defect size (and 40mm scaffold) for our final series of surgeries. The resulting free segment of bone will be removed, creating a critical-size defect.

**IM Nail Procedure:**

The intramedullary (IM) nail will be inserted through the proximal incision. The IM nail will be inserted in an antegrade fashion from the proximal bone fragment, through the central canal of the scaffold, terminating in the distal bone fragment, ensuring tight apposition between the cut bone ends and the scaffold. The IM nail will then be locked with 2 locking screws proximal and 2 locking screws distal to the segmental defect. The fascia and subcuticular layer will be closed with Vicryl suture. The scaffold will be placed into the segmental defect. The scaffold will be circumferentially surrounded by a type I collagen sponge soaked with BMP-2, TPO, or saline control and the joined ends will be secured with Vicryl suture.

**For Compression Plate Procedure:**

A standard narrow nine hole 4.5 mm limited contact dynamic compression plate (Synthes; Paoli, PA) will be placed on the anterolateral surface of the tibia. Any necessary contouring to optimize conformity of the plate with the bone surface will be performed with a table-top bending device. The plate will be secured with four 4.5 mm screws inserted proximal and four more 4.5 mm screws distal to the defect inserted with standard techniques through both cortices. In addition, a screw will be inserted through one surface of the scaffold to
maintain its position. Subsequently, the scaffold will be circumferentially surrounded by a type I collagen sponge soaked with TPO, BMP-2, or saline and the joined ends will be secured with an appropriately size absorbable suture.

The fascia and subcuticular layer will be closed with an appropriately sized absorbable suture. An appropriately sized suture will also be used for skin closure. From our preliminary minipig study, we have not observed deformation of locking screws but have needed to tighten the screws. We did not have these problems with the compression plate.

Amoxicillin, benzylpenicillin and clavulanate will be given 24 hrs prior to the surgery and daily for 3 days after the surgery as prophylactic antibiotics; the animals will be monitored postoperatively and given analgesic drugs such as dexmedetomidine, buprenorphine, hydromorphone, and ketamine for three postoperative days at which time tramadol will then be given for up to 4 weeks based on veterinarian recommendations. Anteroposterior and lateral radiographs of both tibiae will be taken during the acclimation period before implantation to serve as controls for normal tibia mineralization (Toshiba Infinix VC with Vitrea 2 work station) and to exclude animals with pre-existing bone pathology.

4. KEY RESEARCH ACCOMPLISHMENTS: Key accomplishments from the previous reporting period:
We completed surgeries and tissue collection from all 27 minipigs with IM nails. 8 = saline control, 8 = 1.5mg BMP-2, 8 = 1.5 mg TPO, 3= 7.5 mg TPO. As the sample size was low in the high dose TPO group and there were complications observed with a pig in that group below we focus on data from the 3 groups with the higher sample sizes.

Figure 1 demonstrates the key methods.

![Figure 1](image1.png)

Figure 1: (A) Pig tibia with scaffold in place. (B) Manipulation of the surgical site to place collagen sponge loaded with treatment. (C) Fixation of the intramedullary nail. We created critical size defects in the tibiae of 24 Yucatan mini-pigs. Into these defects were placed synthetic scaffolds composed of polypropylene furmarate/tricalcium phosphate supported by an intramedullary nail that was further fixated with screws. Overlying the scaffold was a collagen sponge impregnated with saline (control), BMP-2 ( 1.5 mg), or TPO (1.5 mg). After surgery, the animals were allowed to heal for 6 to 9 months during which they ambulated as tolerated. Healing progress was monitored with plain radiography at baseline and then monthly until euthanasia. Whole blood was collected at baseline, 1 and 2 weeks post-operatively, and then monthly until euthanasia. At euthanasia, experimental tibiae with the scaffold in place were collected and the specimens are being processed for micro-CT and histological examination.

Figure 2 shows the key x-ray findings.

![Figure 2](image2.png)

Figure 2: TPO promotes bone healing. (A) A representative 6 month X-ray of the tibia from a saline treated animal shows that the induced defect was critically sized, and did not heal. (B) A representative 6 month X-ray of the tibia of a BMP-2 treated animal shows that the defect could heal with intervention. A prominent callus can be seen around the site of the defect. (C) A representative 6 month X-ray of the tibia of a TPO treated animal shows cortical bridging across one side of bone.

Figure 3 shows the biomechanical data.
Figure 3. Both operated tibia and contralateral un-operated tibia were retrieved at sacrifice and were subjected to non-destructive torsional test using a digital torque gauge. All operated tibia in the BMP group healed and demonstrated a torsional stiffness of $114 \pm 15\%$ of the contralateral tibia. Four out of eight tibia in the 1.5 mg TPO group healed and showed a torsional stiffness of $100 \pm 12\%$ of the contralateral tibia. Another four tibia in the 1.5 mg TPO group did not heal. None of the tibia in the saline group healed. There were no statistical significant differences between the BMP and the healed TPO group ($p > 0.05$). These two groups are statistically significantly higher than the unhealed TPO and the saline groups. Due to retrieval issues and/or hardware/technical failures we unfortunately lost 3 of the saline specimens (experimental limb or contralateral limb), and thus only have $n=5$ rather than $n=8$ for the torsional stiffness data.

Figure 4 shows the key platelet data.

Figure 4. Blood was collected from the minipigs prior to surgery (baseline) as well as 1 week, 2 weeks, 1 month, 2 months, 3 months, 4 months, 5 months, and 6 months post-surgery. A complete blood count was completed on all blood samples. Platelet concentrations are reported as the mean ± standard deviation. Platelet concentrations were significantly elevated in all minipigs 1 week after surgery (compared to respective baseline samples, $p<0.001$). No differences were observed in platelet concentrations between minipigs treated with saline or TPO. However, using a 2-way anova we determined that platelet concentrations were significantly reduced in BMP-2 treated minipigs compared to that observed in saline treated controls ($p<0.001$).
Key accomplishments from this reporting period: We completed surgeries and tissue collection from all 12 minipigs with compression plates. 4 = saline control and 8 = 1.5 mg TPO.

Figure 5: Compression plate model. (A) Compression plate (arrow) is placed across defect and secured in place with locking screws. (B) Representative lateral and anteroposterior (AP) views of saline treated animal 4 weeks after surgery. Minimal healing (#) is visible across the defect. (C) Representative lateral and AP views of TPO treated animal 4 weeks after surgery. Partial healing ($) is visible and is more robust than saline treated animal.

![Figure 5](image)

Figure 6: Modified RUST score. (A) 4 weeks after surgery, The TPO treated animals (n=8) scored significantly higher than controls. (B) At 3 months the difference between TPO and saline treated animals was not significant.

![Figure 6](image)

Preliminary blood and pathology analyses have not raised any safety concerns.
5. CONCLUSIONS:

**IM Nail Conclusions**

- All eight of the saline control treated animals failed to demonstrate healing across the induced tibial defect.
- All eight of the BMP-2 treated animals showed healing across the induced tibial defect and had a torsional stiffness of 114±15% of the contralateral tibia.
- Four of the eight TPO treated animals showed healing across the tibial defect and had a torsional stiffness of 100±12% of the contralateral tibia.
  - No adverse effects from TPO treatment have been identified from blood measurements, organ pathology, or veterinary inspection.
  - Healed tibiae had torsional stiffness values which were not statistically different from their contralateral counterparts.
- While healing with TPO is better than that observed with saline, TPO did fail in 4 of 8 of our pigs. Based on our 4 healed tibia and our previous mouse/rat data, TPO morphologically appears to promote robust bone growth by direct bone healing, which takes longer to accomplish than BMP-2. Thus, if our fixation fails before our healing process is allowed to occur (which appears to have been the problem in the 4 tibiae that failed to heal), we cannot properly assess the value of TPO as a bone healing therapy. To better investigate this we have recommended completion of one more group of pigs with a different fixation strategy (more rigid fixation). As we secured internal funding to assist with defraying our expenses to date as well our revising our protocol to euthanize the pigs earlier than the original 1 year time point, we would have sufficient funds to complete this testing. Dr. Todd McKinley discussed this with Dr. Yadav in person at the August meeting in Florida.
- Platelet concentrations were significantly elevated in all minipigs 1 week after surgery (compared to respective baseline samples, p<0.001).
- Platelet concentrations were significantly reduced in BMP-2 treated minipigs compared to that observed in saline treated controls (p<0.001).
- TPO treatment did not result in a significant systemic increase in platelet concentration as significant differences were not observed in platelet concentrations between minipigs treated with saline or TPO.

**Compression Plate Conclusions**

- TPO treated minipigs had significantly improved healing at 1 and 2 months post-surgery.
- All saline and TPO treated minipigs healed over time.
- The 25 mm defect is not a critical sized defect when compression plating fixation is used whereas it is with IM nails.
- To more robustly demonstrate the effectiveness of TPO to heal a critical sized defect with sufficient fixation we proposed testing a larger, 40mm defect with compression plating. ACURO approval was just obtained and we plan to begin this work next month.

**Future plans:** Complete uCT and histological analysis of tibias. Complete blood analyses and organ pathological analyses. Create larger defect in 12 minipigs with compression plate fixation. Apply for expansion grants related to these studies. Related to the latter, identify all opportunities to fund safety studies so that once safety is confirmed we can obtain FDA approval to begin a first in human (for bone healing indications), phase I clinical trial.

Abstract

Segmental defect regeneration has been a clinical challenge. Current tissue-engineering approach using porous biodegradable scaffolds to delivery osteogenic cells and growth factors demonstrated success in facilitating bone regeneration in these cases. However, due to the lack of mechanical property, the porous scaffolds were evaluated in non-load bearing area or were stabilized with stress-shielding devices (bone plate or external fixation). In this paper, we tested a scaffold that does not require a bone plate because it has sufficient biomechanical strength. The tube-shaped scaffolds were manufactured from poly(propylene) fumarate/tricalcium phosphate (PPF/TCP) composites. Dicalcium phosphate dehydrate (DCPD) were used as bone morphogenetic protein-2 (BMP-2) carrier. Twenty-two scaffolds were implanted in 5 mm segmental defects in rat femurs stabilized with K-wire for 6 and 15 weeks with and without 10\,mg of rhBMP-2. Bridging of the segmental defect was evaluated first radiographically and was confirmed by histology and micro-computer tomography (\(\mu\)CT) imaging. The scaffolds in the BMP group maintained the bone length throughout the duration of the study and allow for bridging. The scaffolds in the control group failed to induce bridging and collapsed at 15 weeks. Peripheral computed tomography (pQCT) showed that BMP-2 does not increase the bone mineral density in the callus. Finally, the scaffold in BMP group was found to restore the mechanical property of the rat femur after 15 weeks. Our results demonstrated that the load-bearing BMP-2 scaffold can maintain bone length and allow successfully regeneration in segmental defects.

1. Introduction

Segmental bone defects resulting from trauma or pathology represent a common and significant clinical problem. Limb amputation was historically the principal treatment option for these defects as they typically do not heal spontaneously [1]. With advances in medicine and science, alternative treatment options have developed such as the use of bone-grafting techniques. Autologous bone grafts are preferred as they possess inherent osteoconductivity, osteogenesis and osteoinductivity. However, there is often limited supply of suitable bone for autologous grafting, and its collection is frequently associated with donor-site morbidity. An alternative is to use allogeneic bone grafts from donors or cadavers. These circumvent some of the limitations associated with harvesting autologous grafts, but allogeneic bone grafts lack osteoconductivity, have limited osteoinductivity and present a risk of disease transmission. These limitations necessitate the pursuit of alternatives for the management of segmental bone defects, with the latest approach being to use tissue-engineering techniques.

Tissue engineering for bone typically involves coupling osteogenic cells and/or osteoinductive growth factors with osteoconductive scaffolds [2,3]. In terms of osteoinductive growth factors, most research has focused on the use of the bone morphogenetic proteins (BMPs) and, in particular,
BMP-2 [1,4–8]. BMP-2 is a bone matrix protein that stimulates mesenchymal cell chemotaxis and proliferation, and promotes the differentiation of these cells into chondrocytes and osteoblasts [6,8]. These cellular effects bestow BMP-2 potent osteoinductive capabilities, which are primarily evident by the induction of new bone formation via a process of endochondral ossification when implanted at ectopic sites [9,10]. This osteoinductive action of BMP-2 is well established to be beneficial during the repair of fractures and segmental bone defects [1,5,7,8].

