Science and Technology Section

Air Information Division
This is the thirteenth in a monthly report series reviewing Soviet development in tracking missiles and space vehicles. It is based on source materials received at the Air Information Division during July and August 1961. Information not directly related to the assigned subject has been included because of its broad implications for study in this field.

The materials in this report deal with the following topics:

II. Ion clouds and ionosphere perturbations
V. Radio Astronomy
TOPIC II. ION CLOUDS AND IONOSPHERE PERTURBATIONS

Ionospheric perturbations caused by rockets and satellites are considered in terms of the interaction of a moving body with ions and electrons. Since the effect of the body on these particles is different there is a difference also in the perturbation of electron and ion densities. The quasi-neutrality of the plasma is disturbed and the disturbance is accompanied by the occurrence of an electric field. Both the variation in density of neutral particles near the surface of the body and the variation in density of electrons and ions are examined, and the magnitude of the electric field which affects the distribution of particles is determined. Because the velocity of bodies moving in the ionosphere \( v_0 \approx 10^6 \text{ cm/sec} \) is considerably higher than the thermal velocity of molecules and ions \( (v_m \approx 10^5 \text{ cm/sec}) \) but lower than the thermal velocity of electrons \( (v_e \approx 10^7 \text{ cm/sec}) \) it is assumed that the following inequality is satisfied:

\[
\sqrt{\frac{kT}{M}} < v_0 < \sqrt{\frac{kT}{m}},
\]

where

\( T \) is the gas temperature, \( M \) is the mass of a molecule, and \( m \) is the mass of an electron.

1. Density of neutral particles

In the case of a sphere with a radius of \( R_0 \) moving in a gas at supersonic speed, it is assumed that there is a specular reflection of particles from the surface of the sphere. In the process of particle collision with the body a rarefied, low-density, region is formed behind the body and a high-density region in front of it. If the process lasts long, i.e. if \( \Delta t \gg R_0/v_0 \), a steady-state distribution of particles occurs. The following expression is derived for the excess density of particles in the high-density region, i.e., the density which results from the presence of particles reflected from the sphere and which is additional to the gas density encountered by the sphere:

\[
n_{m_1} = n_{m_0} \frac{R_0^2 \sin^2 \theta_1 \cos^2 \theta_1}{r^2 (1 - \frac{R_0}{r} \sin^3 \theta_1)}
\]

where \( n_{m_0} \) is the excess density, \( n_{m_0} \) the density of the gas encountered by the sphere, \( \theta_1 \) the angle between the normal to the sphere at the point of collision and the horizontal axis, and \( r = R_0 \sin \theta_1 \). With the use of this expression it is shown that the density of molecules in the high-density region varies considerably. At the surface of the body the relative density \( n_{m_1}/n_{m_0} \) is 100%; at a distance
of $R_0$ from the body's surface, $n_{m_1}/n_0 \approx 50\%$; at $0.5 R_0$, $n_m/n_0 \approx 20\%$; and at $R_0$, $n_m/n_0 \approx 10\%$. In the case of a nonspecular reflection, i.e., a diffusion reflection, the excess density was found to be $n_m \approx n_0 \left(1 + \frac{1}{\Delta R}ight)$.

where $\Delta R$ is the distance from the surface of the sphere. To determine the density of particles in the rarefied region, account is taken of the velocity distribution of particles. Under the assumption of a Maxwellian distribution, the following expression is derived for the density:

$$n_m = n_0 \exp \left(\frac{(R_0/Z)^2 (MV_0^2/2kT)}{2}ight).$$

2. Density of ions and electrons and the electric field

Solution of a system of equations consisting of a kinetic equation for ions and an equation for the electric field shows that the density of electrons near the moving body is approximately equal to the density of ions. Expressions are also obtained for equipotential surfaces around the moving body. The above discussion is limited to cases where the surface of the moving body is a dielectric which reflects totally all particles. In the case of a metallic surface, electrons are absorbed by the surface and ions are neutralized, at least partially. Comparison of the distribution of equipotential surfaces around a dielectric body with that around a metallic body shows a difference in distribution only near the body. The maximum value of the electric field potential is of the same order of magnitude; it occurs, however, not near the body's surface but at a distance of approximately $R_0$.

