118. Kolendovich, A. I., On the epidemiology and prophylaxis of brucellosis in the Tselinograd Oblast.
(Author's review.) Zh. mikrobiol. 40 (1963) 2: 106-107. (From the Sanitary-Epidemiological Station of the Tselinograd Oblast.)

As stated in this note, the decrease in the incidence of human brucellosis in the Tselinograd Oblast from 9.1 per 10,000 population in 1952 to 0.4 in 1961 was mainly due to mass inoculation of the population (1343, 344 vaccinations in 1961). However, the author concludes, a complete disappearance of the disease could result only from a thorough sanitation of the animal-breeding farms. Vaccination of the animals is not fully successful in this respect unless combined with the prompt killing of the diseased animals (mostly sheep).

Selected Abstracts-II/109

122. Babenko, L. V. and Rubina, M. A., Simplification of the method of forecasting the density of Ixodes ticks and some data on their biology. Med. parazit. 32 (1963) 1: 13-18. (From the Entomological Department of the E. I. Martsinovskii Institute of Medical Parasitology, etc.)

123. Nikitina, N. A. and Zhmaeva, Z. M., Factors determining the tick infestation rate on various host species. Med. parazit. 32 (1963) 1: 39-43. (From the Department of Diseases Occurring in Foci of the Gamaleia Institute of Epidemiology and Microbiology, AMS, USSR.)

The three preceding articles can be quoted by title only.

124. Naumov, R. L. et al., On the participation of birds in the circulation of the tick-borne encephalitis virus. Med. parazit. 32 (1963) 1: 18-29. (From the E. I. Martsinovskii Institute of Medical Parasitology and Tropical Medicine, M1, USSR and the Poliomyelitis and Virus Encephalitis Institute, AMS, USSR, Moscow.)

The conclusions reached in this amply documented article were that:

1. Antibodies against the virus of tick-borne encephalitis were found in 87 specimens of birds belonging to 46 species.

2. Presumably ixodes ticks are not the only means of conveying the infection to the birds.

3. Only birds permanently feeding on the ground play an essential part in the infection of the tick larvae and nymphs.

(The enumeration of the affected birds species by both their common Russian and their Latin names will be most useful for reviewers and translators of the Soviet medical literature in general.)

125. Rositskii (Rosicky) B., Comparative sketch of the horizontal and vertical structure of some natural foci of
Selected Abstracts-II/110

tick-borne encephalitis in Central and South-Eastern Europe. Med. parazit. 32 (1963) 1: 29-35.
(From the Institute of Parasitology of the Czechoslovak AS, Prague.)

The details of this comparative ecological investigation must be studied in the original or a full translation. Of fundamental importance for the persistence of the natural foci were *Ixodes ricinus* and mostly small mammalian reservoirs of the infection.

(From the Khabarovsk Anti-Plague Station.)

Virus studies conducted during the winter of 1961-1962 in a mountainous region of the Khabarovsk Krai led to the isolation of 6 strains of the tick-borne encephalitis virus—3 times from the liver of "grey-red" voles and one time respectively from (a) the brain of a rodent of the same species; (b) the liver of a field mouse and (c) the brain of a field mouse.

As the author concluded

"The isolation of the causative organism of tularemia from the liver of rodents points to the presence of a virusemia and speaks for a circulation of the virus also at the time of the hibernal anabiosis of the ixodes ticks."

127. Nel'zina, E. N. et al., Frequency and spatial distribution of the micro-populations of blood-sucking arthropods in the micro-biotypes of the small suslik (sisel). Med. parazit. 32 (1963) 1: 45-54. (From the SR Anti-Plague Institute in Rostov-on-Don and the Astrakhan Anti-Plague Station.)

The conclusions of the authors were that

1. During the period from March to June the frequency of the various species of blood-sucking arthropods in the suslik burrows of the Kharabalinsk Raion of Astrakhan
Selected Abstracts-II/III

Krai reached the following maximal figures: Neopsylla setosa — 422; Ceratophyllum tesquorum — 29; Ctenophthalmus pollex — 24; Oropsylla ilovaikski — 41; Hirstionyssus criceti — 187; Rhipicephalus schulzei — 28; and Anoplura — 100.

2. One could observe an alteration in the periods of parasitation by the various arthropod species. This non-coincidence of the parasitation rendered it possible for the suslik to feed several species of blood-sucking parasites without a perceptible detriment to its vitality.

3. The spatial distribution of the various arthropod species was different: the micro-populations of H. criceti were located partly in the burrow nests and partly on the host, the fleas and ticks also partly in the corridors of the burrows; the lice (anoplura) remained all on the body of the hosts.

129. Taran, I. F. et al., Characterization of the immunity due to cutaneous vaccination and re-vaccination with the *Br. abortus* 104-M strain. Report I. The immunogenesis after cutaneous administration of the vaccine prepared with the strain *Br. abortus* 104-M in experiments on guinea-pigs. *Zh. mikrobiol.* 40 (1963) 3: 21-25.

(From the Gamaleia Institute of Epidemiology and Microbiology, AMS, USSR and the Anti-Plague Institute of the Caucasus and Transcaucasus.)

Summarizing the results of their observations, the authors stated that

1. The minimal dose of the vaccine prepared from the strain *Br. abortus* 104-M for cutaneous inoculation of guinea-pigs is 1 million organisms.
2. The intensity of the immunological reactions and the frequency with which cultures of the vaccinal strain can be isolated from the internal organs of the cutaneously inoculated animals depends upon the dose of the vaccine. The overwhelming majority of the animals became free from the vaccinal organisms within 3 months, but some of the test guinea-pigs harbored the organisms up to 6-9 months.

3. Histological examinations of the vaccinated guinea-pigs showed the presence of a stormy cellular reaction in the lymph nodes and organs which became maximal at the end of the first month after vaccination. The cellular reaction remained manifest for up to 6 months after vaccination and terminated with an active hyperplasia of the lymphoid elements. In a few instances guinea-pigs vaccinated cutaneously with 1-5 billion doses showed necrotic granulomata in some of their lymph nodes.

(From the SR Anti-Plague Institute of the Caucasus and Transcaucasus.)

The authors found that the STI anthrax vaccine, if administered cutaneously to guinea-pigs at the same time as the combined plague-tularemia-brucellosis vaccine, or with any two components of this tri-vaccine, lost to a marked degree its immunogenicity. On the other hand, the STI vaccine exerted no untoward influence on the efficacy of the tri-vaccine.

Testing the anti-anthrax vaccine prepared by them (see Abstract No. 97) on small groups of human subjects, the authors arrived at the following conclusions:

1. The chemically prepared anti-anthrax depot vaccine, if administered subcutaneously in two doses of 2.5 and 5 mg or 5 and 5 mg proved to be innocuous and to
Selected Abstracts-II/115

cause moderate reactions. The local and general reactions in the vaccinated persons could be classified as slight and did not at all interfere with their working capacity.

2. The changes in the blood picture observed in the vaccinated during the 10-day periods following the first and the second vaccination indicated a definite and sufficiently marked immunizatory stimulation of the lymphatic system.

3. The clearly positive results of allergic tests with "anthraxin" (anthrax allergen) in 11 out of the 12 test persons indicated the presence of a specific immunizatory process.

4. Since the vaccine under test appears thus suitable for human vaccination, further studies of its large-scale administration are desirable.

132. Koturga, L. N., Comparative characterization of the pathomorphological changes caused by the experimental cutaneous or subcutaneous administration of the vaccinal brucella strains 19, 19-BA and M-104. Zh. mikrobiol. 40 (1963) 3: 39-45. (From the Central-Asian Anti-Plague Institute.)

Summarizing the results of his well documented and illustrated findings, the author stated that

1. The vaccinal brucella strains 19 and 19-BA produced in guinea-pigs a characteristic vaccinal hyperplasia of the reticulo-histiocytary system with formation of solitary granulomata in the lymph nodes, liver, and spleen without signs of necrobiosis or necrosis as well as moderate dystrophic changes in the liver and kidneys.

2. The brucella strain M-104 caused a marked irritation of the reticulo-endothelium, and a more frequent formation of massive granulomata in remote as well as in the regional lymph nodes as well as in the liver, spleen, and lungs. In the liver one could note a necrosis of the granuloma cells, fatty dystrophy and focal necroses of the liver cells.

3. The findings made are suggestive of a greater residual virulence of the strain M-104.

These investigations, partly made with Q-fever and brucellosis conjugates, can be mentioned by title only.

134. Leshkovich, L. I., On the relation of the patho-morphological manifestations of the vaccinal process with the immunogenicity of live plague vaccines. Zh. mikrobiol. 40 (1963) 3: 86-90. (From the Central-Asian SR Anti-Plague Institute.)

This amply documented article ought to be studied in detail by those interested in the problems of plague immunology. The conclusions of the authors, which alone can be quoted here, were that

1. Live vaccines, if tested on animals in admittedly large doses, produce patho-morphological changes of the reticulo-endothelial system, which are not of specific immunological importance, but represent a reaction to the antigens and ballast proteins.

2. The varying frequency with which epitheloid granulomata appear in the liver and spleen of vaccinated guinea-pigs depends upon the antigenic and invasive properties of the various live plague vaccines, their dosage and the physiological state of the test animals. The granulomata are not morphological manifestations of the state of immunity of a given individual, inasmuch as immunity may be present in the absence of such patho-morphological changes. According to the appearance of granulomata in the test animals, one may to some extent evaluate the immunological efficacy of the various plague vaccines.

3. Indications of the innocuousness of live vaccines are the degree of distribution of the proliferative changes produced by them, the reversibility of these changes, and the absence of necrotic manifestations in an overwhelming majority of the test animals. Inasmuch as these manifestations increase with an increase of the dosage, one must evaluate the innocuousness of plague vaccines with doses not markedly exceeding those which produce an effective immunity.
4. There exist no absolutely innocuous vaccines, but the degree of harmfulness of live plague vaccines can be limited through their administration in rational immunizing doses. The possibility of this is demonstrated by the presence of an immunity against plague after vaccination with small doses.

Summarizing the results of their observations, the authors stated that

"it was possible to demonstrate the superior value of a study of live preparations with the aid of luminescent microscopy over that of the usual examination of fixed and stained preparations. The large gerbils are highly, but not uniformly susceptible to plague: side by side with highly sensitive animals which succumb to plague, one finds resistant ones which recover and survive. According to the character of their phagocytic reaction the big gerbils may be divided into two groups. In the highly sensitive animals the phagocytic reaction is inhibited and has an incomplete character. In the resistant individuals one notes a stormy activity of the phagocytes leading to a destruction of the plague bacilli. As a result of the recovery from plague there develops in such animals a post-infectious immunity."

The author used the plasma of plague-vaccinated (and partly also irradiated) guinea-pigs and rabbits to determine and plot differences in the optical density of these fluids before and after addition of a specific antigen obtained through autolysis of the EV strain.
Nephelometric tests conducted in this manner with the plasma of immunized guinea-pigs began to become weakly positive 3 days after the administration of 1.5 billion doses of live EV vaccine and proved markedly positive two weeks after immunization. In the case of the rabbits positive results were obtainable only after prolonged hyperimmunization with a total dose of 15-20 billion organisms of the EV strain.

Irradiation of the rabbits one month after the last vaccination did not inhibit the positive reactions with the EV antigen.

(From the Sanitary-Epidemiological Station of the Rostov Oblast.)

Though the great reduction of the planting of alfalfa led to a marked decrease of the population density of Mesocricetus roddii, tularemia enzootics continue to exist in the Rostov Oblast and may periodically lead to epizootics.

(From the Aral Sea Anti-Plague Station.)

The author reports on two small outbreaks of anthrax due to the preparation of horse meat for consumption. One of the five patients died, while administration of penicillin and anti-anthrax serum saved the life of the others.

(From the L'vov Institute of Epidemiology, etc.)

Observations in man as well as findings in cattle and sheep showed that "Q-fever is of definite importance in the local pathology of the western Ukrainian oblasts."

The last chapter of this work, dealing with the prophylaxis of brucellosis, is rather adversely criticized.

Selected Abstracts—II/124

142. Vlodavets, V. V., Determination of the viability of bacteria in aerosols. Zh. mikrobiol. 40 (1963) 4: 46-49. (From the Sysin Institute of General and Communal Hygiene, AMS, USSR.)

The conclusion reached in this article, the technical details of which must be studied in the original or in a translation, is that the number of viable cells in an aerosol may be ascertained with the aid of a simple method, based upon the determination of the proportion of single cells and microcolonies.

143. Sincl'nikova, E. P., Fluid foam filters for the entrapment of bacterial aerosols. Zh. mikrobiol. 40 (1963) 4: 49-53. (From the Kiev Institute for ATP.)

As described in this illustrated article, a foam produced from a fluid consisting of 30% glycerol in meat-peptone broth proved most efficacious for the absorption of bacterial aerosols.

The conclusions reached in this article, the details of which do not lead themselves to the purposes of a brief review, were that

1. The efficacy of vaccination by aerosol depends, besides upon the specific properties of the vaccines used, also upon the anatomical and physiological peculiarities of the respiratory system of man and animals.

2. A considerable barrier for the penetration of large aerosol particles is created by the nasal cavity and the nasopharynx.
3. The nasal cavity and the nasopharynx of small laboratory animals (mice, white rats, guinea-pigs) differ morphologically from the anatomical structure of the upper part of the respiratory passages in man and monkeys.

4. The retention and accumulation of the fine aerosol particles is regulated by differences in the aerodynamic conditions.

This illustrated article, in which studies made with the vaccinal anthrax strain STI-1 are described, can be quoted by title only.

As stated in the introductory part of this article, observations made mainly in the United States have pointed to the important role in the immunogenesis of plague of the Fraction I and also of the "residual" antigen (Baker et al., 1952).