BMP-2 induces bone regeneration following injury and has been approved for limited clinical use in the form of recombinant human BMP-2 (rhBMP-2) [5]. However, rhBMP application has been limited by ongoing delivery issues. To facilitate retention of rhBMP-2 at the treatment site and reduce the effective dose, an appropriate carrier is required [9]. The preferred carrier consists of a scaffold that is both biocompatible and bioresorbable in order to limit tissue rejection and exposure to the scaffold material, respectively [11]. While numerous scaffolds have been manufactured that meet these requirements [12] many lack the ability to tolerate appreciable loads. This is of importance as segmental defects frequently occur in load-bearing bones. Scaffolds need to be able to tolerate loading so that patient morbidity is minimized during reparation and the structure of the engineered bone is optimized to the local mechanical environment. Few load-bearing scaffolds have been described in the literature, with many studies of tissue engineered bone regeneration with BMP-2 being conducted at non-load-bearing sites [13–16] or in defects stabilized with stress-shielding devices (bone plates or external fixation) [17–20].

In the current paper, we present a tissue-engineering strategy for bone regeneration using rhBMP-2 carried by a novel load-bearing biodegradable scaffold. Tube-shaped scaffolds were fabricated from a high strength biodegradable composite and calcium phosphate cement, and implanted into critical-sized defects in an established rodent model [21]. Defects and scaffolds were stabilized with a load-sharing device (intramedullary pin). The aim was to investigate the effect of our novel load-bearing scaffold carrying rhBMP-2 on segmental defect repair in the rat femur.

2. Materials and methods

2.1. Animals

Twenty-two adult male Long-Evans rats (weight = 450–550 g) were purchased from Charles River Laboratory (Wilmington, MA) and acclimatized for a minimum of 1 week prior to experimentation. Animals had ad libitum access to standard rat chow and water at all times, and all procedures were performed with prior approval of the Institutional Animal Care and Use Committee of Indiana University.

2.2. Scaffold manufacture

Polypropylene fumarate (PPF) with a molecular weight of 1750 g/mol and PI = 1.5 was obtained from Prof. Antonios Mikos (Rice University, Houston, TX). A thermal-curable PPF/tricalcium phosphate (TCP) suspension was prepared by mixing PPF, N-vinyl pyrrolidinone (NVP), and TCP at a weight ratio of 1:0.75:0.66 [22]. Tube-shaped structures (outer diameter = 4 mm, inner diameter = 2 mm, height = 5 mm, with four side holes of 800 μm diameter) were created by the indirect casting technique developed by Chu et al. [23,24]. Briefly, a scaffold design was generated using commercial Computer-Aided-Design software and a negative model obtained by using Boolean computer operation. Wax casting-molds were fabricated on a 3-D Inkjet Printing Machine (T66, Solidscape Inc. NH) according to the model design. The PPF/TCP slurry was combined with 0.5% benzoyl peroxide (thermal initiator) and 10 μl of dimethyl p-toluidine (accelerator), and cast into the wax mold. Following polymerization, the wax mold was removed by acetone to reveal the scaffold. rhBMP-2 was aseptically added to half of the scaffolds prior to surgery by adding 10 μg of rhBMP-2 (Wyeth, Cambridge, MA) to porous dicalcium phosphate dihydrate (DCPD) cement previously packed into the side holes of the scaffold (BMP-2 group). In the remaining scaffolds, DCPD without rhBMP-2 was added to the side holes (control group).

2.3. Segmental defect induction and surgical implantation of the scaffolds

All animals underwent surgery to create a unilateral midshaft femur segmental defect into which either a rhBMP-containing scaffold (BMP group) or control scaffold (control group) was implanted. A non-scaffold control group was not used in this study since the non-healing nature of 5 mm segmental defects in the rat femur is well established [25,26]. Following a pre-operative subcutaneous dose of buprenorphine hydrochloride analgesia (0.05 mg/kg; Buprenex®—Reckitt Benckiser Pharmaceuticals Ltd., Inc., Richmond, VA), surgical anesthesia was achieved using a mixture of ketamine (60–80 mg/kg; Ketaset®—Fort Dodge Animal Health, Fort Dodge, IA) and xylazine (7.5 mg/kg; Sedazine®—Fort Dodge Animal Health, Fort Dodge, IA) introduced intraperitoneally. The fur was clipped and cleaned using alternating chlorhexidine and 70% ethanol scrubs. Using a sterile technique, a 30-mm longitudinal incision was made over the lateral thigh, beginning just distal to the lateral knee joint and extending proximally. The intermuscular septum between the vastus lateralis and hamstring muscles was divided using blunt dissection to localize the femur. The lateral structures stabilizing the patella were divided and the patella manually dislocated medially. A 5 mm segment of the midshaft femur was removed following two parallel osteotomies under irrigation using a Dremel drill (Robert Bosch Tool Corporation, Mount Prospect, IL) with attached diamond-embedded wafer blade (Super Flex Diamond Disc, Miltex Inc, York, PA). To stabilize the fracture, a 1.25 mm diameter stainless steel K-wire (Synthes Inc, West Chester, PA) was inserted retrograde into the distal intramedullary canal, beginning in the knee between the femoral condyles. The wire was advanced to the segment defect and a scaffold centered over the tip. The wire passed through the central canal of the scaffold and was further advanced in a retrograde fashion into the proximal intramedullary canal and through the greater trochanter (Fig. 1). The distal tip of the wire was cut flush with the femoral condyles. After thorough irrigation, the patella was relocated and stabilized with an absorbable suture, and the muscle and skin layers closed and sutured.

2.4. Radiographic analysis

In vivo X-rays were taken of eight rats (n = 4/group) at 1, 3, 6, 12 and 15-weeks post-operatively using a portable X-ray machine (AMX-110, GE Corp, Waukesha, WI). The rats were anesthetized using isoflurane (Abbott Laboratories, North Chicago, IL) and placed prone on an X-ray film cassette 29 inches beneath the X-ray source. Exposure was at 60 kVp for 2.5 mAs. All films were evaluated in a blinded fashion by three independent evaluators using a three-point radiographic scoring system (0 = no callus formation; 1 = possible union across the gap; 2 = complete callus bridging across the gap).
2.5. Assessment time points and specimen preparation

Animals were killed at 6 (n = 4/group) and 15 (n = 7/group) weeks post-operatively by inhalation of carbon dioxide followed by bilateral pneumothorax. In four rats per group, both femora were dissected free and prepared for micro-computed tomography (μCT), peripheral quantitative computed tomography (pQCT) and histological assessment by fixing in 10% neutral buffered formalin for 48 h and storing in 70% alcohol. In the remaining six rats in the 15-week group, hind limbs were prepared for mechanical testing operatively by inhalation of carbon dioxide followed by bilateral pneumothorax. A custom-made four-point bending fixture with a span width of 22.0 mm between the lower contacts and 8.0 mm between the upper contacts was used. The femurs were positioned cranial side up across the lower contacts. A preload of 1.0 N and crosshead speed of 20.0 mm/min were used to break the femurs. Measurements made using force-versus-displacement curves included: ultimate force (N) or the height of the curve, stiffness (N/mm) or the maximum slope of the curve, and energy to ultimate force (mJ) or the area under the curve up to ultimate force.

2.6. μCT

μCT was performed on a randomly selected subgroup of segmental defects to visualize in three dimensions the stage of healing at 6- and 15-weeks post-operatively. The intramedullary K-wires were carefully removed before further assessment as metal causes beam-hardening artifacts during quantitative radiographic imaging. Each femur was centered in the gantry of a μCT machine (μCT-20; Scanco Medical AG, Bassersdorf, Switzerland) and scanned at 50 kVp/32 keV (160 μA) with an isotropic voxel size of 8 μm. The scanned slices were reconstructed to show in three dimensions the external and cut-away views of the reparative callus and scaffold.

2.7. pQCT

pQCT was used to assess callus and scaffold volumetric bone mineral density (vBMD; mg/cm³) at 6- and 15-weeks post-operatively. Each femur was centered in the gantry of a pQCT machine (XCT Research SA+; Stratec Medizintechnik, Pforzheim, Germany) and scanned with a 70 μm voxel size. Five 0.46 mm cross-sectional slices were scanned at 1 mm intervals, with the center slice coinciding with the center of the scaffold. Contouring mode 1 with a threshold of 240 mg/cm³ was used to separate bone from soft tissue. Areas containing only the callus or scaffold were selected from the images using the region-of-interest (ROI) tool function, and the vBMD of the callus and scaffolds were determined, respectively.

2.8. Histological assessment

Femurs were processed for histomorphometry by washing, dehydrating in graded alcohols, and infiltrating and embedding undecalcified in methyl methacrylate (Aldrich Chemical Co., Inc., Milwaukee, WI). Thin (7 μm) sections were taken through the long axis of each femur in the sagittal plane using a rotating microtome (Reichert-Jung 2050; Reichert-Jung, Heidelberg, Germany). Alternating sections were stained with hematoxyline-and-eosin and McNeals tetrachrome. Sections were viewed on Nikon Optiphot fluorescence microscope (Nikon, Inc., Garden City, NJ).

2.9. Mechanical testing

For mechanical testing, femurs were brought to room temperature overnight in a saline bath, the gauze wrapping removed, soft-tissue dissected free and the intramedullary pin carefully removed. A custom-made four-point bending fixture with a span width of 22.0 mm between the lower contacts and 8.0 mm between the upper contacts was used. The femurs were positioned cranial side up across the lower contacts, with the center slice coinciding with the center of the scaffold. A preload of 1.0 N and crosshead speed of 20.0 mm/min were used to break the femurs. Measurements made using force-versus-displacement curves included: ultimate force (N) or the height of the curve, stiffness (N/mm) or the maximum slope of the curve, and energy to ultimate force (mJ) or the area under the curve up to ultimate force.

2.10. Statistical analyses

Statistical analyses were performed with the Statistical Package for Social Sciences (SPSS 6.1.1; Norusis/SPSS Inc., Chicago, IL) software. All comparisons were two-tailed with a level of significance set at 0.05, unless otherwise indicated. Mann–Whitney U-tests were used to compare radiographic scores between scaffold groups (BMP vs. control) at each time point. vBMD was compared by two-way factorial analyses of variance (ANOVA), with scaffold group (BMP vs. control) and time since surgery (6 vs. 15 weeks) being the independent variables. Mechanical properties were compared by two-way, one-repeated measure ANOVA, with scaffold group (BMP vs. control) and surgical group (segmental defect vs. intact control) being the between- and within-animal independent variables, respectively. Paired or unpaired t-tests were performed in the event of a significant ANOVA interaction, with a Bonferroni correction to the level significance for the number of pair-wise comparisons. ANOVA main effects were explored in the event of a non-significant interaction. Surgical group effect sizes were assessed using mean percentage differences and their 95% confidence intervals (CIs) between femurs with segmental defects and contra-lateral intact control femurs, whereas time since surgery effect sizes were determined using mean differences and their 95% CI between 6 and 15 weeks.

3. Results

3.1. Radiographic analysis

Qualitative assessment of the X-rays films showed no bone formation in any specimen at 1 week after surgery. At 3 weeks, continuous callus had formed and bridged across the gap defect in two of the four rats in the BMP group.
In the control group, some cortical bone thickening and callus formation was noticed immediately adjacent to the scaffold; however, callus did not bridge the gap. At 6 weeks, the callus bridge in the BMP group showed signs of consolidation and further thickening of the cortex next to the scaffold. In the control group, isolated radiopaque spots were noticed (islands of bone formation), but callus bridging was not present. Further thickening and remodeling of the callus was seen at 12 and 15 weeks in the BMP groups. At 12 and 15 weeks the control group showed increased callus size in the area adjacent to the scaffold, but there was no X-ray evidence of bridging callus (Fig. 2). In the X-ray score, all rats in the BMP group showed a score of 0 at week 1. Three rats received scores of 1 and 2 at week 3. At 6 weeks, all rats received a score of 2. All rats in the control group received a score of 0 till 12 weeks. One rat received a score of 1 at 15 weeks (Table 1).

There were no significant differences on radiographic scoring between the BMP and control groups after 1 ($p = 1.00$) or 3 ($p = 0.11$) weeks. After 6, 12 and 15 weeks, defects in the BMP group had significantly greater radiographic scores than those in the control group (all $p = 0.03$), indicating that the former had more advanced healing.

### 3.2. Histology

Histology sections at 6 weeks showed mineralized callus bridging the gap in the BMP group. Normal trabeculae were found between the periosteal callus and the scaffold (Fig. 3A). Residual DCPD can be seen in the side holes (Fig. 3B). Under H&E stain, normal fatty bone marrow was restored at 6 weeks (not shown). No inflammation reaction was seen in either BMP group or control group.
In the control group, the histology showed characteristics of pseudoarthrosis with cartilage forming at the junction between the scaffold and the bone end. The periosteal callus did not bridge the gap (Fig. 3C). The histology of the BMP group at 15 weeks showed mature trabeculae between the scaffold and the periosteal callus (Fig. 3D). In the control group, the gap was filled with fibrous tissue and the scaffolds started to crumble (not shown).