Radiation of an electron moving in a magnetically active plasma may be divided into two components, a Cherenkov and a synchrotron component. The former predominates when $v_\parallel/v_\perp > 1$, while the latter prevails when $v_\parallel/v_\perp << 1$ and

$$(v_\parallel/c)n_j(\omega, \xi) < 1,$$

where $v_\parallel$ and $v_\perp$ are, respectively, the parallel and the perpendicular component of the velocity of a particle with respect to the magnetic field and $n_j(\omega, \xi)$ is the refractive index of the $j$-th normal wave. For evaluation of the intensity of the electron radio emission in the medium-frequency band, both the Cherenkov radiation and the synchrotron radiation are discussed separately.

Cherenkov radiation. In this discussion a stream of charged particles with a density $\mathbf{q}$ and moving with a constant velocity $\mathbf{v}$ is assumed. The cross-sectional dimensions of the stream are large so that the edge effects may be disregarded. The reabsorption of radiation of particles is also disregarded on the assumption that the intensity of total radiation is a sum of the intensities of radiation of individual particles. Under such conditions, the intensity of the Cherenkov radiation averaged within a half sphere may be determined from the following expression:

$$I_{\text{Cherenkov}} = \frac{\mathbf{q} \cdot \mathbf{v}}{4\pi} \int \frac{d\omega}{\omega} \int \frac{d\xi}{\xi} n_j(\omega, \xi),$$
where \( \nu \) is the intensity of radiation of a charged particle in a unit path, \( z_1 \) and \( z_2 \) are the limits of integration which are determined from the condition \( \cos^2 \vartheta < 1 \) (\( \vartheta \) being the angle between the direction of propagation of the radiated wave and the direction of the magnetic field). On the basis of the above expression and under the assumption that 1) \( z_2 - z_1 = \Delta z = 100 \) km; and 2) \( \beta = (v_n/c) = 0.004 \), the intensity of radiation at a frequency of 0.5 mc and at an altitude of approximately 1500 km was determined as \( J = 5 \times 10^{-20} \) q·watt·m⁻²·cps⁻¹·steradian⁻¹. With \( \Delta z = 300 \) km and \( \beta = 0.01 \), \( J \) was found to be \( 6 \times 10^{-19} \) q·watt·m⁻²·cps⁻¹·steradian⁻¹.

Synchrotron radiation. The frequency of the synchrotron radiation caused by non-relativistic particles is determined by the intensity of the magnetic field. Each altitude in the earth's atmosphere corresponds to a certain generation frequency \( \omega = s \omega_N \) (\( \omega_N \) being the gyrofrequency and \( s = 1, 2, 3 \ldots \)); the intensity of harmonics, beginning with the second harmonic, decreases with an increase in \( s \). The evaluation of the radiation intensity is limited to a case where \( (n_\beta \beta_\perp) < 1 \); the intensity is expressed as follows:

\[
\frac{\gamma}{\alpha_j} = \frac{c^2(\nu_j)^2 n_j |\xi_j|^2 v_j^2}{4\pi c^5 (1 + \alpha_j)^2} \frac{y^2 (s-1)}{2^3 s [(s-1)!]} \, d\Omega
\]

where \( \gamma = n_j \beta_\perp \sin \vartheta \), \( d\Omega \) is the element of the solid angle, and \( \alpha_j \) and \( \xi_j \) are the parameters characterizing the polarization of normal waves propagating in a magnetooactive plasma. With the above expression and under the assumption that \( \beta_\perp \approx 0.3 \) and \( \vartheta \approx 10^\circ \) the intensity of synchrotron radiation at an altitude of approximately 1500 km and at plasma frequency \( \omega_0 \approx 10^7 \) was determined as approximately \( 10^{-20} \) q·watt·m⁻²·cps⁻¹·steradian⁻¹. With \( \omega_0 = 3 \times 10^{11}, \beta_\perp \approx 0.3 \) and \( \vartheta = 20^\circ \), the intensity at an altitude of 3000 km was found to be \( 10^{-22} \) q·watt·m⁻²·cps⁻¹·steradian⁻¹. The above values are not claimed to be accurate. They show the order of magnitude only. The decrease in radiation intensity at 3000 km as compared with the intensity at 1500 km is explained by a sharp decrease in \( (1 + \alpha_j)^2 \); a factor which depends on the nature of polarization of normal waves propagating through the ionosphere. (Gor'kiy Scientific Research Institute of Radiophysics)