"Still," the authors continued, "a sufficiently intense immunity, apt to ensure a resistance of the animals against aerosol infection with P. pestis, can be produced only by repeated administration of these antigens. It is thus possible to postulate that one could overcome this handicap through adaptation of a depot vaccine (adjuvant)."

In their present publication the authors reported on a study of the protection afforded by the different plague antigens with the aim of obtaining an efficacious chemical plague vaccine. They worked with the strain EV/NIIIEG*

* NIIIEG is an abbreviation of "Nauchno-issledovat'el'skii institut epidemiologii i gigieni" = Scientific Research Institute of Epidemiology and Hygiene.
(standard strain 303) cultivated in the casein-hydrolysate medium of Higuchi and Carlin (1957), in which the organisms were grown under aeration of 37°C for 40-42 hours. To maintain the pH, 4 ml of a 25% xylose solution were added every 8-12 hours per 100 ml of the culture fluid. At the end of cultivation the bacterial mass, the concentration of which had reached 18-25·10^9 per ml, was separated off by centrifugation and twice washed with bi-distilled water.

The bacterial mass, containing 10·10^9 organisms per ml, was exposed for 30 minutes to the action of ultrasound and the resulting lysate was used for the production of the antigens by various methods. Preparation No. 1 was obtained by precipitation with alumi-potassium alum, No. 6 by treating the lysate with hydrochloric acid, No. 9 with the aid of acetone. Preparation No. 13 was obtained in the same manner as No. 1 after preliminary treatment with aluminium hydroxide to free the lysate from toxic components.*

Toxic doses of the various preparations for laboratory mice were as follows:

<table>

(Table continued on page 127)

* For technical details of the preparation of these antigens reference must be made to the original or to a translation.
As this table shows, twice repeated vaccination with the preparation 13 gave the best results, but the prepareate 1 and to a lesser degree No. 6 gave also satisfactory results.

The authors thus reported on a further series of tests in which challenge doses of 100 DCL of a virulent plague strain were used:

"In tests on mice the following was found: the preparation No. 1, if given once in doses of 0.1, 0.05 or 0.025 mg protected respectively 50, 60 and 66% of the animals; owing to its high toxicity for mice the preparation No. 6 could not be evaluated in this series; preparation No. 9 protected under the same conditions 75, 60 and 0% of the animals; if single doses of 0.1, 0.05 and 0.25 mg of preparation 13 were given, 100, 85 and 80% of the animals survived; three times repeated immunization with the same doses resulted in a survival of 100%.

"Results in guinea-pigs were as follows: out of the animals once immunized with the preparation No. 1 in doses of 0.5, 0.125 and 0.067 mg survived after challenge with 100 DCL 50, 33 and 0%; three times repeated administration resulted in a survival of 66, 66 and 0%; under the same conditions the preparations 6 and 9 did not protect guinea-pigs."
As shown in the following, better results were obtained in these animals with the preparation No. 13:

* Challenge tests with 100 DCL were made 4 weeks after immunization.

Aleksandrov and his associates emphasized that the preparation No. 13 thus proved efficacious for the immunization of guinea-pigs as well as of white mice; it was little toxic for the latter. They postulated that this preparation might prove suitable for the manufacture of a non-toxic and efficacious chemical plague vaccine.

Summarizing the results of her investigations, Kurdina stated that

1. Studies on the residual virulence of the vaccinal strains Br. abortus, melitensis and suis by three methods (infection of guinea-pigs with various doses of the cultures under test followed by bacteriological and immunological studies; biological titration** and production of a septicemia

---

* The first communication of the author appeared in 1961 under the title "A study of the vaccinal strain of Brucella melitensis." (See Abstract No. 598.)

** I.e., bacteriological studies on guinea-pigs to which mixtures of two vaccinal brucella strains had been administered in various doses.
Selected Abstracts-II/129

through administration of the vaccinal strains to animals, the protective functions of which had been blocked through large cortisone doses) gave identical results. Hence any of these three methods can be used for the determination of the residual virulence of vaccinal brucella strains.

2. All strains were in the S form and were clearly different from the virulent cultures on account of their lowered virulence and invasive power. The residual virulence of vaccinal strains of one and the same type (Br. abortus) is apt to be unequal. Among the presently studied strains the strain Br. abortus 104-M had the highest residual virulence, Br. abortus 112 the lowest, while the strain Br. abortus 19-BA had an intermediate position. The residual virulence of the strain Br. suis 61 stood near to that of Br. abortus 104-M.

3. As shown by investigations on guinea-pigs and white mice, the residual virulence of the strain Br. melitensis Rev I also approached that of the 104-M strain.

The conclusions reached by the authors were that

1. Feeding of highly plague-susceptible midday gerbils with materials containing vitamin C (ascorbic acid) and vitamin E (tocopherol) increased the sensitivity of the animals to infection with P. pestis, as shown by earlier and more numerous deaths among the test animals.

2. Immunization of white mice with the avirulent EV strain or infection of the midday gerbils with sublethal doses of a virulent plague strain led in the animals having the two above mentioned vitamins in their food to an accelerated development of immunity.

Commenting upon these results in the concluding paragraph of their text, the authors stated that

"our findings speak for a probable influence of the interaction of vitamins C and E, which
the rodents obtain in their natural food, on the speed of the development and disappearance of plague epizootics occurring among them during different seasons and in different years.... Our findings also permit to question whether it would be useful to make combined use of these vitamins in connection with the vaccination against plague so as to speed up the development of the immunity."

The conclusions reached by the author through a detailed consideration of the information available in regard to these tularemia-affected raions were as follows:

1. Two territorially separated tularemia foci of the plains-steppe type and one focus of the foothill-brook type were found to exist in the Krasnodar Krai.

2. Tularemia attacks in the krai show a seasonal incidence, occurring in the foci of the first mentioned type from November to March (domestic mice and field mice forming the reservoir of the infection) and from March to June (when hamsters are involved), in the foothill-brook focus, where water-rats are involved, from May to August.

3. Characteristic for the foci of the first category are outbreaks related to agricultural and other occupational activities and such of a domestic nature. The outbreaks in the foothill-brook focus are water-borne.

4. In years favorable for the multiplication of mice and voles and if no modern agricultural techniques are used, there exists a potential danger of local or widespread epizootics followed by manifestations of tularemia in the not vaccinated part of the human population.

5. For the prevention of tularemia in the krai it is indispensable (a) to watch constantly over the frequency of the rodents and ixodes ticks; (b) to start antirodent and anti-tick campaigns in good time; and (c) to make systematic use of anti-tularemia vaccinations (to which latter the marked decrease in the incidence of the
disease since 1953 was mainly due). These measures must be implemented not only within the foci but also in the potentially endangered surrounding areas.

(From the Gamalcia Institute of Epidemiology and Microbiology, AMS, USSR.)

Tests in guinea-pigs as well as a limited number of observations in persons who had suffered from tularemia or had been vaccinated against it, showed that tularin prepared from vaccinal strains (Gaiskii No. 15 or Gaiskii No. 15 reconstituted) is apt to remain potent for at least 4-5 years (as actually observed for 5 years and 7 months).

In order to avoid stormy reactions, the bacterial standard of the tularin preparations used for skin tests should not exceed 2 billion organisms per ml.

As stated in an earlier publication (see Abstract No. 678 of these reviews), the authors had found that all six phage strains examined by them showed an identical morphology of their negative colonies and a similarity of their antigenic structure. The present studies again showed that all these strains fell in a common group. However, the authors maintained that they were able to observe some differences in the length of interaction between the various phages and a standard plague culture as well as in the rapidity with which the phage strains were inactivated by various physical and chemical agents (ultraviolet irradiation, heating to 55°C, action of urea, photodynamic action of methylene blue and sensitivity to the action of 0.5% sodium citrate). The authors recommend the further use of the above mentioned tests in view of the possibility of thus arriving at a differentiation of the plague phage strains.
(From the Tomsk MI and the Tomsk SR for Vaccines and Sera.)

The main statements made in this well documented survey may thus be summarized:

1. As the author claims, it is accepted at present that "the virus of spring-summer tick-borne encephalitis is apparent in the form of some biological variants with an identical antigenic structure, which produce various forms of disease in man: the more severe paralytic form; the slight two-wave form of meningo-encephalitis; two known hemorrhagic fevers (the non-fatal Omsk hemorrhagic fever and the more severe and highly fatal Kyasanur Forest disease in India); and affections in sheep (louping ill) in Scotland and northern England."

Natural foci of the disease are met with in many parts of the Soviet Union and in a number of other countries. Since attacks of it are occasionally observed in autumn, the designation "spring-summer" is apparently no longer justified; and with increasing frequency one speaks now simply of tick-borne encephalitis.

2. Within recent years further information on the properties of the virus has become available, for the details of which the original must be consulted.

3. The known antibiotics do not act on the virus, but, as detailed by the author, ultra-sonic waves do exert an action on it, especially if acting in combination with formol or ethyl alcohol.

4. Under the conditions of cold storage the virus may survive for 2 weeks in milk and it may survive for not less than 2 months in cream and butter.

5. The virus is capable of causing agglutination of the erythrocytes of a number of animal and bird species and because of this property ample use is made of the hemagglutination and hemagglutination inhibition reactions for the laboratory diagnosis of the disease.

6. As specified in the original, great progress has been recently made in growing the virus in tissue cultures.
7. Vilecek (Acta virologica 5 [1961] 5: 278) has shown that the infected cells of the tissue cultures produce a protein substance called interferon, which exerts an inhibitory action not only on the tick-encephalitis virus but also on unrelated viruses. Further work with this substance, now available in purified and concentrated form, is of great theoretical and potentially practical importance.

8. Pogodina (Vop. virusol. 3: 272) was to produce a clinically typical disease in white mice through infection of various parts of the alimentary tract. The virus was found apt to multiply there, especially in the intestine. It has been established also that the tick-borne encephalitis virus persists in the blood of experimentally affected goats for 3 days and in their milk for eight days (Drozdov, 155 Thesis).

9. Experimental infection of monkeys (M. rhesus) offers a possibility of differentiating the different encephalitis viruses.

10. As discussed in the original, the susceptibility of various wild animal and bird species to tick-borne encephalitis has been studied. Bats have been inculpatd in this manner, and the common voles and house mice were found highly susceptible.

11. Strains with a lowered virulence have been isolated from patients with an inapparent form of tick-borne encephalitis and from ticks and may also be produced experimentally.

12. Toxic properties of the tick-borne encephalitis virus have been observed under special conditions.

13. The antigenic properties of the virus have been studied with the aid of neutralization, complement fixation and hemagglutination inhibition tests and the latter have been used for a classification of the viruses.

14. The clinique of tick-borne encephalitis has been discussed in various publications, including monographs by Panov (Leningrad, 1956) and Shapovalov (Leningrad, 1961). Details of the findings made, especially of the laboratory methods recommended (which now include the use of allergens) must be studied in the original.

15. The availability of fairly simple methods of laboratory diagnosis and an increasing familiarity of the physicians with the clinical features of tick-borne encephalitis
serum purified by the diaferm method of the USSR Academy of Medical Sciences. With the help of this therapy the mortality of the disease can be reduced to a minimum (0.6% according to a 1957 thesis).

16. Ample epidemiological studies showed among other findings the particularly important role of *Ixodes persulcatus* in the eastern raions of the Soviet Union and of *Ixodes ricinus* in its western part.

   Increase attention is being paid to the role of birds in the spread (including the long-distance spread) of tick-borne encephalitis. In connection with these studies evidence has been obtained indicating a role of the ectoparasites (gamaside ticks and fleas) of wild animals and birds.

17. While formerly only ixodes ticks seemed responsible for a conveyance of tick-borne encephalitis to man, during recent years evidence has been found for a role played in this respect by the consumption of raw goat-milk, leading to alimentary infections.

18. The problem of the prophylaxis of tick-borne encephalitis (including a study of ways and means to eradicate the foci of this infection) has been the subject of ample research. The efficacy of DDT preparations, distributed on the ground or from airplanes, has been established.

   Systematic treatment of the domestic animals with 10% DDT dust was found efficacious, but now chlorofos is recommended for this purpose. However, the remarkable success obtained in the Tomsk Oblast by Karpov and his associates (1962) with 10% DDT dust deserves great attention.

19. Continued efforts are being made to devise a method of specific prophylaxis against tick-borne encephalitis. The author draws in this respect special attention to the vaccines prepared from virus cultures by Levkovich and Zasukhina (*Acta virologica* 3 [1959] 2: 73) and some other workers.

20. Promising results have been obtained by administering the above mentioned serum preparations (see paragraph 15) prophylactically to tick-bitten individuals.

A long reference list enhances the value of the survey.
Selected Abstracts-II/135

This survey, which deals with the subject stated in the title in a general manner, can be mentioned only by title.

Zh. mikrobiol. 40 (1963) 5: 3-8. 
(From the Gamaleia Institute of Epidemiology and Microbiology, AMS, USSR.)

The conclusions reached in this well documented article were:

1. Simultaneous infection of guinea-pigs with brucellosis and tularemia caused a process identical with that produced in animals separately infected with these two diseases.

2. In guinea-pigs infected with tularemia 15-30 days after brucellosis infection, one could observe a delayed development of the former (tularemia) infection.

3. After simultaneous infection of rabbits with brucellosis and tularemia one observed a delay in the spread of the brucelae in the body of the test animals, a reduced invasion of the organs by the organisms, and a reduced accumulation of brucellosis antibodies.

4. These changes in the course of mixed infection were caused by the development of corresponding immunological reactions in the test animals.