3.3. μCT analysis

μCT scans showed continuous callus formation around the scaffold in the BMP group at 6 weeks. Bone has also formed inside the marrow cavity next to the intramedullary pin (pin removed prior to scanning). Normal trabecular bone was found between the cortical layer of the callus and the BMP group scaffolds. In contrast, the control group at 6 weeks shows minimal bone formation outside the scaffold and the callus did not bridge the gap. At 15 weeks, the bridging callus and the trabeculae between the scaffold and the cortex of the callus is evident in the BMP group (Fig. 4).

The histology and μCT results confirms the radiographic finding that defects in the BMP group to be bridged with mineralized callus that was integrated with the scaffold.

3.4. pQCT analysis

At 6 weeks, the measured vBMD of the callus for the BMP group and the control group was 724.05 ± 108.71 and 742.00 ± 54.46 mg/cm³, respectively. At 15 weeks, the vBMD of the callus increased to 959.06 ± 81.47 and

Fig. 3. Representative histological images of segmental defects in the (A) control and (B and C) rhBMP groups at 6-weeks post-operatively. Sections are stained with McNeal’s tetrachrome, which stains bone black. (A) Segmental defects in the control group demonstrated cartilaginous union, whereas (B) defects in the BMP group were bridged by mineralized callus that (C) invaded the side hole and was on the surface of the scaffold, indicating scaffold osteoconductivity. Inflammatory cells were not present in either scaffold group. (D) By 16-weeks post-operatively in the BMP group, the osteoconductivity of the scaffold is evident by the formation of new bone on its surfaces. * = original cortex of the femoral diaphysis, # = weight bearing biodegradable scaffold, † = cartilaginous tissue, ‡ = mineralized callus, § = side hole within the scaffold, || = residual dicalcium phosphate dihydrate cement carrying rhBMP-2, Δ = mineralized callus within the side hole and on the surface of the scaffold.
894.66 ± 59.82 mg/cm³ for BMP group and control group. The measured vBMD in the native femur was 920.95 ± 49.53 mg/cm³.

The mineral density of the scaffold was measured to evaluate the in vivo absorption of TCP in the scaffold. The mineral density of the scaffolds after 6 weeks of implantation in vivo was 625.96 ± 26.14 mg/cm³ in the BMP group and 613.59 ± 16.35 mg/cm³ in the control group. After 15 weeks of implantation in vivo, the mineral density of scaffold was 579.42 ± 13.99 mg/cm³ in the BMP group and 574.82 ± 37.50 mg/cm³ in the control group.

There were no significant interactions between group (BMP vs. control) and time since surgery (6 vs. 15 weeks) on either callus or scaffold vBMD. Similarly, there were no group main effects on either callus or scaffold vBMD. In contrast, there were significant main effects for time since surgery on both callus and scaffold vBMD. Callus vBMD was 26% greater (mean difference = 193.2 mg/cm³) and scaffold vBMD was 6.9% lower (mean difference = −42.4 mg/cm³) at 15-weeks post-surgery than at 6 weeks.

3.5. Mechanical property results

Mechanical properties of the femurs were only measured at 15 weeks. There were significant interactions between scaffold group (BMP vs. control) and surgical group (segmental defect vs. intact control) on ultimate force (p = 0.01) and stiffness (p < 0.05), but not energy to ultimate force (p = 0.10) (Fig. 6). Segmental defects in the BMP group had 290%, 286% and 234% greater ultimate force, stiffness and energy to ultimate force than segmental defects in the control group, respectively (Fig. 6). There were no side-to-side differences in ultimate force (%diff = −1.4%, 95% CI = −35.7% to 32.8%), stiffness (%diff = −15.5%, 95% CI = −68.5% to 37.6%) or energy to ultimate force (%diff = −11.7%, 95% CI = −28.8% to 5.3%) in the BMP group between femurs with segmental defects and contra-lateral, intact control femurs (all p = 0.15–0.64). In contrast, femurs with segmental defects in the control group had lower ultimate force (%diff = −66.1%, 95% CI = −105.8% to −26.5%) and stiffness (%diff = −62.6%, 95% CI = −96.6% to −28.5%) than contra-lateral, intact control femurs (all p < 0.02). Energy to ultimate force between femurs with segmental defects and control femurs was not significantly different (p = 0.15–0.64).
contra-lateral, intact control femurs did not differ in the control group (%diff = -61.4%, 95% CI = -126.4% to 3.6%) (p = 0.06).

4. Discussion

We have shown that scaffold made from high-strength biodegradable composite can be used as BMP-2 carrier to facilitate segmental defect regeneration in partial load-bearing condition, such as in the intramedullary pin fixation. This is clinically relevant since intramedullary pin fixation is commonly used for segmental defect fixation. In a retrospective study of ten patients treated for large bone defects, six of the 10 treatments involve the use of intramedullary pins [27]. In another retrospective study, six of the seven patients treated for acute segmental defects involve the use of intramedullary pins [28]. In research, Tiyapatanaputi et al. [29] demonstrated the use of pin to stabilize autograft, isograft and allograft in rat femoral defect model and found that the fixation using K-wire as intramedullary pin provided reproducible results in stabilized structural allograft. However, studies using intramedullary pin for stabilization tissue-engineering scaffolds has been lacking.

In this paper, we stabilized the PPF/TCP tissue-engineering scaffold by a 1.25 mm K-wire as intramedullary pin. This is a load-sharing model since the loads are shared by the friction between the intramedullary pin and the contact areas in the medullary canal and by the scaffolds. All BMP groups show bridging callus, indicating...
a stable biomechanical environment conducive to the formation of callus. Our previous experience showed that the scaffolds made from DCPD by itself (compressive strength = 0.5 MPa) collapsed 1 day after implantation, indicating that the rats bear load on the scaffolds (unpublished results). The PPF/TCP scaffold has an initial compressive strength of 23 MPa, but gradually reduces to 12 MPa after 12 weeks of incubation in phosphate buffered solution at 37 °C [30]. The fact that PPF/TCP scaffold did not collapse during implantation indicates that the initial strength of the scaffold is sufficient to sustain the femoral loading in the rat model. When callus bridging failed to occur, the PPF/TCP scaffolds eventually collapsed after 15 weeks demonstrating that the degraded compressive strength of PPF/TCP at 15 weeks is no longer sufficient to support rat locomotor loads. This result together with the fact that the scaffold in the BMP group is still intact at 15 weeks also indicates that the bridging callus in the BMP group has assumed loading sharing/bearing function in the defect.

DCPD is biodegradable and has been used as BMP-2 carrier [25]. In this study, a dose of 10 μg of BMP-2 was found to induce callus formation, similar to the results by Ohura et al. [25] and Yasko et al. [26]. PPF/TCP is biodegradable [31], though very slowly, as pQCT measurements demonstrated that the scaffold density was reduced by less than 10% in 15 weeks of implantation. The long effect of the degradation byproduct on tissue is critical and will need to be studied in the future. Nonetheless, this study established that a compressive strength of 23 MPa will provide sufficient strength to withstand the initial load placed on the scaffold when the scaffold is implanted in rat femoral gap stabilized with intramedullary pin.

In BMP group and control group, we found no difference in callus vBMD, in consistent with the findings by Hyun et al. [32] where bone density in BMP-2 induced new bone was the same as normal bone. From our results, we conclude that it is the quantity and the distribution of the callus, but not the bone mineral density, that makes the difference between the BMP group and the control group.

5. Conclusions

In this study, investigated a tissue-engineering strategy for bone regeneration using BMP-2 carried by a load-bearing biodegradable scaffold. We found that critical-sized segmental defects in the rodent femur have advanced radiological, histological and mechanical healing using our tissue engineering strategy of load-bearing scaffold stabilized with intramedullary pins. Radiographical and histological healing is enhanced with weight-bearing biodegradable scaffolds of rhBMP-2.

The weight-bearing biodegradable scaffold of BMP-2 do not influence the callus mineral density. Finally, the mechanical properties of the segmental defects are restored with weight-bearing biodegradable scaffolds of BMP-2.

Acknowledgments

The authors would like to thank Prof. Antonio Mikos for providing the poly(propylene fumarate) used in this study. The authors would also like to thank Wyeth Co. for providing the rhBMP-2. The research was supported by NIH EB005426.

Abstract

Although it is generally accepted that the rate and strength of fracture healing is intimately linked to the integrity of surrounding soft tissues, the contribution of muscle has largely been viewed as a vascular supply for oxygen and nutrient exchange. However, more is becoming known about the cellular and paracrine contributions of muscle to the fracture healing process. Research has shown that muscle is capable of supplying osteoprogenitor cells in cases where the periosteum is insufficient, and the muscular osteoprogenitors possess similar osteogenic potential to those derived from the periosteum. Muscle’s secretome includes proteins capable of inhibiting or enhancing osteogenesis and myogenesis following musculoskeletal injury and can be garnered for therapeutic use in patients with traumatic musculoskeletal injuries. In this review, we will highlight the current knowledge on muscle-bone interaction in the context of fracture healing as well as concisely present the current models to study such interactions.

Keywords: Muscle, Bone, Fracture, Mesenchymal Stem Cells, Paracrine

Introduction

In the orthopaedic field, the muscle-bone relationship is of utmost importance as surgeons must often battle increased complications, morbidity, and delayed fracture healing in cases with extensive soft tissue damage resulting from high energy trauma. The Gustilo-Anderson open fracture classification scale, which has been commonly used for nearly 4 decades, classifies severity almost solely on soft tissue (primarily muscle) injury, and the complication rate is much higher in fractures with soft tissue damage\(^1\). Although it has long been accepted that intact surrounding soft tissues are important in the fracture healing process, the underlying mechanisms have not been fully elucidated. However, basic science and translational research have made advances in the understanding of how muscle injuries impede fracture healing.

To understand muscle’s potential role in fracture repair, a comprehension of the repair process is necessary. In brief, fracture repair consists of three chronological and overlapping phases: a reactive phase, a reparative phase, and a remodeling phase. The reactive phase peaks within the first 24-48 hours and lasts less than 1 week. During this phase, endothelial damage to the vasculature causes a hematoma, drawing in inflammatory cells (lymphocytes, polymorphonuclear cells, monocytes) and fibroblasts to form granulation tissue\(^2\). The granulation tissue is important for vascular ingrowth as well as the recruitment of mesenchymal stem cells (MSCs). The inflammatory cells release cytokines such as TNF-α, IL-1, IL-6, IL-11, and IL-18 to induce osteogenic differentiation of MSCs as well as promote angiogenesis\(^3\). The reparative phase begins within a few days after fracture and lasts several weeks. Pluripotent mesenchymal cells, dependent on local strain and oxygen tension, differentiate into fibroblasts, chondroblasts, or osteoblasts. Healing can occur through intramembranous ossification alone (direct healing) or a combination of intramembranous and endochondral ossification (indirect healing), depending on the degree of mechanical stability\(^4\). In endochondral ossification, a fibrocartilage callus forms and is subsequently replaced by a bony callus with woven bone deposition. In intramembranous ossification, lamellar bone regeneration occurs without the need for remodeling, but it requires stable fixation\(^2\). Thus, the ossification process is dependent on
the stability of the fracture site. During the remodeling phase, the woven bone is replaced with lamellar bone, and the bone is gradually remodeled under mechanical stress to its original contour. This phase can last for several years.

**Vascularization and fracture healing**

The importance of vascularization in osteogenesis cannot be overemphasized, as a nearby vascular supply is required for both normal development and bone regeneration. Indeed, an early step in the fracture healing process is the formation of granulation tissue consisting of connective tissue and small blood vessels, reinforcing the importance of vascularization in healing. Surrounding soft tissues at the fracture site primarily have been considered an important vascular source to deliver oxygen, nutrients, and potential osteoprogenitor cells to the injured area. In the surrounding soft tissue are MSCs and pericytes, which are crucial for angiogenesis in the wounded tissue. In the clinical arena, the rate of non-union is 4 times higher in cases with reduced vascular function, and in animal fracture models that disrupt angiogenesis, bone formation is hindered through the suppression of osteoblast proliferation. Muscle flap coverage has been shown to increase bone blood flow and the rate of osteotomy union compared to skin tissue coverage, supporting the vascular role of muscle in bone regeneration.