In a study of the interaction of a beam of charged particles with low-frequency, primarily magnetoacoustic, waves in a plasma, in the presence of a constant magnetic field acting in a direction parallel to the motion of the beam,
the assumption is made that the beam density is much lower than the plasma density and that the thermal scattering of electrons in the beam is small. Under this assumption, a dispersion equation describing the magnetoacoustic waves is solved and it is shown that if the electron temperature is much higher than the ion temperature the plasma-beam system is unstable because of the interaction of the magnetoacoustic waves with the beam. When the electron temperature is lower than or equal to the temperature of ions the instability occurs only when the natural plasma oscillations become strongly attenuated. It is also shown that, in general, a beam of particles with low density and high thermal scattering of electrons and ions does not generate magnetoacoustic waves in a plasma.

TOPIC V. RADIO ASTRONOMY

In the summer of 1959 and 1960, studies were conducted for the purpose of registering solar flares at frequencies of 25, 18, 13, and 10.5 mc. For the first three frequencies, the antenna systems consisted of multidipole cophased arrays suspended at a height of \( \lambda /4 \) above metal-covered ground. The radiation patterns of these antennas were identical; the width of the major lobe at half-power points was \( 30^\circ \times 30^\circ \). At 10.5 mc, reception was carried out with the aid of either a horizontal rhombic antenna, having a narrow directional pattern in the horizontal plane, or a half-wave dipole. Standard receivers with an intermediate-frequency bandwidth of 3 kc were used. The time constant of the receiver output circuit containing a pulsed noise limiter was about 0.5-1 sec during decrease in signal magnitude and several tens of seconds during increase. Sporadic radio emission and a considerable number of solar flares were observed in the 25 to 10.5-mc frequency range. The intensity of solar flares was high in the entire experimental frequency range, but evaluation of the intensity was possible only at a frequency of 10.5 mc. Under the assumption that the effective temperature of the galactic background at this frequency is several hundred thousand degrees, the intensity was determined to be as high as \( 10^{-19} \) w/m\(^2\)-cps. It is believed that solar flares occur also at frequencies lower than those used in the study.

Since December 1958, a special system has been used which makes it possible to measure orbits and velocities of meteor particles as well as the velocity and the direction of motion of ionized wakes by recording signals reflected from meteor trials at three different points on the surface of the earth. The system consists of a high-power pulse transmitter and a high-sensitivity receiver which operate on an 8-m wavelength. The other two receivers are placed at a distance of 4 and 6 km from the main receiving station. Signals received at these points are relayed to the main station and recorded. Analysis of the data obtained on the position of the radiants and on meteor velocities for the 1959 Geminid showers shows good agreement with the results obtained in other studies. It was found that the accuracy of determining the radiants of individual meteors is affected by the action of turbulent winds in the meteor zone. The meteor velocity in the Geminid showers above the earth's atmosphere was determined as 36.1 km/sec. It was also found that the error in recording the radiants of meteors moving with a velocity of 35 km/sec is \( \pm 3^\circ \) and the error of determining the velocity is \( \pm 1.5 \) km/sec. (Kharkov Polytechnic Institute)
3.) Bel'kovich, J. I. Determination of the mean-square error of the number of meteors observed in a unit of time. Astronomicheskii zhurnal, v. 38, no. 3, 1961, 532-535. QBL.A47

An expression for the mean-square error of number of meteors observed in a unit of time is derived and experimentally verified. It is shown that the time distribution of meteors follows Poisson's equation and that the mean-square error of the number of meteors observed in a time unit depends on the total number of meteors observed and the length of observation. In order to detect possible meteor showers, consideration is also given to a method based on the dispersion analysis for preliminary determination of maximum of meteor activity.

4.) Kisl'yakov, A. G. Results of an experimental study of lunar radio emission in the 4-mm wavelength range. Astronomicheskii zhurnal, v. 38, no. 3, 1961, 561-565. QBL.A47

An experimental study of lunar radio brightness on the El'brus mountain (3150 m above sea level) was conducted in the summer of 1960. A radio telescope consisting of a parabolic image antenna with a beamwidth of 25° and a radiometer operating in the 4-mm wavelength range were used. The observations made it possible to obtain a curve showing the variation in intensity of lunar radio emission with the phase of the moon. The curve, having an almost sinuoidal shape, may be approximated by the following expression: T = [230 + 73 cos(\(\varpi + 2\))]

where T is the radio temperature of the moon in °K and \(\varpi\) is the lunation frequency. The accuracy of measurement was ±15°.