Work with the avirulent plague strains EV and 17, two virulent pseudotuberculosis strains, the STI anthrax strain, one Brucella suis strain, one Br. melitensis strain,
the *Br. abortus* strains 544 and BA, four *Br. rangifers* (reindeer) strains, five virulent and one avirulent (No. 15) strains of tularemia bacilli led to the following conclusions:

1. The presence of lipase was observed in the vaccinal anthrax strain, the virulent and avirulent tularemia strains and in all types of the brucellae. The highest lipase activity was noted in the case of the tularemia bacillus which evidently easily discharged this enzyme into the surrounding medium. Lipase was absent from the vaccinal plague strains and the virulent pseudotuberculosis strains.

2. An optimal lipase activity of the tularemia and anthrax bacilli was observed at a pH ranging from 6.5-7.0. The rate of tributyrin splitting in phosphate and cytric-phosphate buffer solutions was two times higher than that in acetate-veronal or borate buffers. With a rise of temperature from 40°C to an optimal temperature (e.g. 240-370 in the case of the anthrax bacillus) the rapidity of the reaction was accelerated almost threefold.

3. The lipase activity continued after lyophilization of the organisms.

(From the SR Anti-Plague Institute of the Caucasus and Transcaucasus MI, USSR, Stavropol'.)

As stated in the introduction to this article, previous observations* had shown that (a) if grown on meat-peptone media with an increased iron content, the EV strain intensively utilizes this element and at the same time the catalase activity of the organism becomes increased and (b) the administration of iron protosulfide to guinea-pigs leads to an increase of the virulence of weakly avirulent plague strains passed through such animals. The object of the present study was to assess the influence of iron on the vaccinal plague strains EV and No. 1 in white mice. The authors found that

---

1. Passage of the avirulent plague strains EV and No. 1 through white mice led to an enormous increase of the residual virulence of the strains.

2. White mice proved more sensitive in such tests than guinea-pigs.

3. If passed through white mice simultaneously with the administration of iron to the animals, the two plague strains became more immunogenic for guinea-pigs than the original cultures of these strains.

(The well documented detailed findings of the authors must be studied in the original or a full translation.)

Discussing the various methods available for a differentiation of plague and pseudotuberculosis bacilli, the author stated that the fluorescent antibody technique is tedious and hardly or not at all applicable under field conditions. It was, therefore, important to establish whether the use of carbon-saturated immune sera would be suitable for such tests. The commercially produced plague sera proved unsuitable for this purpose because they gave positive reactions with pseudotuberculosis as well as with plague bacilli. The author produced therefore as serum of his own by immunizing rabbits intravenously with two-days-old broth cultures of the EV strain grown at 28°C. The animals were given at first at five-day intervals five injections of 0.1, 0.2, 0.4, 0.8 and 1.6 ml respectively; after 1-1/2 to 2 months they got three further injections of 0.4, 0.8 and 1.6 ml, respectively, at the same intervals (5 days). They were bled two weeks after the last injection. The method of carbon saturation is not stated.

As shown in a table, only plague bacilli grown at 37°C (and therefore possessing a sufficient amount of Fraction I) were well agglutinated by the carbon-containing serum in slide agglutination tests. Sera raised in rabbits with the Fraction I gave identical but weaker reactions. Anti-pseudotuberculosis sera adsorbed to carbon reacted neither with plague nor with pseudotuberculosis bacilli.
The diagnostic reactions were carried out thus:

"One drop of the carbon-saturated serum was put on a slide and two drops of a suspension of the organisms (under test) in normal saline, containing 500 cells per ml, were added; the fluid was mixed and spread out on half of the slide in the form of a triangle; tests with immune and normal carbon-saturated sera were made on the same slide. The reaction was read after the slide had been gently shaken a few times. In positive cases the carbon particles agglomerated and the fluid became clear."

Tests with 26 virulent and 6 avirulent plague strains and with 50 pseudotuberculosis strains gave the following results:

Remarks - (a) One old avirulent culture and two strains isolated respectively in 1956 and 1958.
(b) Isolated from rats in Leningrad - one strain in 1913, two in 1956, interestingly all three in one and the same locality.

It is curious that carbon-saturated commercial cholera 0 sera gave a markedly positive result with 29 of the plague strains and 3 of the pseudotuberculosis strains which latter all contained Fraction I.

Two of the atypically reacting plague strains and the three atypical pseudotuberculosis strains showed the following properties:

(See table on page 139)

Thus, the author pointed out, these cultures could be classified neither as plague nor as pseudotuberculosis strains. The presence of Fraction I in supposed pseudotuberculosis strains was particularly noteworthy. Possibly these strains, which had proved avirulent from the moment of their isolation, occupied an intermediate position between P. pestis and P. pseudotuberculosis.

This brief but amply documented enumeration of the localities affected by hemorrhagic fever in the Soviet Union and elsewhere can be quoted by title only.

159. Martinevskii, I. L. et al., On the fate of plague bacteriophages in the body of healthy and plague-affected big gerbils and the possible routes of the transmission of the phages under experimental conditions. Zh. mikrobiol. 40 (1963) 5: 31-34. (From the Central-Asian SR Anti-Plague Institute, MI, USSR.)

The conclusions reached by the authors were that

* Plague bacteriophages, if administered subcutaneously, persist in the body of healthy big gerbils (Rhombomys opimus) up to 7 days and in plague-infected animals of this species up to 19 days.
2. In order to detect the phages under field conditions, an examination of the spleen and the lymph nodes is indispensable. In the blood the phages may persist up to three days.

3. The plague bacteriophage exerts a lytic action in the body of the gerbils, but this is not so marked as on artificial media.

4. If "shadow colonies" are detected in growths from field material, it is indispensable to transfer these colonies to agar plates containing anti-phage serum.

5. For a direct observation of the phages it is necessary to keep the growth in the incubator for a prolonged time (in a number of instances up to a month).

6. A transmission of plague phages through contact of the gerbils or through fleas has thus far not been observed.

160. Pilipenko, V. G. et al., An experimental study on the cutaneously administered combined tri-vaccine prepared with the plague strains EV, 1 and 17, the brucellosis strain 104-M, and Gaiskii's tularemia strain 15 (reconstituted) and on the selection of optimal antigen doses in this vaccine. Zh. mikrobiol. 40 (1963) 5: 35-40. (From the SR Anti-Plague Institute of the Caucasus and Transcaucasus, Stavropol'.)

Previous investigations by Pilipenko and his associates had shown that the administration of the triple vaccine referred to in the title did not produce as long-lasting an immunity in guinea-pigs as inoculations with the corresponding mono-vaccines. The authors made therefore two further series of tests, in which the vaccine dose of two drops or 1 ml contained (a) 3 billion plague bacilli, 2 billion brucellae, and 50 million tularemia bacilli or (b) increased doses of brucellae (4 billion) and of tularemia bacilli (250 million). They pointed out that with the method of standardization by turbidity used the actual number of tularemia bacilli present in the vaccine dose was not 250 million but 1.2 billion, i. e., 5-6 times the dose of 160-200 million organisms used for the vaccination of man with the usual dry tularemia mono-vaccine.

Experiments with the reinforced triple vaccines, the detailed results of which must be studied in the original or a translation, led to the following conclusions:
1. The cutaneously administered combined vaccine, containing in the vaccinal dose (2 drops dispensed from an eye-dropper) 3 billion plague bacilli of the EV strain or the strains 1 and 17, 2-4 billion organisms of the brucellosis strain 104-M and 250 million of tularemia bacilli, was proved to cause slight reactions and was throughout the observation period (up to 6 months) not less immunogenic than the corresponding mono-vaccines.

2. If using these quantities of antigens in the vaccinal dose, one observed no more the instability of the immunogenic properties met with when the formerly tested antigen doses were embodied into the live combined triple vaccine.

3. When preparing this triple vaccine from the corresponding dry vaccine, suspensions and mixtures of the latter must be made in such a manner that in the vaccinal dose of the combined vaccine 3-5 times more tularemia bacilli are present than is prescribed for the tularemia mono-vaccine. The number of plague bacilli and of brucellae needs no change. This increased dose of tularemia bacilli must be used also when manufacturing a dry triple vaccine.

The conclusions reached by the author were that

1. Sixty-three tularemia foci were detected in the TSelinograd Oblast (Kazakh SSR), of which 43 were of the floodland-river type and 20 of the lake-floodland type.* The reservoir of the infection was the water-rat while mosquitoes of the genus Aedes and D. marginatus ticks served as vectors.

2. The appearance of tularemia in these foci were closely related to the hydrological condition of the lakes and rivers in the oblast: the rise and fall of the water levels led to a migration of the water-rats. This migration

* As added in the text, from 1946 to 1961 tularemia epidemics were recorded in 39 of the 63 foci.
exerted an influence on the appearance of epizootics by leading on the one hand to an increased contact between these animals and on the other hand to increased chances of their coming in touch with immature phases of the vector ticks.

3. Epidemic manifestations of a vector-borne character occurred simultaneously in the foci of both types every 3-5 years when the atmospheric precipitations were considerable and the water-level was high.

4. It is necessary to intensify anti-tularemia work in years with much precipitation and increased numbers of water-rats.

The presence of tularemia in the Khabarovsky Krai was first confirmed in 1958 by Shapiro and his associates (Zh. mikrobiol. [1958] 2: 21) through the observation of two patients suffering from this disease in Khabarovsky. In the opinion of these authors the infection had been imported with contaminated grain. The validity of this surmise was doubted by Olsuf'ev* who postulated the existence of natural tularemia foci in the Far East. This contention was confirmed by the present authors who were able to isolated tularemia cultures from Ixodes persulcatus and from Haemaphysalis concinna in two widely distant localities of the Khabarovsky Krai. They were also able to show that nymphs of Ixodes persulcatus, developed from tularemia-infected larvae, were capable of transmitting the disease to white mice on which they had been fed.

(From the Irkutsk SR Anti-Plague Institute.)

The author summarized that

1. Tularemia was first recorded in IAkutia in 1944 and reappeared since then perennially with particularly severe epidemics in 1959 (459 cases) and 1960 (1,107 cases—total cases from 1944 to 1961--2,261).

* See the book Laboratornaia diagnostika osobo opasnykh i maloizvestnykh bacterial'nykh infektsii (Laboratory Diagnosis of Especially Dangerous and Little Known Bacterial Infections), Rostov/Don (1959): 182.
2. The endemic tularemia focus is situated in the central part of IAkutia along the course of the Lena and its major tributaries (where water-rats abound).

3. The human outbreaks in the republic are mainly vector-borne (mosquitoes and gnats).

4. Human infections take place mainly in summer and autumn on islands in the Lena River on the occasion of the hay harvests, fishing and collection of berries. Adult males are mainly affected.

5. Since ixodes ticks are absent from Central IAkutia, further investigations are necessary to study the mechanism of the infection.

6. Systematic vaccination is the principal means of fighting tularemia. With its aid the incidence of the disease was reduced from 1,107 attacks in 1960 to 111 in 1961.

The conclusions to this article state that

1. The specificity of the antibody neutralization reaction for plague was tested with the aid of 212 strains of different microorganisms, but only the plague strains and 3 pseudotuberculosis strains with radically atypical properties neutralized the antibodies to the Fraction I in anti-plague sera. Out of the 32 plague strains one did not synthesize Fraction I and in connection with this showed no neutralizing

* The first of these reports, with the sub-title "Observation of the antibodies in the sera of experimentally infected animals with the aid of passive hemagglutination tests" was dealt with in these reviews (see Abstract No. 548); the second, "A study on the specificity of the passive hemagglutination test in plague," appeared in Laboratornoe delo 7 (1961) 9: 44-46; Nos. 3, 4 and 7, in the Sbornik rabot Elistinskoi protivochumnoi stantsii (Collected Works of the Elista Anti-Plague Station, 1961) Installment 2; Nos. 5 and 6 in press.
activity. The antibodies to the complete antigen in anti-tularemia serum became neutralized only in the presence of tularemia bacilli. The strains of other microorganisms did not show this property.

2. The sensitivity of the antibody neutralization reaction in plague and tularemia exceeds that of all other serological methods which needed for observation specific antigen or liver organisms. If one considers also the comparative expediency of the method, the adequacy of a large-scale use of the antibody neutralization reaction for diagnostic purposes becomes evident.

3. This reaction permits an easy distinction between plague and pseudotuberculosis bacilli.

With regard to the last point of the conclusions the following statement is made in the text:

"...we prepared water-salt extracts of plague and pseudotuberculosis bacilli which had been grown at 37°C on agar for 3 days and had been killed with acetone. To prepare the extracts we added to 10 mg of the powdered dry bacilli 1 ml of normal saline and 1 drop of tufluol. After agitation in a shaking apparatus for 24 hours and centrifugation we tested the neutralizing activity of the extracts. Such were prepared from the bacterial mass of 13 plague strains and 34 pseudotuberculosis strains. Among the former the extract of the strain 1253 (which did not synthesize Fraction I) had no neutralizing activity whereas the extract of the strain EB-4, which synthesized a small quantity of Fraction I, was active in dilutions of 1:20,000 to 1:40,000; the extracts of the other (plague) strains showed a neutralizing activity if diluted hundred of thousands or millions of times."

Out of the 34 pseudotuberculosis strains, 31 showed no neutralizing activity, while three did so at low titers. However, live suspensions of these strains with a standard of 2.5 billion organisms showed no neutralizing activity.