Although vascularization has been shown to be critical for regeneration, there has been evidence of nearly equal vascularization in healed bone and non-unions in animal studies as well as in human patients. In a murine open tibial fracture model, Harry et al. observed faster fracture healing in musculocutaneous compared to fasciocutaneous flaps, despite the musculocutaneous flaps having decreased vascularization. These studies point to a more extensive role of muscle in the repair process than solely as a vascular supply.

**Osteoprogenitors derived from muscle**

The relationship between muscle and bone has been observed for decades and continues to be elucidated. Urist first deduced muscle’s ability to induce bone formation in 1965 when decalcified bone implanted into muscle resulted in new bone formation. In fracture healing studies in multiple species, callus formation tends to be the largest and most dense at the interface between bone and muscle, suggesting that muscle contributes to callus formation or provides a suitable environment for its occurrence.

Muscle is also a common site for ectopic bone formation following physical trauma, orthopaedic surgery, or due to disease like fibrodysplasia ossificans progressiva, which has been identified to be a result of a mutation in a gene encoding a bone morphogenetic protein (BMP) receptor. BMPs, a group of growth factors involved in tissue architecture throughout the body, are of particular importance to bone formation as they induce osteoblast differentiation.

In the presence of BMPs, cells derived from muscle are capable of differentiating into cells expressing bone markers. That muscle-derived cells capable of displaying osteogenic potential under proper conditions could partly explain the importance of muscle in fracture healing aside from their role in vascularization. In addition, muscle may be able to influence bone in a manner unlike any other tissue. When both muscle and fat are activated by exposure to a BMP-2 encoded adenovirus, the “gene-activated” muscle results in more consistent bone regeneration than the “gene-activated” fat. Furthermore, when muscle-derived stem cells (MDSCs) are recruited and driven to osteogenic differentiation by BMPs, they display an osteogenic potential that is equivalent to those derived from bone marrow. Lineage-traced MDSCs in a fracture healing model have been found to alter gene expression to give rise to chondrocytes, up-regulating chondrogenic markers Sox9 and Nkx3.2 and down-regulating the muscle marker Pax3. These studies provide evidence that, in the appropriate environmental conditions, muscle can supply osteoprogenitor cells required for the fracture repair process.

It should be noted, however, that MDSCs are not the sole osteoprogenitor cells derived from muscle. C2C12 myoblasts infected with a retroviral vector have been found to overexpress osteoactivin (OA) and transdifferentiate into osteoblasts and express bone-specific markers. Muscle-derived stromal cells, when administered TNF-α at low concentrations, are also capable of undergoing recruitment and osteogenic differentiation. Muscle satellite cells were originally believed to be muscle stem cells restricted to the myogenic lineage, but the osteogenic potential of these cells has been observed under several conditions. Satellite cell-derived myoblasts have been shown to differentiate into osteocytes following treatment with BMPs, into osteoblasts in vivo and in vitro in the presence of platelet-rich plasma, and the osteogenic potential of satellite cells can increase in response to cutaneous burn trauma. Satellite cells have been observed to express both myoblastic (Pax7, MyoD) and osteoblastic (alkaline phosphatase, Runx2) markers and are capable of differentiating into osteoblasts spontaneously.

The abundance of potential osteogenic cells derived from muscle could have applications in the future in tissue engineering techniques, particularly in cases where the bone marrow or periosteum is compromised. It has been commonly believed that in fractures in which the periosteum is intact, repair occurs largely through endochondral ossification driven by a periosteal supply of cells. Indeed, in open fractures with a stripped periosteum, Liu et al. found that myogenic cells of the MyoD lineage contributed to fracture repair, but MyoD-expressing cells were not incorporated into the callus in the case of a closed fracture with intact periosteum. Such a study demonstrates that myogenic cells can be activated to serve as a secondary supply of cells when the periosteal supply becomes compromised. These recent findings of muscle’s ability to augment the periosteal supply of osteoprogenitor cells provide insight into the clinical observations of prolonged recovery time and increased morbidity that is especially seen associated with high energy fractures with substantial soft tissue damage.
Muscle-bone paracrine interactions in bone repair

Only within the past two decades has the muscle secretome been identified and explored. With the recent advent of improved characterization instruments, the muscle secretome has rapidly expanded to over 200 proteins\(^44\). Muscle secreted proteins important in muscle-bone interactions include, but are not limited to: myostatin, BMPs, secreted protein acidic and rich in cysteine (SPARC or osteonectin), interleukin (IL)-1, IL-4, IL-6, tumor necrosis factor (TNF)α, and insulin-like growth factor (IGF)-1\(^41,54-56\). Many of the muscle derived factors have previously been described to play a role in muscle-bone interactions without addressing the interactions specifically during fracture repair. Importantly, the presence of inflammation differentiates fracture repair from bone formation during development. That is, fracture healing is initiated by an inflammatory cascade, which is mediated by a number of factors, including but not limited to: neutrophils, macrophages, lymphocytes, and various inflammatory cytokines (i.e., IL-1, IL-6, TNFα)\(^2,57-59\). Mounting and maintaining an appropriate inflammatory response in early fracture healing is critical for adequate repair and multiple studies have demonstrated that interference with the inflammatory process can either impair\(^60,61\) or improve\(^62\) fracture healing. This review focuses primarily on four factors known to be involved in muscular injury and fracture repair and are therefore likely to contribute to muscle-bone interactions in the presence of inflammation.

Insulin-like growth factor-1

IGF-1 is recognized as a key myokine that may direct local fracture healing\(^62\). IGF-1 is expressed by maturing osteoblasts in culture\(^64\) and expression has been localized using in situ hybridization to osteoblasts during phases of matrix formation and remodeling in fractured human bone\(^65\). Further signifying the importance of IGF-1 to fracture healing, delivery of IGF-1 to ovine bone defects promotes accelerated bone formation\(^66,67\). The association of low systemic levels of IGF-1 with osteoporosis\(^68,69\) suggests that local production of IGF-1 by nearby skeletal muscle tissue may support bone healing. Given that skeletal muscle up-regulates expression of IGF-1 in response to injury\(^70-72\), the context of fractures involving muscle trauma specifically highlight this possibility. Overexpression of IGF-1 in skeletal muscle can result in increased systemic concentrations evidencing the capacity of skeletal muscle as a paracrine organ to support nearby bone healing\(^73\). IGF-1 plays a role in muscle fiber repair and regenerative processes via a number of mechanisms to include increasing protein synthesis via PI3- AKT-mTOR pathway and by activating and promoting proliferation of satellite cells\(^73,75\). Perhaps most interesting in the context of complex musculoskeletal injury is the anti-inflammatory (i.e., inhibition of NF-κB) role of IGF-1 in muscle\(^76,77\) and bone\(^67\).

Myostatin

Perhaps the most well-known muscle derived protein, myostatin, has been implicated to play a significant, albeit inhibitory, role in fracture repair. Myostatin is a member of the TGF-β superfamily, negatively regulating muscle growth, development, and regeneration\(^74,75\). Its negative trophic influence has been supported in myostatin null mice that demonstrate increased bone strength and increased bone mineral density\(^80,82\). Furthermore, myostatin inhibition by decoy receptors increases musculoskeletal mass\(^83\). Interestingly however, expression of myostatin is elevated with significant musculoskeletal injury, specifically in the early part of bone repair\(^84,85\). Due to its negative role in musculoskeletal development, interventions were targeted toward inhibiting myostatin after skeletal injury. Small molecule inhibition of myostatin following orthopaedic trauma has been demonstrated to improve muscle regeneration and fracture healing\(^70,85,86\). These data suggest that inhibition of myostatin may be a plausible intervention to improve fracture healing outcomes in patients with significant musculoskeletal injuries. However, the conundrum of elevated myostatin after musculoskeletal injury remains poorly understood.

Bone morphogenetic proteins

Generally speaking, BMPs are growth factors for various skeletal tissues and are required for skeletal development. Conditional knockout mice deficient in BMPs displayed a wide range of skeletal defects\(^87,88\). There are 7 members of the BMP family, of which BMPs 2-7 belong to the TGFβ superfamily\(^89\). Multiple BMPs have been demonstrated to promote osteoblastic differentiation of bone marrow stromal cells\(^90,91\). Specifically, BMP-2 and BMP-7 are FDA approved for use in clinical musculoskeletal therapeutics due to their role in osteoblast differentiation and musculoskeletal repair. Unfortunately, concerns have arisen regarding the multiple side effects and off-label usage of BMPs including a recent link to oncogenic side effects with use of BMP-2\(^92,93\). More novel approaches to utilization of BMP-2 in fracture healing includes modified muscle cells that secrete BMP-2. Critical size rat femoral defects underwent quicker bridging and restored mechanical strength when receiving activated muscle secreted BMP-2\(^38\). Though not a member of the TGFβ superfamily and not used in the clinical setting currently, BMP-1 is secreted by muscle and may play a role in fracture healing. BMP-1, specifically, is a protease secreted by muscle that cleaves procollagen\(^94\). In patients with traumatic blast injuries, both BMP-1 protein and mRNA levels were elevated\(^95\), suggesting a significant role for BMP-1 in musculoskeletal repair. Therefore, better understanding of the roles of muscle derived BMPs in skeletal tissue regeneration is warranted to improve musculoskeletal repair in patients who suffer extensive traumatic injuries.

SPARC or osteonectin

Osteonectin is a phosphorylated glycoprotein present in developing bone in many animal species\(^96\). Osteonectin is suggested to serve multiple functions in the developing bone
matrix, including collagen organization, osteoblast growth and proliferation, and matrix mineralization. Mice deficient in osteonectin display osteopenia and decreased bone mineral content. Importantly, osteonectin is secreted by injured and regenerating myotubes and muscle fibers. Osteonectin expression by these sources is dependent on injury severity, suggesting that more severe musculoskeletal injuries result in greater osteonectin expression. Longitudinal studies of fracture healing show detectable osteonectin transcripts throughout the healing phase, most notably from days 9 to 15. These studies provide evidence for the significant role osteonectin plays in bone regeneration and suggest muscle may be a source of osteonectin during musculoskeletal repair.

**Mechanical muscle-bone interactions**

It would be remiss to forego some discussion of the mechanical influences involved in muscle bone interactions. The cellular mechanisms by which mechanical strain affects bone are largely uncharacterized, but some data suggest it is due in part to gap junctions in bone formed by connexin 43. Though characterization of mechanically induced cellular mechanisms remains limited, multiple studies have pointed to the importance of muscle’s mechanical interactions on bone health. Disuse atrophy via denervation or immobilization has been shown to decrease bone integrity in animal models. Furthermore, multiple studies have demonstrated that muscle paralysis induced by administration of botulinum toxin impairs bone quality and/or fracture healing. Further research into the cellular mechanisms of the mechanical influence of muscle is warranted to better understand how bone can be further modified by muscle during the healing process.

**Muscle in fracture healing - current models**

**Murine**

Multiple murine studies have been conducted to examine the extent to which muscle enhances bone repair after significant musculoskeletal injury. Zacks and Sheff conducted early sentinel research addressing the potential for muscle to contribute to bone regeneration in 1982. Zacks and Sheff utilized experimental groups where after limb muscle resection, isotopic or heterotopic minced muscle implants were placed immediately adjacent to the periosteum. Their control groups consisted of liver minced implant or no implant. They concluded that isotopic and heterotopic minced muscle preparations implanted adjacent to the periosteum could directly induce new bone formation in situ as demonstrated by the formation of exostoses and metaplastic nodules in the minced muscle implants. The work of Zacks and Sheff confirmed the importance of studying the trophic influence of muscle on bone.

As previously mentioned, Harry et al. conducted a murine study addressing the importance of muscle in open tibial fracture repair. The authors demonstrated that musculocutaneous flaps performed superior to the fasciocutaneous flaps, though the fasciocutaneous flaps provided more angiogenic capacity. Therefore, the osteogenic capability of muscle is greater than that of cutaneous flaps and extends beyond simply angiogenesis.

**Rattus**

Multiple studies have also been conducted utilizing rat models to assess bone healing in light of soft tissue injuries. A study by Hao et al. evaluated the effect of muscle atrophy and paralysis on femoral fracture healing. Atrophy of the quadriceps muscle, induced by administration of botulinum toxin, negatively impacted the healing capacity of femoral fractures in rats. Utvag et al. conducted three critical studies assessing the role of periosteum or surrounding soft tissue in bone healing. In 1998 Utvag et al. demonstrated that fracture healing was impaired when periosteal tissue was mechanically removed from interacting with surrounding muscle. Additionally, Utvag et al. showed that significant muscle injury and absence of muscle by resection, or by traumatic injury in the clinical setting, significantly compromised the regeneration potential of non-augmented healing bone. The importance of muscle for bone healing was further confirmed by the work of Willett et al. that demonstrated that volumetric muscle loss (VML) also impairs the effectiveness of BMP-2 in the healing of a critical size bone defect. Taken together, it is clear that frank loss of muscle tissue (VML) is a significant comorbidity to poor bone healing outcomes.