5.) Basov, N. N., V. V. Nikitin, and A. N. Orayevskiy. Study of the dependence of maser frequency on various parameters. Part I. (Theory. Line J = 3, K = 2). Radiotekhnika i elektronika, v. 6, no. 5, 1961, 796-805. QBL.A47

A study is reported on the feasibility of the ammonia maser as an absolute frequency standard with an accuracy of 10⁻¹⁰. An attempt was made to derive the frequency characteristic based on an approximation of the actual velocity distribution. Particular attention was given to maser frequency dependence on the natural frequency of the cavity, uneven molecular emission along the cavity, hyperfine structure effects, and pressure changes. The experiments were carried out with ammonia masers utilizing the J = 3, K = 2 line and featuring two opposed beams to improve the oscillation characteristics and to compensate for the uneven molecular emission along the axis of the cavity. The cavity with the power take-off in the center, was 11.2 cm long, yielding the E₀₁₀ mode; a tuning range of several megacycles was achieved through a liquid nitrogen cooled diaphragm with an aperture of 0.6 cm. It was found that an opposed-beam maser has a point on the cavity frequency characteristic where the maser frequency does not depend on pressure. The opposed-beam principle also yields a frequency characteristic where the maser frequencies plotted at equal intervals against pressure and sorting voltage are symmetrical with respect to the resonance line. Two masers with opposed beams could be tuned to the spectrum line frequency with an error of 3 cps. It is noted that while these experiments were made with NH₂H₃ gas, a more
detailed investigation should be attempted with $\text{N}_2\text{H}_3$ gas because of the wider range of parameter variation possible in the latter case. The conclusion is reached that a maser utilizing two identical and opposed beams and a symmetrical design can serve as an absolute standard of frequency with an accuracy of $10^{-10}$. (Physics Institute imeni P. N. Lebedev, Academy of Sciences, USSR)

In order to analyze the tuning accuracy and frequency stability of a molecular oscillator, several experiments were conducted to determine the effect of cavity tuning, sorting voltage, and pressure in the beam source on maser frequency. In the setup used for measuring maser frequency (see illustration),

Block diagram for measuring maser frequency

1, 2, and 3 - masers; 4 - hybrid rings; 5 - klystron oscillator; 6 - klystron power supply; 7 - intermediate-frequency amplifier and an oscillograph; 8 - intermediate-frequency amplifiers and second detectors; 9 - oscillographs; 10 - audio-frequency oscillator; 11 - frequency meter; 12 - 75-kc amplifier and a discriminator
frequency measurements were made by comparing three masers in pairs whose fre-
quency differed by several hundred cps. The output of each pair was first mixed
in a hybrid ring and then fed to a second ring. The latter was used as a mixer
of the maser signal with that of a klystron oscillator which was tuned to
23,830 mc, i.e., 40 mc lower than the maser frequency. The output of the mixer
was fed to an intermediate amplifier with a gain of 10,000 and bandwidth of
2 mc. The i-f signal with a frequency equal to the difference between the fre-
quencies of two masers was then fed to an oscillograph and measured. The masers
used in the experiments had cavity resonators 80 mm in length operating with the
E_{10} mode. The resonators, made of invar, had a Q of 6000-8000. They were
tuned by means of a stub 2 mm in diameter. The resonator temperature was main-
tained with an accuracy of 0.01°C; a change in temperature by 0.01°C changed
the maser frequency by 1 cps. The results showed that the change in pressure in
the beam source from $1.5 \times 10^{-2}$ to $5 \times 10^{-2}$ mm Hg changes the maser frequency by
15 cps; the change in sorting voltage by 1 kv changes the frequency by 5 cps;
and the change in temperature by 1°C changes the frequency by 100 cps. There-
fore, to obtain a long-term maser frequency stability of $\Delta f/f = 10^{-11}$ it is
necessary to maintain the following accuracy range for the above parameters:

1. Beam source pressure, 1%
2. Sorting voltage, 0.2%
3. Resonator temperature, 0.002°C.

Since the maser frequency depends less on the change in sorting voltage
than on pressure, the latter may be used in tuning, although both types of tun-
ing (variation either in voltage or pressure) can provide for a tuning accuracy on the
order of $10^{-8}$. Still better tuning accuracy can be achieved by using an
opposed-beam maser. (Physics Institute imeni P. N. Lebedev, Academy of
Sciences, USSR).