164. Smirnov, V. P., From the diary of a physician who survived experimental plague infection. Zh. mikrobiol. 40 (1963) 5: 68-72. (From the Irkutsk SR Anti-Plague Institute for Siberia and the Far East.)
In order to compare the efficacy of immunization with the live EV vaccine by the subcutaneous, cutaneous or conjunctival routes or by the combined subcutaneous and conjunctival administration of the vaccine, experiments were made on 1,240 guinea-pigs, which after the immunization were challenged intratracheally with a virulent plague strain (Smirnov, Tezisy dokladov nauchnoi konferentsii po prirodnoi ochagovosti i epidemiologii osoboi opasnoi infektsionnoi zabolevanii [Abstracts of Papers at the Scientific Conference of the Natural Foci and Epidemiology of Especially Dangerous Infectious Diseases], Saratov [1957], pp. 364). Since these tests proved the high efficacy of the combined method, the author decided to experiment on himself. For this purpose he was vaccinated by the combined method on 10th of March 1950, receiving a dose of 1.5 billion plague bacilli each subcutaneously and through the conjunctiva. For his subsequent challenge he used material from the spleen of a guinea-pig which had succumbed to infection with a strain isolated from a victim to pneumonic plague in 1948 and had been kept highly virulent through animal passages. On March 25 he rubbed this material into a scarified part of the skin on his left leg. The virulence of the material was proved once more through guinea-pig experiments made at the same time.

Dealing with his subsequent plague affection in a summary manner, the author stated:

"After infection the author was kept in isolation for 17 days. He was under regular observation, including the taking of the temperature twice daily, bacteriological examinations of the blood, sputum, urine and the secretions from the site of infection. After 5 days the crust at the site of infection, under which a plague ulcer had developed, was removed. On the 7th day the temperature rose to 38.5°C and kept at a high level for 36 hours. On the 8th day it came to the formation of a regional femoral bubo with a characteristic painfullness. From the secretions of the plague ulcer material for growth on agar plates was taken several times on each day during the two weeks following its appearance; 6 times material was also taken for the infection of guinea-pigs. On the 6th, 7th, 8th and 9th day 7 plague strains were grown and an additional strain was obtained from one of the guinea-pigs which had succumbed to the infection. For 13 days daily cultures were made on
agar plates from the blood, sputum and urine, which all gave a negative result. When tested biochemically, the 8 plague strains were found to be identical with the original culture. All the strains remained virulent."

"Thus," the article concluded, "a person vaccinated against plague by the combined method (through the conjunctiva and subcutaneously) and then infected with a virulent plague strain through the scarified skin, even though not specifically treated, had a slight attack of cutaneous-bubonic plague."

The large-scale use of the combined method of plague vaccination was therefore recommended by the author.

165. Praidkina, M. D. et al., The biological and chemical properties of the GKI* pest-allergen. Report I. Zh. mikrobiol. 40 (1963) 5: 72-77. (From the Tarasevich State Control Institute of Medical Biological Preparations.)

As stated in the introduction to this article, Korobkova (Zh. mikrobiol. [1955] 4: 40) and some subsequent Soviet workers quoted by the author tried to use allergic skin tests for an assessment of plague immunity. Korobkova's "pestin" was not sufficiently purified to serve well for this purpose. Pavlova (Transactions of the "Mikrob" Institute [1958] Installment 2, p. 28) and Bakhrakh and associates (ibidem [1960] 4: 63) proposed as allergen the use of the polysaccharide-containing fraction of P. pestis obtained from the EV strain through hydrolysis with acetic acid. After purification the intracutaneous administration of these products caused a specific reaction in plague-immune test animals.

Since claims had been made that bacterial proteins could serve as allergens, the present authors investigated whether this held true in the case of the plague bacillus. They used for this purpose the method of Baker and co-workers (J. Immunol. 68 [1952], p. 131) of which they gave a description. Guinea-pigs immunized with live plague vaccine prepared from the strain EV 76 served as test animals, but a limited number

* GKI is the often used abbreviation for the Russian name of the Tarasevich State Control Institute: Gosudarstvennyi kontrol'nyi institut meditsinskikh biologicheskikh preparatov imeni Tarasevicha.
of tests was made also on human volunteers. The results of these well documented observations were thus summarized by the authors:

1. With the aid of ammonium sulfate precipitation (40-60% saturation) a fraction was prepared from extracts of acetone-dried plague bacilli to which the name "Pest-allergen GKI" was given.

2. This pest-allergen, in a dose of 0.01 mg contained in 0.1 ml of normal saline, produced an allergic reaction in plague-immune guinea-pigs but not in normal controls.

3. The pest-allergen did not produce positive reactions in animals immunized with live vaccines against tularemia, brucellosis or tuberculosis.

4. Preliminary tests on 59 volunteers showed that the pest-allergen, administered intracutaneously, was innocuous for man. It produced a marked allergic reaction in persons who had been vaccinated against plague intracutaneously and many times by the cutaneous route.

166. Zil'fian, V N. and Noramirian, A. V., Comparative action of novembichin, histamine and chicken egg-yolk on the development of experimental plague. Zh. mikrobiol. 40 (1963) 5: 77-83. (From the Armenian Anti-Plague Station.)

In the introduction to this article it is stated that, in order to detect latent forms of rodent plague or the natural occurrence of weakly virulent plague strains, recently various methods have been proposed to lower the resistance of the test animals and make them more susceptible to the infection.

Thus Kratinov (Voprosy patologii i immunologii chumy [Questions of the Pathology and Immunology of Plague], Stavropol', 1959) showed that a vitamin C deficiency lowers the resistance of the animals to different infections.

The possibility of using for the same purpose cortisone or allied preparations has been demonstrated by numerous workers abroad and in the Soviet Union.

Kuraev (Trudy n.-i. inst. "Mikrob," Saratov [1960] Installment 4, p. 369), trying various methods, obtained best results with the administration of trypan-blue and chicken
egg-yolk. Bratkova (1960--no reference given) found the last mentioned substance most useful. Avanian and Gubina (Zh. mikrobiol. [1961] 3: 92) used iron compounds to increase the virulence of P. pestis in experimentally infected guinea-pigs.

For their own work, in the course of which they experimented with 700 white mice and 66 guinea-pigs, the present authors used (a) Soviet-produced novembichin (embikhin No. 7), a new therapeutic preparation of the group of chlorethylamines; (b) histamine and (c) chicken egg-yolk, all subcutaneously administered together with the infecting dose. The latter was obtained either from a one-day old culture of the EV strain or from one of two plague strains isolated from common voles in 1959 which were weakly virulent for guinea-pigs but more virulent for white mice.

Summarizing the results of their well documented observations the authors stated that

1. The administration of novembichin, which exerts a strong action on the blood and the blood-producing organs and weakens the phagocytic activity of the body, creates conditions for an unimpeded multiplication and invasion of the plague bacillus. As a consequence of a marked suppression of the activity of the reticulo-endothelial system the mice become extraordinarily sensitive to plague infection. An adverse feature of the action of novembichin is a generalized auto-infection which penetrates from the intestines into the blood and not rarely kills the animals before the development of the plague infection.

2. Single administrations of chicken egg-yolk to white mice markedly increase their susceptibility to infection with weakly virulent or avirulent plague bacilli. The action of the egg-yolk was much more marked in white mice than in guinea-pigs; in the former it came to an acute infection; in the latter, to the development of chronic plague.

3. Under the action of histamine these resulted only an insignificant increase of the sensitivity of white mice to plague infection. The sensitizing action of histamine did not exert an influence on the length of life of the test animals. Consequently the use of histamine for speeding up the laboratory examinations offers no advantages.

4. The best results related to a lowering of the protective functions of the body against plague infection and an acceleration of the laboratory diagnosis of this
infection were obtained with chicken egg-yolk and novembichin. Their use could be advantageous for more profound studies of plague foci, detection of a residual tendency to infection and the detection of weakly virulent plague strains under natural conditions.

(From the Omsk Kalinin MI.)

As a result of a considerable water-rat epizootic in 1961 a major vector-borne tularemia epidemic in Omsk resulted. In the course of this epidemic the author was able to make careful clinical observations on 183 patients. It is noteworthy that only 14 of the sufferers had been vaccinated against tularemia - 3 three to four years previously and 11 shortly before they fell ill. Thus, as the author concluded with great reason, the epidemic was the result of an interaction of two factors - the presence of a large infection quantum among the water-rats and the absence of a herd immunity in the human population.

(From the Institute of Regional Pathology, AS, Kazakh SSR and the Gamaleia Institute of Epidemiology and Microbiology, AMS, USSR.)

In the summary to this article it is stated that

1. A study of the biological properties of 7 Q-fever strains, isolated in the natural focus of this infection in the foothills of the Zailiiskii Ala-Tau showed their moderate pathogenicity for laboratory animals.

2. The antigens of 4 of these local strains were serologically identified as Q-fever antigens; their specificity and the absence of anti-complementary properties were established.

3. In cross titration tests all antigens of the local strains either did not react at all with the type immune serum raised with the Grita strain or reacted but weakly--this shows that there were antigenic differences between the local and the Grita strains.
4. All the antigens of the local strains studied reacted at high titers with the type immune serum raised with the Central-Asiatic strain Termez and the Soviet strain Shorsher, which indicated a close antigenic relationship between these two and the local strains.

5. There was a close antigenic relationship between all locally isolated R. burneti strains.

169. Grennaus, G. I. et al., Some data on the study of Q-rickettsiosis in the city of Gor'kii and the Gor'kii Oblast. (Author's review.) Zh. mikrobiol. 40 (1963) 5: 90. (From the Gor'kii Institute of Epidemiology and Microbiology, the Oblast Veterinary Laboratory and the Oblast Sanitary-Epidemiological Station.)

As stated in this brief note, complement fixation tests with Q-fever antigen gave a positive result in 8.6% of 255 patients with feverish diseases hospitalized from 1956 to 1961. Such tests also gave a positive result in the sheep and goats and, to a lesser extent, also in the cattle of one raion of the oblast.

170. Ponomareva, T. N., To the problem of the bacteriological diagnosis of anthrax. Zh. mikrobiol. 40 (1963) 5: 107-112. (From the Central Anti-Plague Observation Station MI, USSR.)

The conclusions to this article, which alone can be quoted, were that

1. The identification of the anthrax bacillus ought to be based upon the consideration of a complex of signs: the morphology of the bacilli and the colonies, the formation of spores, the formation of capsules in the body of animals (white mice and guinea-pigs), absence of motility, character of growth on gelatin, absence of hemolysis, pathogenicity for guinea-pigs and a positive outcome of precipitation tests according to Ascoli's method.

2. Of great diagnostic help are tests with specific phages, a positive result of "bead" tests (see Jensen and Kleemeyer, Zbl. Bakt., 1. Abt. Orig. 159 [1963], p. 494) and the method of fluorescent microscopy.

3. From anthrax patients who were treated with antibiotics the causative organisms could be isolated only during the first 3 to 4 days of illness.
4. Except one strain isolated from a patient with cutaneous anthrax, the colonies of which were morphologically atypical, all strains isolated from man were typical in their fundamental properties.

5. One has to count, however, with the possibility of meeting atypical anthrax strains in the external environment. One such strain was actually found in the ground of an old burying ground for cattle.

171. Makarov, N. I. et al., Incidence of anthrax in animals and man in the Pre-Caucasus and Transcaucasus in 1960-61. (Author's review.) Zh. mikrobiol. 40 (1963) 5:112-113. (From the SR Anti-Plague Institute of the Caucasus and Transcaucasus, the Azerbaidzhan, Armenia, Georgian, North-Ossetian and Checheno-Ingush Republic Sanitary-Epidemiological Stations and the Azerbaidzhan Anti-Plague Station.)

The contents of this brief note do not lend themselves to a condensation.

This interesting article must be read in the original or in a full translation.

(From the Sanitary-Epidemiological Station of Tselin Krai.)

The author describes a vector-borne tularemia outbreak taking place in August-September 1958 on a sovkhoz near Tselinograd and also involving inhabitants of that city who had visited the vicinity of the communal farm. In the latter tularemia manifestations had been recorded already in 1946, 1949 and 1954. At the time of the last mentioned outbreak tularemia vaccinations had been administered on the farm but apparently to only part of the inmates and, though many new people had afterwards arrived, immunizations were not continued. Conditions for an appearance of tularemia in 1958 were also favorable because a water-rat epizootic and an abundance of mosquitoes coincided with the hay harvest in which also city inhabitants participated.
The total number of tularemia attacks recorded in August-September 1958 amounted to 232, of which 173 occurred on the farm and 77 among inhabitants of St. Petersburg.

The energetic measures to combat the outbreak included wholesale vaccination on the farm. It was thus inevitable that persons were vaccinated who incubated tularemia or became infected soon after immunization. It is noteworthy that no untoward influence of the vaccination could be observed in this group of people.

In an area of 250 hectares in the floodlands of the Ishim River, where the hay harvest took place, anti-mosquito work was done with the aid of hexachlorane smokepots. Dimethylphthalate was issued to the farm workers as an insect repellent.

In his conclusions the author stressed the necessity of (a) verifying in tularemia-endemic localities the state of immunity of the population every year so as to be able to vaccinate all newcomers and (b) providing for the detection of all tularemia attacks through house-to-house inspections. Specific treatment with antibiotics had to be administered even if at first the attacks appeared to be slight.

(From the Sanitary-Epidemiological Station, Smolensk Oblast.)

Summarizing the results of observations made in the Smolensk Oblast in 1959 when 15 human attacks were recorded, the author stated that

1. Invariably cattle served as the source of infection in these instances.

2. All patients suffered from the cutaneous form of anthrax.

3. No instance of infection was noted among persons who consumed the raw milk of anthrax-affected cows.

4. A milder course and a somewhat atypical character of the disease was noted in the patients to whom for prophylactic purposes anti-anthrax serum had been administered.
Levtova, K. Z. and Klodnitskaia, S. N., To the 50th anniversary of the detection of the role of camels in the epidemiology of plague. Zh. mikrobiol. 40 (1963) 5:152-153. (From the Order of Lenin First Moscow Sechenov MI and the SR Clinical Institute of the Moscow Oblast.)