**Humans**

Since the mid 1970s, open fractures have been graded clinically according to the Gustilo-Anderson classification scale, which is largely based on the severity of soft tissue injury associated with open fractures. Gustilo and Anderson identified 3 types of fractures: Type I - open fracture with a wound <1 cm and clean; Type 2 - open fracture with a wound >1 cm without extensive soft tissue damage; and Type 3 - open fracture with extensive soft tissue damage. Type 3 fractures were later subdivided into 3 subcategories. The Gustilo Anderson classification makes it evident that soft tissue injury plays a significant role in the musculoskeletal repair process in the clinical setting. Specifically, open fractures (Type 3) with extensive soft tissue injury demonstrate greater complication rates than open fractures without soft tissue injury (Types 2 & 3). Similar to the results observed from animal studies, substantial clinical data exist characterizing the importance of muscle integrity in bone repair. A multitude of studies have demonstrated soft tissue damage associated with fractures impairs the ability of bone to repair properly, while the quality of the muscle bed is essential for appropriate bone formation and bone healing.

Similar to the murine study conducted by Harry et al., Gopal et al. specifically examined the treatment of open tibial fractures with fasciocutaneous flaps versus muscle flaps in humans. The results of their study were then later confirmed by Harry et al. in the mouse model, with both groups concluding that muscle flaps are superior in bone healing. Even in clinical
practice, the gold standard of treating critical size defects or extensive fractures includes soft tissue coverage, supporting the significance of muscle-bone interactions during bone healing. A more recent meta-analysis by Reverte et al. analyzed 16 studies addressing the union rate and time to fracture union in patients with tibial fractures and associated compartment syndromes. Reverte et al. demonstrated that tibial fractures with associated soft tissue injury significantly impaired fracture healing. The rate of delayed union or non-union in tibial fractures with associated compartment syndrome was 55% compared to only 18% in patients with tibial fracture without associated compartment syndrome. This study points to the importance of soft tissue integrity in the quality of fracture healing.

Conclusion

Taken together, these studies illustrate the importance of muscle-bone interactions in bone regeneration. Exact mechanisms by which muscle is responsible for bone formation in the healing process are not well elucidated. Most of the current literature is limited to qualitative findings of muscle’s role in bone healing. Therefore, more rigorous models with aims directed toward identification and quantification of muscle-derived effectors of bone regeneration are required. Identifying and characterizing the muscle-derived factors responsible for bone healing may provide opportunities to develop therapies to augment normal physiologic mechanisms underlying bone regeneration.

Current strategies, such as the use of BMPs, in fracture healing have recently been thought of as having more limited benefit due to the more robust understanding of detrimental side effects. This review outlines some potential targets for therapeutic development, including stimulation of MDSCs, inhibition of myostatin, or administering or enhancing the targeted expression of osteonectin. Future studies addressing muscle factors associated with bone healing may provide insight into these mechanisms necessary to promote bone regeneration. Soft tissue integrity is crucial to appropriate bone regeneration, but our understanding of the mechanisms is limited at the present time. A better understanding of muscle’s effect on fracture healing at the cellular and molecular levels will open translational opportunities to incorporate the findings into clinics and operating rooms abroad.

Surgical Fixation Hardware for Regeneration of Long Bone Segmental Defects: Translating Large Animal Model and Human Experiences

Emily Jewell¹ · Jeff Rytlewski¹ · Jeffrey O. Anglen¹ · Todd O. McKinley¹ · Karl D. Shively¹ · Tien-Min G. Chu² · Melissa A. Kacena¹

Abstract Orthopedic fracture surgery has made significant advances in recent years, but large segmental bone defects remain a significant clinical problem. While surgical techniques have been developed or modified to address these issues, challenges remain. Further, to effectively address this issue, a suitable path from the benchtop to the clinic must be established. This is most commonly done using large animal models, which provide the opportunity to test different treatment options. This is certainly more complicated than it appears, as various anatomic and physiologic differences can produce complications not normally seen in humans. For this reason, proper species and bone selection is critically important. Here we review the current experimental methods, types of internal and external fixation, and large animal models used in segmental bone defect studies conducted in weight-bearing long bones. This review will also provide insight into the efficacy of hardware fixation strategies and the translatability of said strategies into clinical practice.

Introduction

Critical-sized defects in long bones have historically been defined as the minimal size defect that will not heal without intervention over the lifespan of the animal [1, 2]. This has recently been redefined as being at least 2.5 times the cortical diameter [3]. Critical-sized defects can be due to traumatic injuries, infections, and malignancy, and previous nonunions with subsequent bone resorption. No matter what the root cause, these critical-sized defects remain a major treatment hurdle for orthopedic surgeons today. This has created a need for research and development of techniques to aid in treatment. Bone defect research necessarily spans from molecular level experimentation through preclinical models. Translation is dependent on developing physiologically relevant large animal models for preclinical testing. Large animal models share geometric proportions, anatomic positions, and load-bearing patterns with human beings. In addition, proper large animal models also have bone biologic similarities to human bones with comparable mineral composition, turnover, and remodeling when compared to humans. This provides an environment to test new scaffolds and hormones that are very similar to human bone biology and mechanics without the difficulty of implementing a human trial.

Physiologic realism is dependent on optimal species and bone selection. Species including non-human primates, dogs, pigs, goats, and sheep are most similar to humans in regard to bone biology [4]. Weight bearing needs to be comparable; therefore, bone selection needs to be considered. For example, in four-legged animals, an argument could be made to consider the radius and ulna as weight-bearing bones. However, there may be stress shielding of the fractured bone by the intact one. This alteration in mechanical loading would alter the bone healing
environment and make it harder to translate to human application. Ultimately, bone selection typically mimics the human tibia, as the tibia is the most commonly fractured long bone as well as the most common site of segmental bone defects. This is because it has one of the harshest environments for healing. It lacks the same level of soft tissue coverage along its anteromedial aspect that other long bones have. The decreased level of vasculature probably plays a large role because vascularization plays a significant role in the healing process [5].

After the species and specific anatomic location for experimentation have been selected, the fixation method for stabilizing the critical-sized defect must be chosen. Similar to the surgery to stabilize defects in humans, multiple options are available for preclinical models and there has not been a standardization of surgical technique. All of this adds to complexity in understanding the relevance of preclinical models. This manuscript reviews the current literature using large animal models for the healing of critical-sized bone defects. It includes studies done using weight-bearing long bones in large animals, types of fixation used, and complications.

### Fixation Methods

There are many portions of animal model studies that have not been standardized. One is the method of fixation, so the following is a brief overview of the common methods that have been used in studies. One concern is that the different types of fixation that were not originally designed for animal use lead to significant discrepancies in bone loading in animal applications [6]. In many cases, human implants are being used in animals without any purposeful design for the application. There are various methods for fixing a long bone defect in humans. The most common include either external fixation or internal fixation. Internal fixation is then subdivided into two primary groups: use of a single plate or an intramedullary (IM) nail. There are many pros and cons to each method, and their use depends upon the specific circumstances.

### External Fixation

In humans the external fixator is often clinically used as a temporary fixation method. It is most commonly used in severe open or contaminated fractures where the compromise in soft tissue is significant. Once the soft tissue component resolves, the external fixator is often exchanged for internal fixation. The external fixator may also be the definitive fixation method as well. Animals can be viewed as the ultimate non-compliant patient, so it is a viable method for final fixation [7]. The following method is an external fixation procedure as described by the AO (Arbeitsgemeinschaft für Osteosynthesefragen, a group established by orthopedic surgeons to study internal fixation and improve operative outcomes) Surgery Ref. [8]: prepare to apply external fixation by determining the safe locations for threaded pin insertion as well as the number of pins needed on either side of the critical-sized defect. The threaded pins will be placed through a small incision in the skin and then into the bone. Care must be taken to avoid surrounding nerves, vessels, and other soft tissues. Once the threaded pins are in place on both sides of the defect, clamps are applied to the pins. Bars are then attached between the clamps to stabilize the site.

**Pros:** The main positive of external fixation is the relative ease and speed with which an external fixator can be applied and removed. It does not require surgical dissection or require any periosteal stripping that would be needed for internal fixation [9]. If the surgeon has proper knowledge of the cross-sectional anatomy of the affected limb, then the risk of intraoperative complications is low. Due to minimal bone contact, it causes less damage to the bone’s blood supply. Also, the external fixator does not interfere with the defect site or scaffold.

**Cons:** The most common complication is pin track loosening leading to pin track infection. It has also been found that external fixation requires longer healing periods and leads to more malalignment [10, 11]. Other drawbacks can be seen specifically with animal use. External fixators, with their propensity for infection, can be even more problematic in animal models because there will be increased difficulty in keeping them clean [12]. The animal may also try to pull the fixation device off/out, and the device itself may be large and cumbersome to the animal often resulting in a confounding variable when assessing gait and healing.

### Internal Fixation

Internal fixation is the mainstay of correcting large defects and unstable fracture patterns in humans. These fractures require a stable construct to limit motion at the fracture site and improve the overall likelihood of healing. There are many parameters that are important to consider when selecting a method of internal fixation. One critical detail is the location on the long bone of the defect. For example, if the fracture is through the diaphysis, then an IM nail is more commonly used, but if it is through the metaphysis of the same long bone, then a plate is more common [13, 14]. Other things that must be taken into consideration are how the fixation device affects the axis of loading, how stiff the construct is and how that affects motion at the fracture site,
and the extent of tissue dissection that is required to apply the fixation device.

**Single Plating**

The following method is a single plating procedure as described by the AO Surgery Ref. [15]. The plate may either be inserted through an incision over the critically sized defect or through a minimally invasive approach. Most likely an incision will be required to create the critical-sized defect, so this may be used for plate insertion. Excess soft tissue is removed, so that the plate can be placed in an extraperiosteal position flush to the surface. The plate will bridge the critical-sized defect to maintain proper defect size. It will then be fixed in place with screws on both sides of the defect.

Pros: Plates have the advantage of being outside of the medullary canal. This allows the surgeon to directly visualize where the plate is being placed, and it is easier to modify its placement. Its extramedullary position also allows it to not interfere with the defect site, scaffold, or bone graft placement. The plate is not as limited by the difference in contour of the animal bone versus the bone for which it was originally designed. Plates can be contoured intraoperatively to allow for better apposition along the length of the bone [16]. It has also been found that, when compared to IM nails and external fixation, plates have a lower rate of infection, infection related complications, and non-unions [17].

Cons: It has been found that the eccentric placement of plates relative to the load-bearing axis requires that plates be stiffer to resist weight-bearing forces and properly stabilize the fracture. The difficulty is that excessive rigidity of fixation can prevent proper healing [18]. One reason is because it minimizes the micromotion at the fracture site, some of which is actually required for proper bone healing. It also causes stress shielding. The stiffness of the construct does not allow the bone to be under physiologic loading. This lack of stimulus for continued remodeling will result in osteopenic changes of the surrounding bone [19]. Another observation is that the high compressive forces between the plate, periosteum, and bone result in a compromised blood supply [20]. The impaired vascularity may prolong fracture healing, increase risk of infection, and increase re-fracture rate after implant removal due to increased cortical bone porosity along the bone plate interface [21, 22]. There are also more screws needed to secure the plate versus other constructs, and the weakness through the screw holes may compromise mechanical testing [23].

**Double Plating**

The following method is a double plating procedure as described by the AO Surgery Ref. [24]. An incision is made to allow for plate insertion. Excess soft tissue is removed, so that the plate can be placed in an extraperiosteal position flush to the surface. The plate will bridge the critical-sized defect to maintain proper defect size. It will then be fixed in place with screws on both sides of the defect. A second plate is then placed, so that it is sitting ninety degrees from the first plate. This plate should also be placed flush to the surface in the extraperiosteal position. The second plate is then fixed in place with screws on both sides of the defect.

Pros: It has been found that there is a significant increase in stiffness of a double-plate construct when compared to a single plate when placed under torsional stress as well as four-point bending [25].

Cons: One of the plates must be radiolucent to allow for proper imaging. Radiolucent plates are much less common, and their ability to be properly contoured is not the same as normal plates [26]. It was also found that using two plates may lead to late onset healing and incomplete ossification due to load sharing [26]. Another thing to consider is that there will be twice the surface area being subjected to blood supply compression [12].