In this historically interesting article the authors describe the discovery of natural plague in camels in the Astrakhan Government by Klodnitskii in 1911 and give an account of the subsequent observations made in this respect as well as of the experimental investigations undertaken in order to study the pathogenesis of the disease in these animals. They conclude their publication by stating that

"The problem of plague in camels is still of actual importance practically as well as theoretically. For instance in 1953 some camels succumbed to plague in western Turkmenia. In connection with the plague epizootic in 1953 special investigations were made by the workers of the Institute of Microbiology and Epidemiology of the South-East of the USSR, of the Central-Asian Anti-Plague Institute and also of the Turkmenian Anti-Plague Station. Together with other problems that of the mechanism of the natural plague infection of camels was solved.

V. N. Fedorov, in a report rendered at the scientific conference on the natural locality and epidemiology of specially dangerous infectious diseases held in 1957 recorded interesting data on the experimental plague infection of camels. The findings made led to the conclusion that the camels are susceptible to plague and can be experimentally infected with this disease. However, they show an individual susceptibility to P. pestis, as a result of which many camels recover from the disease and for this reason by far not all instances of the infection among them are recorded. A fundamental role in the mechanism of the infection is played by blood-sucking insects, among which the fleas are most important.

Thus the discovery of a role of the camels in the epidemiology of plague made almost 50 years ago by N. N. Klodnitskii was once more confirmed and fully documented by Soviet scientists.

The evidence adduced clearly shows the great practical importance of a constant prophylactic veterinary survey of the camels."
176. Votiakov, V. I., The types of the foci of tick-borne encephalitis and the fight against this disease in Belorussia. 
(From the Belorussian SRI of Epidemiology, Microbiology and Hygiene, Minsk.)

A consideration of the ecological conditions led the author to the conclusion that in the fight against tick-borne encephalitis in Belorussia emphasis ought to be laid on endeavors to keep the cattle free from the vector-ticks (Ixodes ricinus).

177. Peterson, O. P. and Li IUi, Homologous interference between activated and inactivated vaccinia virus on the chorio-allantoic membrane of the chick embryo. 
Vop. virus. 8 (1963) 2:159-163. 
(From the D. I. Ivanovskii Institute of Virusology, AMS, USSR, Moscow.)

The conclusions of the authors were that

1. The vaccinia virus inactivated by heating and by ultraviolet irradiation interferes with the homologous virus on the chorio-allantoic membrane of the chick embryo.

2. The suppressive action of the inactivated virus is manifested not only by a lowering of the hemagglutination titer, but also of the infectious titer.

3. The interfering action was observed if the inactivated virus was introduced 48 hours after the active virus and not later than 8 hours after the introduction of the latter.

4. The interfering effect was linked to the virus particle itself and not to the hemagglutination of the virus.

The technical details of this article do not lend themselves to the purposes of a brief review.

(From the Belorussian Institute of Epidemiology, Microbiology and Hygiene.)

Observations on ten *Macaca rhesus* monkeys which had been infected with tick-borne encephalitis strains isolated at the time of a considerable human outbreak of the disease in 1959 from patients and other sources led to the following conclusions:

1. In the monkeys experimentally infected with tick-borne encephalitis strains isolated in Belorussia one could observe two phase in the clinical course of the disease, the first being characterized by general manifestations of the infection, the second by neurological disturbances.

2. Characteristic for the first phase were an increase of the body temperature, congestion of the conjunctivae and the face, signs of headache, weakness and rapid faintness and an early disappearance of the defensive reflexes.

3. The phase of neurological disturbances ran its course with signs of meningo-encephalitis. The monkeys showed marked cerebellar disturbances (uncoordinated movements, ataxy) and hemipareses and paralyses of a central origin.

4. The virus is present in the blood up to the 12th day of illness, maximally between the 4th and 7th day. In the brain it is observable for 14 days with a maximal occurrence from the 9th to the 14th day.

5. Anti-hemagglutinins appear in the blood during the first days of illness and show titers of up to 1:160.
(From the Omsk SRI of Infectious Diseases with Natural Foci and the Department of Nervous Diseases of the Novosibirsk MI.)

An examination of 151 blood specimens from 49 patients led to the following conclusions:

1. Differences were detected in the dynamics of the accumulation of virus-neutralizing antibodies in relation to the various clinical forms of tick-borne encephalitis in its acute stage.

2. The titer of the antibodies rose very rapidly and highly in the frustrane form of the disease, reaching often high levels already in the first week.

3. In patients with affections of the membranes and substance of the brain the antibody accumulation took place rather slowly, reaching only in the third week of illness titers of diagnostic significance.

4. In the case of a two-wave course of the disease usually the virus-neutralizing antibodies could be detected only during the second period of fever or even after it.

(From the Institute of Poliomyelitis and Virus Encephalitides, AMS, USSR.)

In the introduction to this article the authors state that convalescent serum had been successfully used for the treatment of Omsk hemorrhagic fever (Akhrem-Akhremovich, Tez. doklad. 4-i nauchn. sessii Inst. Nevrologii AMN SSSR, posviashch. probleme kraevoj infekts. patologii [Abstracts of Papers at the 4th Scientific Session of the Institute of Neurology, AMS, USSR, Devoted to the Problem of the Pathology of Regional Infections, 1949]), but that no further studies on the serotherapy of this disease had been made. In the course of recent studies the authors were able to produce in horses an anti-encephalitis serum, the gamma-globulin of which proved effective under experimental conditions. In the present paper they record satisfactory results in the treatment of mice and monkeys infected with
hemorrhagic fever with the gamma-globulin of a serum which had been obtained from horses hyperimmunized simultaneously against tick-borne encephalitis and Omsk hemorrhagic fever.

185. Segal, L. S. et al., Materials to the characterization of the focus of tick-borne encephalitis in Trans-Carpathia. (Annotation.) *Vop. virus.* 8 (1963) 2: 245.

(From the Uzhgorod Institute of Epidemiology, Microbiology and Hygiene and the Sanitary-Epidemiological Station of the Trans-Carpathian Oblast.)

As stated in this brief note, 63 attacks of tick-borne encephalitis have been recorded in the Trans-Carpathian Oblast during the period from 1947-1960, infection being mainly due to the consumption of raw goat milk. Vaccination of the consumers of such milk against tick-borne encephalitis is recommended.

(From the Khabarovsk SRI of Epidemiology and Microbiology.)

* There is evidence that this distinguished scientist died recently.
Since alimentary infections are responsible in the Khabarovsk Krai for severe attacks of tick-borne encephalitis with a high mortality, the author of this note studied this problem with the aid of experiments on two goats. One of these animals, infected intramuscularly and subcutaneously, showed the virus in its blood and milk and both animals showed serological evidence of the infection.

Alimentary infection of white mice with sublethal doses of the virus did not cause illness but led to the appearance of antibodies in the blood.

Because of these findings the author expresses belief in the importance of the alimentary mode of infection in tick-borne encephalitis.

(From the Moscow I. I. Mechnikov SRI of Vaccines and Sera.)

This brief note, wherein the author records data on the action of various disinfecting agents on the smallpox, vaccinia and alastrim viruses, does not lend itself to a condensation.

Q-fever

Tularemia

Insect repellents

(From the Central-Asian SR Anti-Plague Institute.)

The aim of the author of this article was to study the peculiarities of the development of streptomycin resistance in various (9) plague strains serially subcultivated on Hottinger's digest agar with a successively increased content (up to 1,000 units per ml) of this antibiotic. The conclusions reached through these observations, for the details of which the original or a translation must be consulted, were that

1. According to the character of their reaction to the presence of streptomycin in the nutrient media one may distinguish 4 types of plague strains: sensitive; weakly resistant; highly resistant and streptomycin-dependent; and highly resistant and not dependent strains.

2. The dynamics of the development of the streptomycin resistance of the various plague strains in the course of serial subcultivation on agar with a successively increased
streptomycin content may show substantial peculiarities. Schematically one may distinguish three types of adaptation of the bacterial populations to streptomycin: 1) Full type: Sensitive \( \rightarrow \) weakly resistant \( \rightarrow \) highly resistant and streptomycin dependent; 2) Transitory type: Sensitive - weakly resistant \( \rightarrow \) highly resistant and not dependent; and 3) Reduced type: Sensitive \( \rightarrow \) highly resistant and independent form.

It is important to note from the text that all strains found to fall into the second or third categories (transitory or reduced types) differed from the classical type of \( P. \) pestis by the fermentation of rhamnose or the loss of virulence. In the author's opinion these two types of adaptation to streptomycin were indicative of a "saprophytization" of the organisms.

The author admitted that in view of the limited number of strains examined his results might not be universally valid.

(From the Aparansk Raion Hospital.)

In this brief note the author records the results of alternate administrations of the blood of persons who had recovered from brucellosis and of brucellosis vaccine to 70 patients suffering from this disease. At an average each of the sufferers was given five blood transfusions and four vaccine injections. Clinical recovery was observed in 40% of the patients, considerable improvement also in 40%, some improvement in 17% and slight improvement in 2.9%. Relapses were observed in 10 instances.

The author recommends his method of treatment.

(From the Moscow SRI of Virus Preparations.)

For their study the authors administered to white mice intracerebrally 0.03 ml amounts of horse serum containing antibodies against tick-borne encephalitis and after 24 hours
Infected groups of the animals intraperitoneally with (a) RNA prepared from the tick-borne encephalitis strain Pan and (b) native virus. Mice preliminarily treated with normal horse serum served as controls.

To illustrate the results of their experiments, the authors stated that in one of their typical tests the administration of 3 lg LD50/ml of the native virus or of 3.5 lg LD50/ml of its RNA caused not a single instance of illness among groups of 10 mice each, which had been injected with the immune serum. There were 4 instances of illness each in the corresponding control groups which had been preliminarily treated with normal horse serum. The incubation period was 8-9 days when RNA was used and 7 days after infection with the intact virus.

The authors postulated that the appearance of illness in the mice injected with RNA was due to the development of the complete virus at the site of inoculation. The above mentioned differences in the length of the incubation period supported this view.

(From the D. I. Ivanovskii Institute of Virusology, AMS, USSR, Moscow.)

The concluding sentence of this article, the contents of which do not lend themselves to the purpose of a brief review, is that

"The data recorded in this as well as in our preceding publication (see Vop. virus. 8 [1963] 2: 3) show that the vaccinal interferon differs from the inactivated vaccinia virus which is also endowed with inhibitory properties."

193. Chumakov, M. P. et al., Comparative study of the epidemiological efficacy of tissue cultures and brain vaccines against tick-borne encephalitis. Vop. virus. 8 (1963) 3:307-315. (From the Institute of Poliomyelitis and Virus Encephalitides, AMS, USSR, Moscow and the Sanitary-Epidemiological Station of the Kemerovsk Oblast.)

The conclusions reached in this well documented article were that
1. In 1961-1962, in the course of epidemiological studies in the Kemerovsk Oblast, investigations were made on the epidemiological efficacy of inoculations with the tissue-culture and brain vaccines against tick-borne encephalitis.

2. In 1961, when the risk of infection was lowered, a 22-35-fold decrease of the morbidity was noted among the persons immunized with the culture vaccine and only a 1.7-3.6-fold decrease among those protected with the brain vaccine.

3. In 1962, when there was an increased risk of infection, one could observe a 2.5-4.3-fold lowering of the morbidity in the persons protected with the culture vaccine and a 10-15-fold decrease after re-vaccination. The corresponding figures in the persons inoculated with the brain vaccine were 1.3 and 1.9-2.8.

One could note a disappearance of the paralytic form of tick-borne encephalitis and a 2.3-fold decrease of attacks of the meningeal form of the disease. The vaccinations exerted only an inconsiderable influence on the frequency of febrile cases.

4. The adsorbed culture vaccine possesses a marked epidemiological efficacy, surpassing that of the brain vaccine. Still, in order to produce a solid immunological transformation of the body it is indispensable to administer at the onset of the epidemic season besides an initial course of vaccination also re-vaccinations. The optimal time for the administration of the latter has still to be determined.

5. Prospects are good for the large-scale practical use of the cultural adsorbed vaccine against tick-borne encephalitis.

194. L'vov, D. K. and Zaklinskaia, V. A., Use of the hemagglutination inhibition test for investigations of the immunogenic properties of formolized vaccines against tick-borne encephalitis. Vop. virus. 8 (1963) 3:360-361. (From the Institute of Poliomyelitis and Virus Encephalitides, AMS, USSR.)

The authors conclude their article by stating that the hemagglutination inhibition test proved useful for the purpose mentioned in the title in animal experiments as well as for observations on human beings immunized against tick-borne encephalitis.
195. Chervonskii, V. I., An instance of familial infection with orni-
thosis. Vop. virus. 8 (1963): 369. Annotation. (From the D. I. Ivanovskii Institute of Virusology, ANS, USSR, Moscow.)

201. Likhonos, A. N., Experience of the fight against brucellosis in the Stavropol' Krai. Zh. mikrobiol. 40 (1963) 6: 3-8. (From the Sanitary-Epidemiological Station of the Stavropol' Krai.)

The author ascribes the marked reduction of the brucellosis incidence in the Stavropol' Krai since 1957 to the implementation of the following program of measures: (a) Complex anti-brucellosis operations in all farms, regardless whether or not their sheep were infected, undertaken in close cooperation by the medical and veterinary staff and supported by the Soviet and party organs; (b) Closing of the isolation stations for brucella-affected sheep; (c) Improvement of the brucellosis diagnosis in the sheep, immediate slaughter of all animals found infected and anti-brucellosis vaccination of the herds; (d) Mass vaccination of the rural human population.

(From the SR Anti-Plague Institute, Rostov/Don.)

In the opinion of the author of this article the administration of the usual anti-brucellosis vaccines for the prevention of cattle-type brucellosis is not only useless but even harmful because inducing a sensibilization (pathergic state) of the body of the vaccinated persons. He recorded in this connection that, while during the periods from 1958-1960 in the Ukraine (where mass anti-brucellosis vaccinations were administered) the number of brucellosis foci of all types continuously decreased, at the same time the incidence of human brucellosis infections contracted from the cattle incessantly rose. He postulated that

"Without any doubt a part of these attacks were connected not only with an infection from the brucellosis-affected cows but also with prior or subsequent vaccinations and re-vaccinations of the people with live brucellosis vaccine."
It appeared necessary under these conditions to use general sanitary measures for the fight against cattle-type brucellosis.

The conclusions reached by the author of this well documented article were that

1. Tularemia attacks were recorded in the Arkhangelsk Oblast from 1949 to 1959 (the total case incidence amounting to 1,245). This confirms the existence of natural foci of the infection.

2. The tularemia foci in the oblast are mainly of the floodland-marsh type and in correspondence with this the outbreaks are mostly vector-borne.

3. The outbreaks in the Krasnoborsk and Verkhne-Toemsk raions in 1957 (84 and 104 cases respectively) were vector-borne and occurred from July to September in the floodlands of the rivers and rivulets. 98% of the attacks were of the ulcero-bubonic type.

4. Notwithstanding the presence of natural tularemia foci in the oblast the occurrence of the disease in man could be cut short through timely conducted vaccination campaigns. It is indispensable, however, to implement at the same time other measures, such as regularly organized hunting of the water-rats, musk-rats and hares and a systematic fight against the blood-sucking arthropods and diptera.

The two authors summarized the results of their carefully made observations by stating that

1. The phasic variants of R. burneti, due to the adaptation of the organisms either to the yolk sacs of chick embryos or to the body of laboratory animals differ not only
in regard to their serological activity but also immunogenically. The strains in the first phase proved to be more immunogenic than those in the second phase (i.e., adapted to the yolk sacs of chick embryos); if used for the infection or immunization of experimental animals they produced "early" and "late" antibodies.

2. During adaptation to chick embryos the immunogenic activity of the R. burnetii strains decreased. If guinea-pigs were infected with strains in the second phase, mainly "early" antigens were produced, the "late" antigens becoming present only at very low titers; the latter antibodies did not at all appear after immunization.

3. During adaptation to the yolk sacs of chick embryos apparently the change of the serological activity of the R. burnetii strains took place more rapidly than that of the immunogenicity. Strains, the antigens of which did not react any more with immune sera of the early stages after infection, were still capable of producing "late" antibodies in infected or immunized laboratory animals. The strains lost the ability of producing these antibodies only after numerous passages through chick embryos.

4. Guinea-pigs immunized with the antigen of rickettsiae in the first phase (and thus possessing "early" and "late" antibodies) proved more resistant to challenge than the animals immunized with the antigen of Phase II rickettsiae.

5. In skin tests on rabbits and in neutralization tests in mice no difference could be found between immune sera containing both "early" and "late" antibodies or solely the former.

6. Because of this evidence it is advisable to manufacture Q-fever vaccines with R. burnetii strains in the first phase.

The conclusions reached by the author of this amply documented study were that
"1. An indispensable prerequisite for the development of an active immunity following aerosol vaccination is the interaction between the vaccine and lymphoid tissue of the respiratory system.

2. The penetration of the vaccinal cells into the lymphatic system from the upper respiratory passages takes place through the capillaries of the lymphatic system of the mucosa and the lymphoid agglomeration of the throat which are best developed in man and in the highest animals.

3. The penetration of the live cells of the vaccine into the lymphoid tissue takes place on account of the resorptive function of the lymphatic capillaries as a whole, the barrier-creating properties of the lymph nodes and the phagocytic activity of the macrophages, which transport all foreign materials from the lung parenchyma into the lymphatic system."

The investigations of the authors, the technical details of which must be studied in the original or in a translation, led to the conclusion that treatment of the vaccinal detritus with penicillin for the purpose of freeing it from the contaminating microflora did not exert an adverse influence on the period of potency of the smallpox vaccine.

207. Taran, I. F. et al., Characterization of the immunity following cutaneous inoculation and re-vaccination with a vaccine prepared from the Brucella abortus strain 104-M. Zh. mikrobiol. 40 (1963) 6: 128. Authors' summary. (From the SR Anti-Plague Institute of the Caucasus and Transcaucasia.)

The authors of this note concluded from their observations that

"the immunity against brucellosis is most of all of a barrier-creating character and able to inhibit only small doses of the infectious agent immediately after their introduction. Even after the optimal intervals (6 and 9 months) the
intensity of the immunity remains relative. Thus, though the vaccinal strain Br. abortus 104-M proved to be more immunogenic than the Br. abortus 19 vaccine, its use does not finally solve the problem of the specific prophylaxis against brucellosis."

208. Tav'ev, B. M. and Malysheva, M. N., Some epidemiological peculiarities of an anthrax outbreak in one of the sovkhozes of the Saratov Oblast. Zh. mikrobiol. 40 (1963) 6: 129. Authors' summary. (From the Saratov Oblast Department of Public Health and the Sanitary-Epidemiological Station of the Oblast.)

One of the peculiar features of this anthrax outbreak was that only one out of the affected persons was in direct contact with domestic animals, whereas the other four came in contact only with the meat of a sheep (?) which had succumbed to anthrax. 375 persons who ate food prepared from the meat of animals slaughtered because of illness (Notschlachtung) remained healthy. The diagnosis was confirmed through microscopic and cultural examinations and tests on the affected animals, while tests with anthraxin, made 24-38 hours after onset of the disease on the patients, invariably gave a negative result.

According to the authors,

"Important factors conditioning the appearance of the disease in man were the absence of regular vaccination of the domestic animals against anthrax, insufficient attention paid by the veterinary workers to deaths among the sheep and goats (summarily called "small horned cattle" in Russian) and the late use of bacteriological methods."

The authors made proposals for an improvement of this state of affairs, emphasizing the need for the use of bacteriological examinations in addition to the anthraxin test.

As described by the author of this note, 488 samples of cow milk offered for sale on the Novokuznetsk markets were
tested in 1960-1961 for the presence of brucellosis infection. Three methods were used for this purpose - agglutination tests with the whole milk and with its serum, and ring precipitation tests with colored antigen. Positive results with at least one of these tests were obtained in 48 instances (9.8%), doubtful results in 22 instances (4.5%). Uniform results with all three tests were obtained in 86.7%.

The author pointed out, however, that in Novokuznetsk during the period of these tests (1960-1961) there occurred only one case of recent brucellosis infection possibly due to the consumption of raw marketed milk.

210. Martsupol'skii, B. R., To the problem of the liquidation of infections. (To the statement of Sh. D. Moshkovskii. [See Abstract No. 675].) Zh. mikrobiol. 40 (1963) 6:135-136. (From the Sanitary-Epidemiological Station of the Alma-Ata Section I of the Kazakh R.)

211. Drankin, D. I. et al., To the liquidation of infectious diseases. Zh. mikrobiol. 40 (1963) 6:136-140. (From the Novokuznetsk Institute for ATP.)

The general idea of both these articles, the contents of which do not lend themselves to the purpose of a brief analysis, is expressed by the concluding statement of Martsupol'skii to the effect that

"one can speak of the liquidation of an infection only in the case of a destruction of its causative agent as a biological species in the whole world. It is not permissible today to announce the liquidation of an infection and tomorrow to begin again with its liquidation or to continue prophylactic measures against it. At present we can speak only of the prevention of the manifestation of some infectious diseases and the decrease of the morbidity due to other infections."

This exhaustive and on the whole favorable review can be quoted by title only.
213. Kiseleva, V. M. et al., Isolation of brucellae from the eyes of guinea-pigs after extra-ocular infection. Zh. mikrobiol. 40 (1963) 7:120-125. (From the Kazakh MI, the Central-Asiatic Anti-Plague Institute and the Kazakh SR Veterinary Institute.)

The authors summarized the result of their observations by stating that

1. The frequency of the isolation of brucella cultures from the tissues and fluids of the eye of guinea-pigs one month after subcutaneous infection with virulent strains depends not only upon the infection quantum but also upon the individual properties of the test animals. Still, even if minimal doses of a virulent strain are used, it may be possible to obtain positive cultures from the eyes of all or almost all animals under test.

2. A bacteriological examination of the conjunctival secretions deserves to be widely used for the laboratory diagnosis of brucellosis in man and animals during the early stages of the infection.

3. The period during which brucellae may be cultivated from the tissues and fluids of the eye after subcutaneous infection are not long and stand in relation to the infection quantum and the individual peculiarities of the test animals.

4. In the case of experimentally produced endogenous brucellosis affections of the type of kerato-iridocyclitis it is possible to isolate the brucellae with the aid of cultural methods or animal experiments; chances of obtaining positive results decrease hand in hand with a prolongation of the interval between infection and the onset of the inflammatory process in the eye.

5. Subcutaneous vaccination with brucellae of the strain Br. abortus bovis 19 ensures better results in regard to the appearance and length of a resistance of the eye tissues to an invasion of brucellae than vaccination by the enteral or intranasal routes.

The author concluded from an examination of 10 inagglutinable cultures of Br. melitensis that

1. These cultures proved typical as far as their morphological and cultural properties and the ability to reduce aniline dyes were concerned. Distinguishing features were the presence of signs of dissociation and loss of the agglutinability with specific anti-brucellosis serum. In these respects they were identical with the growths described by Drozhevkina (Zh. mikrobiol. 1954, 5: 24) as V-cultures.

2. The inagglutinable cultures were to a varying degree less virulent than the agglutinable growths. Some of the inagglutinable strains under test possessed a higher degree of residual virulence due to the presence of a small percentage of not dissociated agglutinable organisms.

3. In contrast to the opinion of Drozhevkina the author postulated that the inagglutinable brucella strains are merely cultures in a state of dissociation with a lowered virulence, a changed antigenic structure and weak antigenic properties.

4. For the identification of such freshly isolated brucella cultures the use of corresponding agglutinating sera is advisable.

In this paper, the technical details of which must be studied in the original or in an adequate translation, the author describes a method of determining the influence of various antibiotics by the observation of the differences of growth of the organisms in tissue cultures made from chick embryo fibroblasts to which these therapeutic agents have added and in control tubes free of them. The antibiotics were found to impede the multiplication of the rickettsiae in the cytoplasm of the fibroblasts, and to reduce the number of cells attacked by the organisms as well as the cytopathogenic activity of the latter.

216. Fedorov, IU. V., The influence of antibiotics on the production of specific antibodies in experimental tick-borne encephalitis. Antibiotiki 8 (1963) 6:520-524. (From the Tomsk SRI for Vaccines and Sera.)
The conclusions reached in this study were that

1. The administration of penicillin or streptomycin in therapeutic doses simultaneously with the immunization of rabbits with the virus of tick-borne encephalitis leads to a stimulation of the virus-neutralizing antibodies during the first cycle of immunization and to an inhibition of the immunogenesis in the subsequent cycles, which was more marked in the case of streptomycin.

2. The administration of small penicillin doses exerts no influence on the increase of the virus-neutralizing activity of the serum. If streptomycin is used in the same manner, one observes a marked increase of the virus-neutralizing activity in the first cycle and an inhibition of this activity in the following cycles.

3. Streptomycin exerts a marked stimulating action on the production of antibodies inhibiting hemagglutination in the first cycle of immunization and in the subsequent cycles a profound inhibition of the formation of these antibodies. The administration of penicillin leads to a clearly marked process of inhibition of the antibodies in question.

4. The administration of penicillin at the acme of immunogenesis exerts no influence on the production of specific antibodies. Under the same circumstances streptomycin administration inhibits the formation of hemagglutination-inhibiting antibodies.

(From the Antibiotics Laboratory of the All-Soviet Institute of Experimental Veterinary Medicine.)

Studies on 93 epizootic and on two vaccineal pasteurella strains showed that all these organisms were highly sensitive to monomycin, colimycin, mycerin, neomycin, polymixin M, oleandomycin, penicillin, chiorotetracycline and oxytetracycline. No difference existed in this respect between freshly isolated and museum strains.

Monomycin, colimycin, mycerin, neomycin, polymixin M, bicillin 1 and 3, oxytetracycline and dihydrostreptomycin proved therapeutically effective in white mice experimentally infected with pasteurellae.
It would seem advisable to use monomyein, polymixin M, bicillin-3 and dibiomycin tentatively for the treatment and prophylaxis of pasteurellosis in domestic mammals and birds.

The results of this study, based upon observations from an airplane do not lend themselves to the purpose of a brief review.

(From the Institute of Biology of the Karelian Branch, AS, USSR.)

The main conclusions of the author were that
1. In southern Karelia there exists an endemic focus of tick-borne encephalitis, situated in the central sub-zone of the taiga zone.

2. Tick-borne encephalitis occurs in the focus in a mosaic-like manner, due to a number of factors which strictly delimit the distribution and multiplication of the tick-vectors of the infection.

3. A marked influence is exerted on the internal structure of the focus by the peculiarities of the distribution of the tick species I. ricinus and I. persulcatus.

4. Out of the two types of tick-borne encephalitis met with in Karelia the two-wave form is met with in the raions of the occurrence of Ixodes ricinus, i.e. in the southwestern part of the area, the spring-summer type in its northeastern part, were I. persulcatus abounds. Both types of the disease occur in the central part of the focus.

(From the Department of Diseases with Natural Foci of the Gamaleia IEM, AMS, USSR.)