**Intramedullary Nail**

The following method is an intramedullary nailing procedure as described by the AO Surgery Ref. [27]. There is an incision made at the level of the proximal tibia. If the surgeon prefers to ream the intramedullary canal, a guide wire is passed through both the proximal and distal segment of the bone. The intramedullary canal may then be reamed over the guide wire. The nail is then passed through the proximal segment of the bone, through the critical-sized defect, and into the distal segment of bone. The proximal and distal ends are fixed with locking screws. This will aid maintenance of length, rotation, and alignment of the two bone segments.

Pros: IM nails are the gold standard for treatment of lower extremity long bone diaphyseal fractures in humans [28]. IM nails also lie in the plane of axial loading. There is also a greater contact surface area, which would reduce stress points [29]. The IM nail is also a medullary cavity space filler. This will allow for less graft to be used. It has also been found to be a guide for tissue growth as well as allows for the formation of a medullary canal during healing [19]. The IM nail is also more flexible, which will allow for micromotion at the fracture site. It has also been...
found that reaming can cause an increase in growth factors such as TGF-beta and VEGF [30]. Additionally, it has been found that osteoblasts are still viable in the bone debris after reaming, which essentially acts as internal grafting [31, 32]. Reaming has also been shown to increase the blood supply to the periosteum six-fold [33].

Cons: While reaming can increase the blood supply to the periosteum, it has also been shown to possibly decrease blood supply to the rest of the bone [34, 35]. Reaming can cause heat-induced osteonecrosis [36]. Tightly fitted nails may also interfere with revascularization and lead to increased risk of nonunion and infection [36]. Reaming and nail insertion will increase intramedullary pressure, which can lead to fat or air emboli [37, 38]. The nail may also interfere with scaffold design and the amount of implant material that is able to be used [13]. It may also block the medullary canal, which might reduce the regeneration potential in the endosteal area [39]. Further, it has been found that it may be difficult to remove the nail after the animal is killed, making it difficult to conduct mechanical testing [26]. Unreamed nails decrease endosteal necrosis from approximately 70–31 %, but healing rates are consistently higher using reamed nails [40–42].

Large Animal Models

The majority of orthopedic research using large animal models utilizes dogs, sheep, goats, and pigs. Dogs have a similar bone mineral density to humans, and there are fixation devices designed specifically for dogs. Primary disadvantages of using dogs include: They have a higher rate of solid bony fusion and lower nonunion rates when compared to humans [4]. Sheep are very docile animals, and their body weight is similar to that of humans. Their tibias also have geometric proportions and load-bearing patterns similar to humans [43]. The primary drawbacks of using sheep are that they have age-dependent bone remodeling, and they have a larger amount of bone ingrowth than humans [4]. Goats have similar bone remodeling and bone composition to humans. The primary drawback of using goats is that they have a more inquisitive and interactive nature and therefore might not tolerate the surgery and postoperative period as well [4]. Pigs have similar bone remodeling and bone composition to humans. They have the disadvantage of being difficult to handle as well as having excessive body weight compared to humans [4].

Several groups have argued that pigs are the animal of choice for large animal modeling due to their similarity to humans in bone remodeling and bone composition [44, 45]. Unfortunately, their tibiae and femora are relatively small and require special implants [3]. As an example, in our ongoing pig tibia segmental defect studies, we are using hardware designed for veterinary applications. Sheep, despite their drawbacks, are used most frequently in large animal modeling primarily because human implants can be used [46]. Despite the anatomic and physiologic similarities between humans, non-human primates are seldom used as a large animal model because many pharmaceutical and biotech companies as well as funding agencies do not permit their use.

Table 1 is a collection of the recent studies investigating healing of long bone defects using large animal models. The comprehensive table includes the type of large animal utilized, the specific bone in which the defect was created, the size of the defect, the type of fixation hardware used, and the reported complications. Table 2 summarizes the tabulated complications listed in Table 1 for each type of fixation examined.

Discussion and Future Directions

There have been many studies using large animal models that assess long bone defects. Unfortunately, these studies have minimal uniformity, and complications are rarely reported. Some researchers are very specific, some vaguely mention adverse events, and others do not report anything at all. This makes analyzing the impact of specific fixation methods on overall outcomes very difficult. Limitations aside, one can make some general observations. The most commonly used fixation devices were IM nails and single plates with approximately the same frequency. The next most common type of fixation was the external fixator. Double plating was the least commonly used. IM nails had the highest rate of infection with 7 of the 18 studies reporting at least one animal with an infection (Table 2). In one study, an animal died due to the infection. IM nails also had the highest rate of plate/nail failure with 4 of 18 studies (Table 2). Single plates had the highest rate of “other complications” with 4 of 17 studies (Table 2). This includes two studies where they found stress shielding due to the plate. Both IM nails and plates also had a relatively high rate of screw failure. External fixator studies had a low reporting rate with half of the studies not including any mention of adverse events.

Of importance, it is unclear why the infection rate is so much higher for IM nails than any other fixation method. Implants in all of the studies had to violate the medullary canal to create the long bone defect, and they all had the slightly unsanitary postoperative conditions due to the animals themselves.

Another obstacle is that the majority of the studies did not report the timing of complications. Early complications, occurring within the initial post-op period, could be

immobilized to reduce complications. This would effectively force the animals to be non-weight bearing or minimally weight bearing for the initial period. However, this may affect healing because mechanical loading is essential for bone remodeling.

Consistency in reporting experimental complications is critical for accurate determination of ideal fixation methodologies. Thirteen of the forty-six studies reported no complications, and an ideal outcome is unlikely in a large animal study regardless of the expertise in performing the procedure. Sixteen of the forty-six studies did not, however, report the complications at all. Both instances represent a deficiency in the literature and only increase the challenge of planning additional animal studies and moving bench work to clinical trials. This complication information is an absolute necessity to accurately plan additional research and as such needs to be reported honestly and accurately. This is one of the focuses of the

National Institute of Health’s multifaceted plan to help improve the validity of studies. They created a 20-item checklist to address the issue and aid researchers in planning studies [47]. Spurred on by this work, multiple journals have adapted checklists, such as animals in research: reporting in vivo experiments (ARRIVE), which includes reporting of adverse events. Hopefully, these requirements become ubiquitous throughout the research community to improve reporting and prevent researchers from withholding pertinent details.

Based on this review, it appears that there is no perfect fixation method for large animals being used to study long bone defects. Animals cannot be counseled on weight bearing nor how to keep their wounds clean. Due to this, they will continue to have higher rates of infection and implant failure than would normally be seen in their compliant human counterpart. Thus, it is difficult to determine whether one would be better off using: an IM nail, which has higher rates of infection and may interfere with scaffold design; a plate that may cause stress shielding or implant failure; an external fixator that may prove too cumbersome for the animal or lead to infection; or a fixation method which is not used clinically. Indeed, as double plating is not currently used in long bone defects in human clinical practice, their utility as an animal model is more limited unless being used for efficacy and safety studies for future FDA applications, such as Phase I clinical trials. The desire for plate fixation due to the apparent lesser rate of complications must be weighed against clinical observations that statically locked IM nailing is the gold standard for tibial and femur fracture fixation in humans [31, 48–50]. This is because the IM nail has been shown to have high mechanical efficacy and decreased incidence of non-unions [51]. Therefore, with this in mind, perhaps the best approach for animal testing of grafts or drug delivery (as opposed to development of new fixation hardware) would be to use an IM nail with prophylactic antibiotics to mitigate the increased rate of infections.

Abstract The regeneration of bone in segmental defects has historically been a challenge in the orthopedic field. In particular, a lack of vascular supply often leads to non-union and avascular necrosis. While the gold standard of clinical care remains the autograft, this approach is limited for large bone defects. Therefore, allograft bone is often required for defects of critical size though a high complication rate is directly attributable to their limited ability to revitalize, revascularize, and remodel resulting in necrosis and re-fracture. However, emerging insights into the mechanisms of bone healing continue to expand treatment options for bony defects to include synthetic materials, growth factors, and cells. The success of such strategies hinges on fabricating an environment that can mimic the body’s natural healing process, allowing for vascularization, bridging, and remodeling of bone. Biological, chemical, and engineering techniques have been explored to determine the appropriate materials and factors for potential use. This review will serve to highlight some of the historical and present uses of allografts and autografts and current strategies in bone tissue engineering for the treatment for bony defects, with particular emphasis on vascularization.

Introduction
Reconstructing and regenerating significant skeletal defects have perplexed mankind for thousands of years. Grafting techniques were utilized as early as 2000 BC when Khurits utilized a piece of animal bone to repair a small skull defect, which proved successful millennia later when anthropologists discovered the remains exhibiting regrowth around the graft [1]. In the modern age, the first documented bone graft was performed in 1668 by Job van Meekeren, a Dutch surgeon. He, too, used a xenograft to repair a skull defect in an injured soldier [2]. Bone grafts and the understanding of orthopedic science were further propelled in the seventeenth century by the work of Antoni van Leeuwenhoek who is famously known for his work on microscopy. He also primitively described the microarchitecture of bone, identifying what we now refer to as Haversian canals [1, 2]. Diligent examination of bone grafting criteria and outcomes surfaced in the early 1900s with the work of Vittorio Putti who outlined the principles of grafting [1]. Putti’s work established a foundation for grafting science in the field of orthopedic surgery. Since then, surgeons and researchers alike have continued to hone the science of bone grafting to allow for the most appropriate surgical intervention with the best outcomes.

Grafted bone can come from the same individual (autograft) or from other individuals of the same species (allograft). Every year, approximately 1 million bone allografts are used [3]. Between 1992 and 2007, an estimated 1.7 million bone autografts were performed [4]. Both grafts possess unique advantages and disadvantages, but autografts began to come into favor over allograft in the early 1900s with recognition of the benefit that vascularization provides to the integrity of the graft and surrounding bone [5, 6]. Evidence continues to suggest autografts provide improved outcomes over allografts [7–14]. However, autologous and allogeneic bone grafts are now often used in combination with bioengineered scaffolds (frames upon which tissue regeneration can occur) or bone substitutes/adjuncts, which may allow for enhanced applications of allografts [15–23], so much so that allografts may be superior to autografts if combined with bone morphogenetic proteins (BMPs) and a bisphosphonate, suggested by larger and denser calluses with increased peak force in BMP + bisphosphonate graft [24].

The advancement of biomaterials’ research in the past few decades has enabled the development of scaffold materials to enhance the regeneration and vascularization of bone in large segmental defects. Scaffolds have been made from many materials and have included growth factors and/or cells to specifically promote vascularization in healing bone grafts. Combinations have included vascular endothelial growth factor (VEGF), platelet-derived growth factor (PDGF), endothelial cells (ECs), and mesenchymal stem cells (MSCs). Addition of these compounds and/or cells to scaffolds has provided potential in improving outcomes in patients undergoing grafting procedures.

As life expectancy continues to increase, orthopedic cases continue to rise as well. In 2008, health care costs for regenerative biomaterials were estimated to exceed $240 million [25], and it is not unreasonable to assume this value will continue to rise, highlighting the importance of regenerative bone materials in orthopedic care in the near future. The most common uses for bone grafts in the USA are spinal fusion and fracture nonunion [4]. This review will address the use and characteristics of enhanced grafts, scaffolds, and bone substitutes as adjuncts in orthopedic reconstruction and bone regeneration.

**Bone Grafts**

Bone grafts and scaffolds are often evaluated for three characteristics: (1) osteoinduction—ability to recruit and induce MSCs to differentiate into mature bone-forming cells; (2) osteoconduction—allowing for cellular invasion of the graft; and (3) osteointegration—functional integration of the graft with the host tissue through new bone formation [26, 27]. An ideal graft harnesses adequate osteoconductive, osteoinductive, and osteointegrative characteristics; however, the necessary properties for optimal bone scaffold design remain unknown. Below, we discuss the advantages and disadvantages of allografts and autografts and touch upon adjunctive therapies that are in development to improve outcomes with use of either graft.

**Allografts**

Bone allografts are harvested tissue from human cadaveric donors. Cancellous allografts provide minimal to no structural strength, mild-to-moderate osteoconductive properties, and mild osteoinductive properties. Cortical allografts, on the other hand, can provide structural strength but little osteoinduction [28]. Studies have demonstrated the advantages of allografts in the setting of very significant bone defects as seen in musculoskeletal malignancies [29, 30]. When autograft use is precluded by the size of the donor site and donor site morbidity secondary to large defect, surgeons turn to allografts for reconstruction. Early research published in the New England Journal of Medicine demonstrated large allografts can prove successful in the reconstruction of bone defects following tumor removal [30]. Furthermore, functional status of patients who undergo massive allograft transplantation has been reported as satisfactory in as many as 70 % of patients [29]. Allografts may also include articular surfaces and even ligaments.

Allografts obviate many complications that arise with xenografts that were used thousands of years ago, but they also pose their own set of complexities and dangers [31–33]. Though these grafts are harvested from human cadaveric tissues, they retain the capacity to induce an immune response in recipients [34–38]. In the early use of allografts for segmental bone defects, various protocols surfaced to minimize graft–host interactions, including cryopreservation, irradiation, decalcification, and pharmacologic immunosuppression [39–43]. Cryopreservation, specifically, was demonstrated to produce shorter and more infrequent graft–host immune responses as compared to fresh, vascularized bone grafts [44]. More recently, however, protocols using nonionic detergents, hydrogen peroxide, and denatured alcohol have demonstrated an improved safety profile of allogeneic grafts [45] with union rates comparable to autologous grafts [46].

Aside from immune reactions, allografts pose a problem when concerned with union rates, structural integrity, and infections. In a large retrospective study, Hornicek et al. [47] demonstrated that of 945 patients who underwent allograft transplantation, 17.3 % of the patients experienced nonunion. Furthermore, nonunion was often
associated with infection and graft fracture [47]. Sorger et al. [48] conducted a retrospective review of graft fracture in patients who underwent allograft transplantation. In a 1046 patient sample, 17.7% experienced structural allograft fracture at a mean time of 3.2 years after transplantation. Patients with graft fractures underwent further reconstruction, but 45.9% of the allografts completely failed (time to complete failure not specified) [48]. Finally, infection is a large concern for allograft transplant procedures. Infection rates have been suggested to reach 12.9–13.3% in patients who undergo allogeneic transplantation [49, 50]. Furthermore, 50% of allograft infections were polymicrobial with poor soft tissue coverage responsible for the majority of the infections [50].

**Autografts**

Autografts are harvested from and implanted into the same individual. The most frequently used donor site for bone autografting is the iliac crest with other options including the proximal tibial, distal radius, and greater trochanter [51]. Autografts obviate graft-host reactions mediated by histocompatibility mismatches because the tissue is removed and transplanted in the same individual. However, autografts present their own set of complications with donor site morbidity and limited tissue availability.

Autografts are considered the standard of bone grafting, especially in craniofacial surgery, due to their significant osteoinductive and osteoconductive properties [52, 53]. Cortical autografts also provide significant structural strength to the graft [28]. Cellular viability and neovascularization are critical properties of autografts that partly account for their use over allografts and aid in the osteoinductive, osteoconductive, and osteogenic potential. Vascularization is vital to the structural integrity of bone during the healing process [54–57], and graft integration is no exception [58, 59]. As one can expect, neovascularization between any graft and recipient site during the healing phase is a complex, dynamic interplay between various cell types and growth factors, which is supported by the use of autografts [58]. Cancellous bone autografts have been demonstrated to initiate vascularization within 2 days of grafting [60]. Harnessing the neovascularization in autografts is vital to the success of grafts in recipients.

Disadvantages to the use of autologous bone include donor site pain [61–63], which can be severe and prolonged, as well as more significant complications such as fracture, pelvic instability, hematoma formation, infection, and nerve palsies [64–68]. In addition, the quantity of bone graft needed further limits the use of autografts and contributes to the likelihood of adverse events after harvest.

The limitations of both autogenous and allogeneic bone graft materials have spurred research resulting in a proliferation of natural and new synthetic biomaterials used to treat bone defects. Nanotechnology and more refined biomechanical techniques have allowed for the analysis and development of osteogenic, osteoinductive, and osteoconductive biomaterials. As the field of bioengineering continues to evolve, allografts and autografts will likely fall out of favor and be replaced by more advanced bone graft substitutes that optimize vascular and cellular potential.

**Scaffold Materials**

Bioengineered scaffolds have evolved dramatically over the past 40 years and provide great potential in orthopedic and maxillofacial applications without immunologic or donor site complications that arise with allografts and autografts. Potential for these materials is virtually infinite with the advancement of nanotechnology and derivation of new scaffold materials, materials that will be developed to harbor significant strength and adequate osteoconductive and osteoinductive properties. Variations in scaffold type and architecture are limitless, including material, porosity, cellular seeding capacity, and growth factor seeding capacity [69–71].

**Natural—Collagen, Alginate, Hyaluronic Acid**

Collagen is the most abundant protein found in bone. Thus, it has been utilized in orthopedic tissue engineering applications because of its availability and biocompatible properties [72]. It obviates many of the complications associated with the use of bone allografts and autografts, but the mechanical properties of collagen remain in question [73]. More recent developments in collagen scaffolds have provided an improved strength profile of collagen scaffolds by modifying collagen cross-linking [74–76]. Tierney et al. [77] refined the properties of collagen scaffolds, including porosity, matrix, and permeability to increase osteoblast activity. These studies point to the potential of collagen scaffolds in tissue engineering, especially in orthopedic and maxillofacial applications. In virtually, all applications of bone grafts and scaffold materials, including collagen, vascularization, remains paramount for graft success.

Alginate is an additional natural material derived from brown algae that offers potential in biomaterial engineering cell [78, 79] through its ability to form a gel in combination with water. It is a polysaccharide that is easily modified chemically and structurally to allow for enhanced application in regenerative medicine. Its viscosity and porosity allow for cellular immobilization, integration, and extended release of factors and cells from the scaffold [80].
However, it lacks intrinsic mechanical strength [81] and is often combined with other compounds (i.e., chitosan, gelatin, and hydroxyapatite) to improve osteoconductive and osteointegrative properties while providing a strong biodegradable structure [82–85]. Furthermore, alginate can be functionalized with growth factors to enhance neovascularization in and around the scaffold to improve bone growth [86, 87]. One issue within biomaterial engineering is the ability to control the release of such factors and cells to enhance their effects. Alginate has been used as a spatiotemporal delivery vehicle for BMP-2 to enhance bone regeneration in comparison with collagen sponge as a result of sustained release in vivo [88, 89] and to deliver angiogenic factors sequentially to improve scaffold vascularization and bone regeneration due to differences in binding affinity between alginate and the factors [90, 91].

Finally, hyaluronic acid (HA) is another natural compound that has been studied for use in tissue engineering. HA is essential to the extracellular matrix in wound healing and is well known in musculoskeletal physiology as a compound that provides lubrication to synovial membranes in joint capsules by aggregating glycosaminoglycans [92, 93]. In tissue engineering applications, HA is similar to alginate in the fact that it is often combined with other compounds [94–96] and functionalized with growth factors [97] to enhance its regenerative potential and provide functional and structural roles in constructs [98, 99]. Like alginate, as a pure compound, it lacks mechanical strength often required for weight-bearing and thus requires either sufficient fixation stability or combination with structural scaffolds.

**Synthetic Materials—Polyethylene Glycol, Polycaprolactone**

Polyethylene glycol (PEG) is a synthetic compound used in tissue engineering due to low toxicity and absence of an immune response. It is hydrophilic and soluble, yielding poor mechanical strength [100], but it can, like the natural compounds, be combined with other materials to improve strength and biocompatibility. PEG can be functionalized with adhesive peptides [101], growth factors, and polysaccharides, such as glycosaminoglycans [102, 103], which have improved bone growth in and around the scaffold. In addition, PEG can be used to functionalize other scaffold materials and link macromolecules to improve bone formation [104].

Polycaprolactone is a synthetic biodegradable compound used in bone tissue engineering for its mechanical profile and manufacturability. It is a porous compound manufactured via numerous processes from photopolymerization to three-dimensional printing [105, 106]. Multiple studies have demonstrated the ability to seed mesenchymal cells and growth factors to improve graft integration at the recipient site [107–110]. The opportunity to functionalize polycaprolactone scaffolds largely stems from its porous structure. For these reasons, polycaprolactone has been identified as a viable scaffold option in bone tissue engineering.

**Ceramics—Bioactive Glass, Hydroxyapatite**

Bioactive glass is an appealing candidate in treating bone defects due to its biocompatibility, strength, and ability to regenerate bone through release of ionic biological stimuli [111]. Pores within the glass also allow for tissue ingrowth and viability [111]. A significant drawback of bioactive glass, however, is its inherent brittleness, making it difficult to handle in implantation [112, 113]. Strategies have been developed to overcome this challenge. For example, coating or combining bioceramic materials such as bioactive glass and hydroxyapatite with a supporting matrix such as poly-l-lactide acid (PLLA) [114], polyethersulfone (PES) [115], poly d,l-lactide-co-glycolide (PLGA) [116], or pN-isopropylacrylamide-co-butyl methacrylate (PIB) [117] improves not only the mechanical properties but the osteogenic potential of such scaffolds as well [115, 118]. Furthermore, the composition of bioactive glass can be altered to a more malleable material, making it easier to manipulate [119].

Another ceramic of interest in tissue engineering is hydroxyapatite (HAp). It is biocompatible, has good osteoconductivity [120], and has been used in bone repair. Similar to bioactive glass, though, it is relatively brittle and is not ideal for bearing weight [121]. However, there are several methods in which the HAp scaffold can be produced to improve the mechanics of these constructs to improve tensile and compressive strength [122, 123]. Interestingly, 3D printing has been utilized to produce HAp scaffolds capable of sustaining cell proliferation deep inside the construct and provides an exciting prospect for the future use of HAp [124].

**Growth Factors and Cells**

While graft or scaffold material is important to consider, the largest hurdle to bone regeneration is arguably in the challenge of creating a vascularized structure capable of nourishing the surrounding environment and removing wastes. To enhance angiogenesis and bone regeneration, various cell and growth factor combinations have been tested in scaffolds and grafts. Such combinations have largely included VEGF, PDGF, ECs, MSCs, and BMPs. In brief, VEGF functions to regulate angiogenesis and capillary permeability, as well as EC and MSC migration and

Springer
proliferation [125, 126]. PDGF recruits fibroblasts and inflammatory cells to sites of injury, induces collagen deposition, and possesses angiogenic potential [127]. ECs are crucial because they form the lumens of blood vessels. MSCs are multipotent cells capable of differentiating into various cells such as osteoblasts, chondrocytes, adipocytes, and muscle cells, but also serve to support neovascularization by acting as mural cells [128]. BMPs function to induce bone formation through the stimulation and differentiation of osteoblasts [129].

VEGF

VEGF has been a popular candidate in tissue engineering for its angiogenic properties. It is a particularly attractive candidate in bone bioengineering for its additional effects on chondrocytes, osteoblasts, and osteoclasts [56]. VEGF has been shown to mediate chondrocyte and osteoblast survival and differentiation as well as recruit osteoclasts [130]. It has been utilized individually, paired with other growth factors, and has been infected into cells through viral vectors to promote vascularization and bone formation [131]. VEGF appears to function best when used in conjunction with other factors [132–136]. For example, VEGF combined with BMP-7 has been shown to result in earlier osteogenesis, more lamellar and trabecular bone formation, and a higher bone density than the usage of BMP-7 alone [132]. In addition, differences in vascular growth between collagen-coated PLGA scaffolds seeded with either bone marrow MSCs (bmMSCs) or VEGF were minimal, but VEGF and bmMSCs seeded together resulted in continued vascularization 14 days after implantation [133]. Combining multiple cells and growth factors in a scaffold better reflects the composition of the extracellular matrix seen in repairing bone, as the regeneration process naturally requires a multitude of factors and cell interactions.

A hurdle in the application of growth factors for bioengineering techniques is the short half-life or dissipation of growth factors after being implanted into the defect, leading to avascular necrosis or prolonged time of healing [137]. In regard to VEGF, techniques have recently been developed that allow for extended, controlled release. Scaffolds constructed of silk/calcium phosphate/PLGA have been shown capable of releasing PDGF and VEGF at a rate so that bioactivity after 28 days is maintained at 82 and 89 %, respectively [138]. Poldervaart et al. [139] demonstrated that when released from gelatin microparticles in a controlled and prolonged manner in 3D bioprinted scaffolds, VEGF promoted significantly more vascular formation than when released quickly both in vitro and in vivo. Furthermore, the gelatin microparticles allowed for the creation of heterogeneous constructs, as it was noted that the microparticles could be administered regionally. A spatiotemporal scaffold construction such as this could be of particular use when considering the potential injurious effects of prolonged action of VEGF. In a nude rat model using genetically modified bmMSCs to express VEGF, Helmrich et al. [140] examined vascular density and bone quantity on osteoconductive material. While VEGF-bmMSCs demonstrated significantly higher vascular density after 8 weeks compared to control bmMSC cells, VEGF expression induced recruitment of osteoclasts and resulted in a reduction in the amount of mature bone. Although VEGF has been supported as a critical player in induction of vascularization and bone formation, overexpression or prolonged expression can lead to deleterious consequences through activation of osteoclasts or increased vascular permeability.

PDGF

PDGF is a critical element of wound healing and has been shown to promote angiogenesis [141–144] as well as increase wound neovascularization and granulation tissue formation [145–147], early elements of the wound-healing process. PDGF and VEGF are closely related, and VEGF can signal through PDGF receptors to regulate MSC migration and proliferation [148]. In the aspect of bone bioengineering, delivering PDGF on collagen-based demineralized bone matrix scaffolds through the cross-linking of heparin enhances and prolongs its local activity, and it increases both the cellularization and vascularization of the scaffold [149]. It also has been shown to increase the amount of collagen present in bony defects [150]. PDGF’s roles in angiogenesis and cellular migration and proliferation, as well as its role in conjunction with VEGF, makes it an enticing candidate in tissue engineering.

BMPs

Recombinant human BMPs (rhBMPs) 2 and 7 have been approved by the FDA for the treatment for open tibial fractures with intramedullary fixation and tibia long bone nonunion [151]. Acknowledged for their ability to induce osteoblast proliferation and differentiation, BMPs are popular choices in graft and scaffold use to increase rates to union [151]. However, usage of BMPs has been known to carry significant side effects likely due to the high dosage required, including swelling, inflammation, heterotopic bone formation, and most significantly, an increased cancer risk [152, 153].

In addition to their osteogenic potential, BMPs have been shown to increase vascularization in scaffolds as well. Zhang et al. [154] demonstrated BMP-producing bone marrow stromal cells have the potential to increase graft
incorporation and vascularization. In a cuttlefish bone scaffold soaked in BMP-2, Liu et al. [155] demonstrated that cuttlefish bone–BMP composite displays more microvasculature and bone trabeculae in rat skull defects than a scaffold of cuttlefish bone alone. The sustained release of BMP-2 seeded on 2-N,6-O-sulfated chitosan nanoparticles on a gelatin sponge induces bridging of segmental defects and a dose-dependent increase in angiogenesis in rabbit radius [156].

MSCs and ECs

Timing of administration of factors is important to consider when evaluating the angiogenic and osteogenic potential of a scaffold or graft, as bone regeneration is tightly regulated both temporally and spatially. MSCs can be used as a sole cell source to enhance osteogenicity in critical size bone defects [157]; however, they can also be co-transplanted with ECs. Co-transplantation of endothelial progenitor cells and MSCs increases blood vessel formation early in the healing process after 1 month and bone formation in later stages after 3 months [135]. Alternative to co-transplanting ECs and MSCs together, McFadden et al. [158] found that vascularization of a collagen-glycosaminoglycan scaffold occurs best when MSCs are added to preformed endothelial networks, as the MSCs can act as pericytes to the newly formed blood vessels. Pirraco et al. [159] also cultured ECs and subsequently added them to osteogenic cell sheets and found that this technique improves in vivo bone and vessel formation. Although MSCs and ECs cultured together provide the appropriate stimulus for vascularization and bone regeneration, MSCs are often derived from bone marrow. A challenge of utilizing bmMSCs lies in the requirement of invasive procedures to harvest the cells, as well as the limited quality of cells that are able to be obtained. It is therefore important to consider other sources. Human umbilical cord MSCs, human embryonic stem cells, and induced pluripotent stem cells have been evaluated as potential alternatives to human bmMSCs, and these alternatives have been shown capable of blood vessel and bone generation comparable to human bmMSCs [160]. These different sources of MSCs provide a potential effective and more cost-effective approach to tissue engineering.

Scaffold Vascularization Techniques

In addressing the issue of vascularization in a bony defect, one of two broad approaches can be taken. Attempts at vascularization can be done prior to placing the scaffold or graft, or the scaffold or graft can be seeded with proangiogenic factors and implanted as previously discussed. Prevascularization includes harvesting vascular bundles for the defect [161–165] or vascularizing sheets of cells prior to insertion [158, 166]. Saphenous vascular bundle constructs have shown promise in both large and small animal models, resulting in higher vascularization and osteogenesis [161, 162]. Contrary to transplanting preformed vessels, prevascularization on a smaller level with sheets of vascularized cells can be done. In an effort to construct a biomimetic periosteum prior to insertion, Kang et al. [166] created a vascularized cell-sheet-engineered periosteum by culturing human MSCs (hMSCs) and subsequently adding human umbilical vascular endothelial cells (HUVECs) to mimic the fibrous layer of the periosteum. A sheet of mineralized hMSCs designed to mimic the cambium layer was wrapped around a β-TCP scaffold followed by the vascularized HUVEC/hMSC sheet. The biomimetic scaffold resulted in enhanced angiogenesis that anastomosed with host vessels and increased bone matrix production [166]. While the use of both preformed vessels and proangiogenic factors shows promise, more research is needed to determine the efficacy among the different strategies.

Another emerging approach is stimulation of vasculogenesis through endothelial progenitor cell delivery. While typically considered important primarily during development, vasculogenesis, the process of de novo neovessel formation from progenitor cells, may also show promise as a therapeutic strategy for postnatal vascular growth. The identification of circulating endothelial progenitor cells [167], now termed endothelial colony-forming cells (ECFCs) or late-outgrowth endothelial cells (OECs) [168, 169], suggests that vasculogenesis may also be active during postnatal neovascularization. Importantly, this developmental process can be replicated postnatally by transplanted ECFCs, which participate in functional neovascular plexus formation and therefore may carry potential for therapeutic vasculogenesis. Both rat and human ECFCs have been shown to undergo vasculogenesis in bone tissue engineering constructs and enhance bone formation in vivo [170, 171].

Mechanical Regulation of Vascularized Bone Regeneration

In addition to biochemical cues, stem cell lineage specification and neovascularization are also regulated by mechanical stimuli. These mechanical cues can be characterized as either intrinsic (i.e., mechanical properties of the extracellular matrix or scaffold) or extrinsic (i.e., mechanical stimuli applied through either static or dynamic boundary conditions). Intrinsic cues such as matrix rigidity have been shown to control stem cell fate decisions.
independent of biochemical signals, with soft substrates promoting adipogenic and chondrogenic differentiation of MSCs and stiff substrates driving osteogenesis [172]. Recently, Mooney and colleagues demonstrated that in addition to the elastic properties, the viscoelastic (time-dependent) properties of the extracellular matrix can also regulate stem cell fate, with stress-relaxing substrates enabling osteogenesis in spite of initially soft elastic moduli [173]. While these observations have been primarily investigated in 2D culture systems, extension of these principles to 3D hydrogels and scaffolds will provide important design constraints in the development of next-generation tissue engineering constructs.

In addition to stem cell differentiation, intrinsic matrix cues have also been shown to influence neovascularization. Early studies controlled matrix rigidity by increasing the ECM concentration [174, 175] or by mixing in additional molecules like collagen to soft matrices such as matrigel [176, 177]. However, driven by the observations that increased or different ligand presentation has the potential to influence cell behavior independent of stiffness, recent studies have developed matrices of variable rigidity that maintain constant ligand identity and density. Several different approaches have been described, including tunable cross-linking polyethylene glycol (PEG) hydrogels [178, 179] and alginate hydrogels [180], which can be modified to control ligand presentation. Other recent studies have explored matrix rigidity control through differential cross-linking of natural ECM materials such as collagen. One such approach is methacrylated gelatin, which features controllable photocross-linking by ultraviolet (UV) light [181]. Another is nonenzymatic glycation [182–184], in which reducing sugars are used to create advanced glycation end products (AGE) on collagen fibers, resulting in cross-link formation [184]. Others have exploited the natural collagen fiber cross-linking that occurs in vivo to form matrices of variable rigidity at constant collagen concentration by missing collagen monomers and oligomers, formed through native in vivo cross-links [74]. Each of these approaches has demonstrated profound effects of matrix physical properties on neovascular growth and remodeling, and may have important implications for biomaterial scaffold design.

Bone has long been known to respond to extrinsic mechanical stimuli caused by physiological mechanical loading [185], but more recent studies have demonstrated that these mechanical cues also dramatically regulate fracture healing [186] and direct tissue differentiation [187, 188]. These observations have significantly influenced clinical practices for fracture fixation and postoperative management, and emerging understanding of the mechanobiological principles that underlie these responses will further enable tissue engineers to develop viable bone graft substitutes in vitro through bioreactor culture [189, 190] or enhance large bone defect regeneration in vivo [191–194]. For example, control of in vivo mechanical loading through modulation of fixation plate stiffness can either enhance or prevent bone regeneration depending on load timing and magnitude [192–194].

Extrinsic mechanical stimuli have also been shown to regulate neovascularization [195, 196] and vascularized bone regeneration [192]. Extrinsic cues that have been shown to influence neovascular growth and remodeling include blood flow-induced luminal shear stress [196–198], luminal pressure-induced circumferential stretch [199], tensile matrix stretch [195, 200], and tissue compression [192]. Collectively, these observations may have important implications for the development of novel vascularized tissue engineering strategies. Ongoing research on the role of both intrinsic and extrinsic mechanical cues for large bone defect regeneration will continue to inform biomaterial scaffold and fixation plate design and physical rehabilitation strategies. Important questions regarding underlying molecular mechanisms and interactions with the biochemical cues described above will continue to be explored.

**Conclusion**

Bone grafting has served a crucial role in the repair of segmental bone defects for centuries. Pioneers in the field of bone grafting recognized the importance of allografts and autografts, including the benefits and limitations of each. Allografts were very commonly used; however, over time, there was a transition to more commonly using autografts as techniques for harvesting the graft improved. Autografts have proved quite successful but not without their own limitations, including donor site morbidity. Due to the limitations of allografts and autografts and the advancement of biomechanical research, emphasis has been placed on developing artificial scaffolds with optimum osteoinductive, osteointegrative, osteoconductive, and angiogenic properties.

Many growth factors and cells have been studied for their various properties in combination with scaffolds. These compounds and cells include: VEGF, PDGF, BMPs, ECs, and MSCs. Novel research has suggested these compounds and cells provide promising opportunities for the development of optimal materials for bone grafting that allows for vascular and regenerative potential. With the materials, growth factors, and cells available for biomechanical research, the potential for bone graft and scaffold development is endless. Taken together, these studies demonstrate opportunities that lie ahead to improve patient outcomes after a bone graft procedure.

Conflict of interest  Kaitlyn S. Griffin, Korbin M. Davis, Jeffrey O. Anglen, Tien-Min G. Chu, Joel D. Boerckel, and Melissa A. Kacena declare they have no conflict of interest. Todd O. McKinley is a consultant for Bioventus.

Animal/Human Studies  This article does not include any studies with human or animal subjects performed by the author.

References

Study/Product Aim(s)

- **Aim 1:** Determine the union rate of tibial mid-shaft critical-size defects in minipigs treated with BMP-2, TPO, and saline control
- **Aim 2:** Evaluate the safety and side effects of treating tibial mid-shaft critical-size defects in minipigs with BMP-2, TPO, and saline control

Approach

Tibial critical size defect will be created in minipigs and treated with BMP-2, TPO and saline control. Blood chemistries will be measured to examine safety/side effect profiles. Animals will be euthanized 6 months post-surgery. Samples will be collected and analyzed for bone volume and tissue volume in the defects and the biomechanical properties of the tibia.

Goals/Milestones

**CY13 Goal**
- Obtain regulatory approvals
  - Obtain IACUC approval
  - Obtain ACURO approval

**CY14 Goals**
- Complete all surgeries in minipigs and identify potential short term side effects
  - Fabricate scaffolds and perform surgeries (completed on first 2 series of surgeries, will start 3rd series of surgeries)
  - Perform biochemistry analysis on blood samples collected up to 4 weeks post-surgery (Blood collected, initial processing completed, ordered supplies for analyses)

**CY15 Goal**
- Evaluate quality and quantity of newly formed callus
  - Perform μCT and biomechanical analysis on retrieved tibial samples (non-destructive biomechanical testing completed on tibia from all pigs)

**CY16 Goal**
- Complete side effects and callus analysis
  - Perform histological analysis on retrieved tibial samples (we have sectioned soft tissue for analysis of pathology from sacrificed pigs)
  - Perform biochemistry analysis on blood samples collected at sacrifice (being processed)

**Comments/Challenges/Issues/Concerns:** N/A