The results of this ecological study cannot be briefly summarized.

(From the Tomsk SRI for Vaccines and Sera.)

The observations of the authors showed that the incidence of tick-borne encephalitis in the population of towns situated within natural foci of this infection can be considerably reduced by dusting a belt 6-8 km wide round the settlements from airplanes with DDT.

(From the Central SR Disinfection Institute.)
The conclusions, which alone can be quoted here, reached in this well documented article were that

1. An analysis of the observations made during many years in natural foci of tick-borne encephalitis led to the detection of signs, with whose aid it is possible to forecast the epizootological and epidemiological situation in these localities.

2. The seriousness of the epizootological situation in the foci changes from year to year and is mainly determined by oscillations of the frequency of the small forest-inhabiting mammals, the principal hosts of the early developmental phases of the ticks. Most dangerous are the years of migration of the animals. During the two seasons following such years one observes an increase in the frequency and infection-rate of the ticks, factors which may lead to an increased incidence of the disease in man.

The authors stated inter alia that

"Recently considerable attention was paid to the problem of a possible role of argaside ticks in the epizootology of plague. T. A. Burlachenko (1957 - see Trudy Trukmenskoi protivochumnoi stantsii 1 [1958], p. 171) established that in some specimens of Alectorobius tartakovskyi plague bacilli may remain alive for 171 days, whereas most ticks of this species become free from these organisms during the first month. The author postulated that these ticks were of importance for the spread of the infection only during the acute phase of the epizootics.

In April 1956 a plague culture was isolated for the first time in Azerbaidzhan from Alectorobius alactagalas (I. A. Murvatov, Trudy Azerb. protivochumnoi stantsii, Installment 1 [1956] p. 250). The ticks were collected from the burrows of red-tailed gerbils within a territory with epizootics."
The authors stated, however, in the conclusion to their article that no further observations in point had been made.

(From the Toxicological Laboratory of the All-Soviet SR Institute of Chemical Substances for Plant Protection.)

This report can be quoted by title only.

(From the Tula and Suvorov Sanitary-Epidemiological Stations.)

This brief note refers to a familial outbreak of tick-borne encephalitis due presumably to the abundance of *Ixodes ricinus*. The diagnosis was confirmed through examination of the sera of the patients.

This well illustrated article can be quoted only by title.

Balabkin, A. K. et al., The natural plague focus in the Gorny Altai. Pp. 3-5.

Most numerous among the 12 rodent species met with in the Gorny Altai area are the Altai marmot, the long-tailed suslik (sisel), Ochotona mongolica and Microtus gregalis. The area inhabited by the first mentioned rodent is over 400,000 hectares large, and up to 210-230 of its burrows may be present per square kilometer. Most noteworthy among the 32 flea species met with in the region are the following:

<table>
<thead>
<tr>

</tbody>
</table>

Twelve of the flea species have been found plague-infected and some of them were found capable to act as vectors of the infection (see Rall, 1960; Zhovtyi and Emel'ianova, 1959; Vasil'ev and Gorbacheva, 1961).

During an epizootic observed in June 1961 and 2 localities 8 km southwest of the town Tashanty, Kosh-Agachskii Raion, plague bacilli could be isolated from Ochotona mongolica, the long-tailed suslik and the steppe polecat as well as from the fleas A. primaris; Ch. homoeus (both collected from steppe polecat); P. skorodumovii; A. runatus and Frontopsylla hetera collected from C. mongolica.

While typical in all other respects these plague strains were found capable of fermenting rhamnose within 1-2 days.

* Found for the first time plague-infected in the Soviet Union.
Though in the opinion of the authors this plague focus had been in existence for a long time, its earlier detection was impeded by the slow development of the epizootics, their limitation to circumscribed areas and also on account of insufficient observations. Human plague manifestations remained absent because the area, used as pasture ground for the cattle in winter, is entered by man only at the time when the rodents are hibernating.

As the authors postulated, the marmots formed the main reservoir of the infection. The absence of positive findings in them was due to limited possibilities for their examination.

References

In a previous paper, entitle "On the isolation of plague cultures from trapped rodents," published in Installment 1 of the Doklady (1961) the author had shown that positive results could be obtained most often when suspensions of the internal organs and lymph nodes of the animals were used for cultivation. In the present paper she deals with analogous observations in white mice and guinea-pigs which had been experimentally infected with the weakly virulent plague cultures recently isolated in Transbaikalia.

The author used for this purpose subcultures of the strains 420, 580, 798, 263 and 803, which were subcutaneously injected into the test animals in sub-lethal doses ranging from 10,000 to 100,000 organisms. The animals were killed with chloroform 2-10 days after infection and cultivation were made from them by (1) Impressing their cut organs on the plates and distributing the material with the aid of a loop; (2) Rubbing the organs and lymph nodes on the plates; and (3) Using suspensions from their organs and lymph nodes for the insemination of the plates.
Examining materials from 178 white mice and 71 guinea-pigs, the author obtained the following results (total of positive cultivations 41.3%):

<table>
<thead>
<tr>

</table>

In rare cases the cultivations made with the suspensions of the organs and lymph nodes gave a negative results while those made from the para-aortal lymph nodes or the spleen or liver proved positive.

For practical purposes the author recommended to use for the examination of each specimen two plates, one of which served for making cultures from the suspensions of the organs and lymph nodes, while separate sectors of the other were implanted with material from (a) the para-aortal and groin lymph nodes; (b) the liver; (c) the spleen.

Contrary to the generally accepted opinion, but in agreement with the opinion of Tumanskii (Mikrobiologii chumy, 1958), the authors found that plague and pseudotuberculosis bacilli were capable of producing hydrogen sulfide if cultivated either in Hottinger's broth (pH 7.2) with an amino-acid concentration of 150 mg %, prepared from hydrolysates with a profound cleavage of the protein molecules (60-70%), or in broth containing 0.1% cysteine.

As pointed out in the introduction to this brief note, diametrically different opinions are held by various observers regarding the degree of the susceptibility of the rodent hosts favorable for the persistence of plague in a given area. While some writers consider a high susceptibility of the rodents as indispensable for the perpetuation of the infection, others maintain that plague can persist only in species more or less resistant to it. The latter view was recently propounded by N. F. Nekipelov (1959) who, studying the plague susceptibility of the various rodent species in Mongolia and Transbaikalia, came to the conclusion that the infection can be perpetuated only by species which are 10-10,000 times more resistant to it than the guinea-pigs.

The present author insisted with much reason that one must distinguish in this respect between hibernating and non-hibernating rodent species. Among the former a perpetuation of plague is possible in any case on account of the seasonal variations of their susceptibility to the infection. The increased resistance of the animals during the hibernation period leads to the occurrence of protracted forms of the disease which are apt to flare up into a generalized type of infection when the animals awake in spring.

Dealing recently with the perpetuation of plague in non-hibernating rodents, L. S. Mala'eeva (1960) postulated that susceptible and not susceptible individuals coexist within one and the same rodent species, the former being capable of carrying over the infection while the latter form the fuel for the appearance of epizooties. Baltazard (1959, 1960) on the contrary was of the opinion that such different roles were played not by individual rodents but by different species. In the opinion of Aparin both these mechanisms might be at work. The possible role of the rodent fleas in the perpetuation of plague should not be disregarded.

As Aparin finally pointed out, it was most necessary to evaluate the possible importance of the weakly virulent plague strains recently isolated in the Soviet Union under natural conditions for the perpetuation of the infection. He quoted in this connection an article by Kraminskii and Domaradskii populations only plague strains producing non-fatal infections were capable of survival.

(Regrettably no reference list is attached to this article.)

Selected Abstracts-II/189

This important article must be studied in the original or in a full translation.

In order to study the length of survival of plague bacilli on the detached skins of wild rodents, the author subcutaneously infected 54 marmots and 176 susliks (sisels) with *P. pestis* and kept the detached skins of those of the animals which succumbed to a generalized infection in a box. At various intervals of time material from the inner side of the skins was cut off, minced and triturated and then used for the subcutaneous infection of guinea-pigs. It was found that under these circumstances the plague bacilli could survive for periods of up to 20 days.

In view of these findings the author stressed the necessity of disinfecting as well disinsecting the skins of wild rodents obtained from plague foci.

The authors found that dry nutrient media, for the preparation of which brief directions are given, were fully suitable for field work.

In order to prove the innocuousness of the conjunctival method of plague vaccination and that of a combined immunization by the conjunctival and subcutaneous routes, the authors first used the former method on over 1,000 guinea-pigs. Moreover the senior author several times during a period of two years instilled the live EV vaccine in doses of 1, 1.5 or 4 billion organisms into his eye. This procedure led to the appearance of a slight cold in the head 4 hours after the vaccination, then after 9 hours to slight itching in the eyes. Both these signs disappeared within one day. 12 hours after the immunization a slight conjunctivitis became manifest which lasted for two days. A slight cough, lasting for the same length of time, appeared at the end of the first day after the vaccination.
Under these circumstances it seemed justified to use the method of conjunctival vaccination against plague first in a group of volunteers and then in 791 hunters and their families living in plague-enzootic raions. The dose for adults was 1.5 billion organisms; children under 10 years received one quarter of this, those from 11-16 half an adult dose. The reactions following the vaccination were analogous to those described above.

The method of combined conjunctival and subcutaneous vaccination was also first tried in guinea-pigs which received 1.5 billion doses of the EV strain by each of these routes. A part of the immunized animals was challenged by the intratracheal route with 10 to 250 DLM of a virulent plague strain—apparently with good success. After further tests on volunteers 1.5 billion doses each were used to immunize 9,927 persons living in plague-enzootic foci with acute manifestations of the infection in the tarabagans simultaneously by the conjunctival and subcutaneous routes. 7,371 of these immunized persons showed a slight rise of the body temperature, 352 slight fever, 4,875 slight conjunctivitis and 5,070 slight cough.

At the end of their article the authors briefly stated that

"In the persons vaccinated conjunctivally or by the combined method one could note a higher epidemiological efficacy than in those immunized only by the subcutaneous route."

The authors suggested that practical use ought to be made of their methods of vaccination at times when acute epizootics were present in the plague foci.

The strain dealt with in this paper had been isolated from the eighth victim of a small pneumonic outbreak (total 10 cases) occurring in 1948 in the Uburkhangaiskii Aimak (district) of the Mongolian People's Republic. Its DLM, equalling 10 organisms, remained unchanged after passages through guinea-pigs.

As discussed already in a previous review (see Abstract No. 164), Smirnov used this strain to test the immunity engendered in him through combined vaccination by the conjunctival and subcutaneous routes. As has been described, he had a slight attack of bubonic plague. The plague cultures which could be isolated only from the ulcer developing at the site of infection, possessed the same virulence as the strain used for challenge.
Domaradskii, I. V. et al., Correlation between the fibrinolytic activity of *P. pestis* and its ability to coagulate plasma. Pp. 27-29.

As has been recorded by several authors (Madison, 1936; Kwashina, 1941; Domaradskii and IAromiuk, 1960; IAromiuk, 1961), *P. pestis* is capable of lysing the fibrin of human and animal blood. On the other hand Jawetz and Meyer (1944) found this organism able to coagulate the plasma of rabbits and analogous results were obtained with human plasma by Eisler (1961).

Inasmuch as both these activities were directed against the same substratum, the present authors explored whether a correlation existed between them. At the same time they wished to establish whether the pseudotuberculosis bacillus, which showed no fibrinolytic activity, could coagulate plasma.

For their tests with plasma the authors used suspensions of *P. pestis* strains grown for 48 hours at 28°C and pseudotuberculosis strains grown at the same temperature and at 37°C. 0.1 ml amounts of the suspensions were placed into small test tubes and 0.5 ml amounts of rabbit, human or guinea-pig plasma were added. The tubes were incubated at 37°C and kept under observation for 48 hours. Control tests were made with plasma alone and with a *Staph. aureus* strain known to give positive reactions.

Lyophilized cattle fibronogen was used as substratum for the fibrinolysis tests made according to the method of IAromiuk and Vasiukhina (1962), in regard to which the authors gave neither details nor a reference.

While 116 plague strains which produced fibrinolysis were invariably also capable of coagulating rabbit plasma, all not fibrinolytic strains of *P. pestis* (57) gave a negative result in the latter respect as well. Only 25 of the fibrinolytic strains gave a positive result with human plasma and 27 with guinea-pig plasma.

In agreement with the statements of Jawetz and Meyer and of Eisler no correlation could be found between the capability of the strains to coagulate plasma and their virulence.

Since all 58 pseudotuberculosis strains tested failed to coagulate plasma, the authors thought that this feature might be useful for a differentiation of this bacterial species from *P. pestis*. 
Kolesnik, V. S. and Domaradskii, I. V., Sensitivity of white mice and white rats to the repeated administration of small doses of plague toxin. Pp. 29-35.

Though in all plague-susceptible animals signs of intoxication are conspicuous both clinically and at autopsy, it is known that many of the species concerned are little susceptible to the administration of plague toxin (Kratinov, 1957). So far it has not been possible to find an explanation for this discrepancy. V. V. Donskov (1944) postulated that the comparatively weak action of the plague toxin is overcompensated by its production in large amounts due to the intense multiplication of \textit{P. pestis} in the infected animals.

"Also," the author continued, "one might assume that the intense intoxication in plague, disproportionate to the power of the toxin, stands in relation to the development of the so-called 'paradoxal sensitivity' of the body, brought about according to some authors (Zdradovskii, 1950; Morgunov and Khatuntsev, 1954) by a 'summation of irritation' including such of a toxic-infectious nature."

For a study of this hypothesis the authors made a series of experiments in white mice and one experiment in white rats. They used for this purpose a plague toxin prepared from the vaccinal plague strain 1 according to the method of Baker and his associates, which as a rule was administered intravenously or subcutaneously in doses more or less near to the DL$_{50}$; sometimes doses near the DCL were used. To a second group of animals the same amounts of the toxin were administered in fractionate at intervals ranging from 30 minutes to 12 hours. For the purposes of comparison some series of white mice were intravenously injected with cholera toxin.

Summarizing the results of these tests, the authors stated that:

"An analysis of the findings made (see tables 1 and 2) shows a clear regularity in the case of the plague toxin: if this is used in fractionate doses, regardless of the mode of its administration and the intervals between its introduction, the mortality of the animals is considerably below that of the animals given the whole dose at once. The fractionate use of cholera toxin shows another type of regularity: if the intervals between the fractionate administrations are short
Selected Abstracts-II/193

(50 minutes), the mortality of the animals is considerably in excess of that caused by the administration of the whole toxin dose at one and the same time; on the contrary, if the intervals between the administrations of the fractionate doses are longer (3 hours), the mortality is considerably decreased, falling below that following the use of the whole toxin dose at one and the same time.

One may conclude from these findings that the test animals tolerate a fractionate administration of the plague toxin better than the administration of the whole dose at once; their mortality decreases hand in hand with a prolongation of the intervals between the introduction of the fractionate doses.

Thus the phenomenon of a 'paradoxal sensitivity,' found present by some observers in regard to some exotoxins (tetanus, diphtheria, botulismus) was not manifest in the case of the plague toxin under the conditions of our experiments.

This phenomenon could be observed in the case of the cholera toxin, but only as long as the intervals between the administrations of the fractionate doses were short. When these intervals were long, the cholera toxin acted in manner similar to that of the plague toxin.

The authors came to the conclusion that, as far as the results of the fractionate administration were concerned, the plague toxin and, to a lesser degree, also the cholera toxin behaved in a manner different from that of the exotoxins.

Kratinov, A. G., Comparative sensitivity of some rodent species to P. pestis and its toxin. Tezisy nauchii.

In the course of a study of the influence of the plague toxin on the aldolase activity of the serum and the liver of test animals the author found that the Fraction II of P. pestis, isolated according to the method of Baker et al. and used as toxin, exerted itself a marked aldolase activity. This was in accord with the findings of Srikatan et al. (1958). In view of these observations it seemed important to establish whether the toxicity of the Fraction II was related to the aldolase activity.

For this purpose the author worked with various fractions obtained from the plague strains 1, 17 and EV with the aid of Baker's method and also with such obtained through treatment of the organisms with urea (Domaradskii et al., 1961).

The aldolase activity was determined according to the method of Sibley and Lehninger (1909), as modified by Korzunova (1950). The LD₅₀ of the toxin was assessed in white mice with the aid of intraperitoneal injection.

Summarizing the results of the above outlines investigations, the author stated that

"the absence of an aldolase activity in extracts obtained through treatment with urea renders it possible to conclude that the toxic manifestations of P. pestis are not related to the aldolase activity."

Selected Abstracts-II/195

The author stated that

"In the present paper we studied the influence of the plague toxin (Fraction II of Baker) on the aldolase activity in the liver and blood serum in healthy white mice and guinea-pigs and in such intoxicated with the toxin. Together with this we studied the action of the toxin on the aldolase activity in the liver white mice in vitro. Inasmuch as preliminary investigations had established that the Fraction II, ordinarily used as toxin, has itself a marked aldolase activity, we used for the in vitro tests the water-soluble extract of P. pestis obtained through urea extraction (Domaradskii et al., 1961).

As our findings showed, one can observe in the liver and serum of white mice 17 hours after the administration of an LD50 dose of plague toxin an increase of the aldolase activity. The aldolase activity of the liver increases 70%, that of the serum 74%. It was not possible to establish an influence of the plague toxin on the aldolase activity in guinea-pigs. In vitro the toxic extract did not exert an action of the ferment."

References

For a study of the opsonic properties of the plasma white mice were used which had been vaccinated with 100 million doses of P. pestis vaccine. 25-30 days after the immunization the animals were decapitated and bled. Their blood was centrifuged for 30 minutes at 3,000 revolutions and the leucocytic layer was washed three times with normal saline before the cells were used for the tests. Leucocytes of not immunized animals were used for control tests.

The main conclusion reached by the author of this note, the contents of which do not lend themselves to the purposes of a brief analysis, was that in the process of immunogenesis a functional transformation of the neutrophiles takes place while the monocytes do not undergo a corresponding transformation.

Korobkova and Vlasova (1961) had shown a parallelism between the resistance of animals against plague and the degree of completeness of the phagocytic reaction. They studied the degree of this reaction according to the method of Berman and Slavskaina (1958, 1959) in white mice which had been immunized against plague 32-40 days previously. Then the animals were infected with plague and a comparison was made of the features of the phagocytic reaction in the animals which had withstood challenge and those which had succumbed at various intervals. It was found that most often the animals which manifested an incomplete phagocytic reaction succumbed.

On account of these findings the present author used the phagocytic reaction for a study of the efficacy of
Selected Abstracts-II/197

anti-plague vaccination in man. The completeness of the phagocytic reaction was determined in workers of the Irkutsk Anti-Plague Institute at different intervals after their immunization against plague, while never immunized students of Irkutsk University served as controls.

These observations showed that the changes in the phagocytic reactions taking place after plague immunization were identical in the mice and in man. In both on the 6th-17th day after vaccination a large percentage of leucocytes was found in which a multiplication of the microbes took place (incomplete phagocytic reaction). This reaction became complete on the 25th-30th day after immunization, but on the 60th day after vaccination and later again incomplete reactions were found. Since, in the opinion of the author, the presence of incomplete phagocytic reactions indicated a low level of immunity, he postulated that most likely the immunity conferred by the EV-NIEE plague vaccine was comparatively shortlived.

References

The contents of this brief note do not lend themselves to a further condensation.

Commenting upon their briefly described observations on white rats intraperitoneally injected with Baker's Fraction II, the authors stated that

"All these data - the drop of the blood pressure, hemoconcentration, decrease of the prothrombin index, the decrease of the number of leucocytes - indicate that under the influence of the
plague toxin there develops in the animals a shock similar to the anaphylactic, hemotransfusion, peptone and other shocks.

Evidently this shock develops as the result of a nervous-reflectory reaction, resulting from a disturbance of the fermentative systems of the body. Such a shock indicates an unspecific reaction of the body which may develop under the action of most different excessively strong irritants.

There is reason to assume that the specific reaction to the toxin is observed only during the early period (after infection); then on this reaction are superimposed disturbances of the hemodynamics and dystrophic changes, in which it is impossible to detect specific features of the action of the toxin on the body of the animals."

The authors of this article stated inter alia that

"In the plague foci, where the birds themselves do not act as carriers of the infection, they serve as feeders of the arthropod vectors of the infection, the fleas and ticks. On the birds of the Transbaikalian plague focus were found 12 species of fleas, among them 9 species of rodent fleas (Dubinin, 1949), including plague vectors like *Pulex irritans*, *O. silantiiewi*, *Nosopsyllus tesquorum sungarica*, *Am. runatus*, *F. luculenta luculenta*, *Am. primaris mitis*. Most often found on the birds is the tarabagan flea *O. silantiiewi*, considered as the main plague vector in Transbaikalia and Mongolia. From rodent fleas (*Neopsylla setosa*) collected from a black kite in Dagestan plague bacilli were isolated (Gusev, 1959). The possibility of a plague infection of rodents through bird fleas has been experimentally demonstrated. A proventricular plug formed in *F. frontalis* on the 16th-50th day, in *C. avicitelli* on the 7th-29th day. The blocked fleas survived for 3-6 days (Bibikova et al., 1956). The transport
Selected Abstracts-II/199

of suslik fleas by pigeons for distances of up to 10 km has been experimentally demonstrated (Shiranovich and Chumakova, 1961). However, it seems that an importation of fleas may take place over distances of up to 250 km (Gusev and Bednyi, 1960).

Also found on the birds of Transbaikalia were ticks of the species *Ixodes crenulatus* (Dubinin, 1948), a tick repeatedly found plague-infected (Emel'ianova, 1959), and of the species *Dermacentos nuttalli*.

(No list of references is included.)

As stated by the author, owing to the gradual extinction of the tarabagans in Western Mongolia, during recent years the long-tailed susliks (*Citellus undulatus*) had gained in importance as a plague reservoir. Further studies of this species and of the methods of fighting it are therefore indispensable.

252. Ol'kova, N. V., Ecological peculiarities of the long-tailed susliks and their relation to the epidemiological and economical importance of this species. Pp. 120-127.

Referring in this well documented study to the subject of plague, the author stressed that the susceptibility of the long-tailed suslik to this infection is subject to marked seasonal variations, highest in spring and summer, when acute forms of the disease are frequent, and becoming low in autumn, during which protracted infections, terminating in recovery, prevail. In the opinion of the author the seasonal changes in the plague susceptibility of the long-tailed suslik are due to the interaction of many ecological-physiological factors, most important among which are the state of nutrition, the body temperature and the degree of excitability of the nervous system.

The author added, without giving details or an exact reference, that four plague outbreaks due to contact with the long-tailed susliks had been recorded by Smirnov (1961) in the Mongolian People's Republic.

The author postulates that observations on the size of the individuals composing a species of wild-living animals are of practical importance because, as shown by Ol'kova for instance (see Abstract No. 252), unfavorable environmental conditions render the animals susceptible to infections and, on the other hand, favorable environmental conditions lead to an increase of the size of the individuals.

Discussing their results, the authors stated that

"All data recorded above show quite convincingly that the fleas live on the body of the rodents under special microclimatic conditions and are not under the influence of the temperature of the not immediate parts of the extrinsic air. The temperature of the layer of the extrinsic air immediately above the ground is of importance for the fleas only if they leave their host outside its burrow. Under natural conditions only an insignificant part of the flea population lives away from the latter or from the body of the host, literally only single specimens."

The authors conclude their article, the details of which do not lend themselves to the purpose of a brief review, by stating that

"We could never observe that the rodents searched for fleas away from their furs, e. g. in the litter of their nests, and devoured them. Evidently these insects are of no interest for the rodents as an article of their diet and they destroy them merely in self-defense."

As a result of his observations the author refuted the idea of a strict tendency of the fleas to feed only on the rodents of certain species. For "Not one of the fleas under observation, if hungry, refused to suck the blood of the animal species offered it for this purpose, though there were differences in the character of the feeding. This widely increases the potential role played by the fleas of the Primor'ie in the transmission of the causative organisms of infectious diseases."

The author obtained best results by gassing the burrows of the rodents with the Soviet-produced hydrocyanic acid compound "cyanplav" (tsianplav). Next in efficacy was the method of the distribution of zinc phosphide baits in early spring before the growth of the vegetation started. The administration of chloropicrin took the third place.

Since the method of baiting was cheapest as well as simple, it appeared most acceptable for practical purposes.

The results of the work described in this article was so satisfactory that the author advocated the large-scale use of carbon monoxide for the purpose of rat destruction.

Dealing with the past history of tularemia in the Irkutsk Oblast, the author stated that (a) Klets (1957) referred to a vector-borne outbreak taking place in 1937 in the Nizhne-Udinsk Raion; (b) Altareva and Potapova (1958) met with instances of human tularemia in the Nizhne-Ilinsk Raion in 1951; and (c) Antsiferov and Potapova (1958) isolated in 1953 tularemia cultures from a water-rat and from the tick D. silvarum in the Bratskii Raion.
The present author, who in 1958-1959 made 2,160 intracutaneous tularin tests in inhabitants of 6 raions, obtained positive results in 70 persons who had never been vaccinated against tularemia but had had contact with water-rats, musk-rat or hares or with their skins. Some of the reactors gave a history of past lymphadenitis or tonsillitis attacks. In the course of his work the author also found three hunters in the Nizhne-Ilinsk Raion who had acute attacks of tularemia (1959). However, examinations of 561 rodents and 219 ticks gave a negative result.

The author recommended the use of tularemia vaccination and a strict control of the hunting of the above mentioned animals in the oblast.

References

To judge from the number of the collected skins, which varies in the different years from tens of thousands to 2-3 millions annually, the frequency of Lepus timidus, the only species met with in IAkutia, is subject to enormous oscillations. So far these hares have not been found tularemia-affected, but they have been insufficiently examined and instances are on record in which contact with them has caused the appearance of the disease in man.

The potential importance of the hares in the epidemiology of tularemia in IAkutia is great, because these animals would be apt to spread the infection over long distances and also because ticks are practically absent in the area.

The authors recorded two instances of tularemia in horses which were obviously infected through the consumption
of oats which had been contaminated by mice. One of the two animals succumbed to the infection; the diagnosis was bacteriologically confirmed in both. It is interesting that the two drivers of the horses, apparently infected through the dust of the contaminated oats, fell ill with tularemia before the disease became manifest in the horses. While up to 1953 epidemics of tularemia occurred in some of the raions of the Kemerovsk Oblast, owing to systematic vaccination campaigns and the implementation of other prophylactic measures the number of the affected raions as well as the incidence of the disease became much lowered during the last years. Whereas in 1949 20 raions were involved and the morbidity was 2.7 per 10,000 population, the corresponding figures for 1956 were 3 and 0.03/10,000.

In the Kemerovsk Oblast as well as in the adjacent krais and oblasts 98% of the human tularemia manifestations were due to a water-borne infection and accordingly the anginose-bubonic form of the disease was prevalent (84%). The author recommends a fight against tularemia through wholesale vaccination, anti-rodent campaigns and health education.

The recent incidence of the disease in the Kemerovsk Oblast and the adjacent regions is shown in the following table:
