STUDY OF RADIATION HEAT FLUX
FROM HIGH PRESSURE AIR ARCS

C. H. Marston
General Electric Company
FOREWORD

This report was prepared by the Space Sciences Laboratory of the General Electric Company Missile and Space Division for the Arnold Engineering Development Center (AEDC), Air Force Systems Command (AFSC). The work was performed from December 1963 to November 1964 under contract AF 40 (600)-1080, Project 8952, Program Element 62405334, Task 895202, entitled "Study of Radiation Heat Flux from High Pressure Air Arcs."

Capt. J. Edwards and Capt. J. R. Cureton were the Technical Monitors.

C. H. Marston and T. K. Pugmire were the principal investigators. The spectrographic temperature profiles were obtained by H. Sajjian and B. A. Bellinger. Dr. H. E. Weber's continuing advice and comment and particularly his assistance with the applications section are gratefully acknowledged. The invaluable assistance of A. M. Schorn, who prepared the ARCRAD computer program, and V. L. Chesser, who ran the arc facility, is also gratefully acknowledged.

Some sections of this report were originally prepared by T. K. Pugmire, who is no longer with the company. These include the discussion of thermal equilibrium in section 2, some parts of section 5, and all of Appendix E. Appendix B was written by A. M. Schorn.

The reproducibles used for the reproduction of this report were supplied by the author December 28, 1964.

This technical report has been reviewed and is approved.

ABSTRACT

A computational model has been developed and applied for calculating radiant heat flux from an electric arc using real gas properties and taking into account both self absorption and space varying temperature. The model requires knowledge of the temperature profile as an input. Temperature profiles were measured spectrographically using an air arc at one and 2.4 atmospheres. These measured profiles plus some simple analytic ones which satisfied boundary conditions were used to calculate radiant heat flux at pressures from 1 to 300 atmospheres. The experimental program also included measurements of radiant flux density at 2.2 and 5.7 atmospheres for comparison with calculations based on the measured profiles. Estimates were made of radiation losses in the AEDC 20-megawatt arc air heater now under development.

SECTION I
INTRODUCTION

One of the primary limitations on entry simulation facilities, such as hotshot tunnels, arc driven shock tubes and electric arc heaters in general, is radiation heat loss. This report describes a project which consisted of a computer study of arc radiation using tabulated spectral absorption properties of high temperature air, combined with spectrographic measurements of temperature profiles and experimental determination of radiation heat transfer rates.

The geometric configuration studied was an idealization of a D.C. arc column in the form of an infinitely long right circular cylinder whose temperature is a known function of radius only. The basic approach, which makes use of detailed spectral absorption data (Refs. 1, 2) developed by Breene and Nardone for analysis of the radiating gas cap of a re-entry vehicle, has application to any reasonably simple geometry with space-varying temperature.

An upper bound on radiation heat flux can be calculated by assuming the arc to be a black body at arc centerline temperature. Another upper bound can be established by assuming the gas heated by the arc to be optically thin so that all the energy radiated by each infinitesimal volume element reaches the chamber walls. At a given pressure, and for a known or assumed temperature profile, radiant flux density can then be calculated by integrating total radiance over the volume of a unit length of arc column and multiplying by 4π steradians. The energy leaving this unit length of arc column is, of course, distributed over the entire column length but, assuming an infinitely long column, the energy radiated from a unit length must be equal to the energy (originating throughout the column) crossing a unit length of boundary surface.

These upper bounds are perfectly adequate as long as radiation is only a small part of the total heat flux. However, at the pressure and temperature levels which are now the goals of, for example, arc heater development, radiation is the predominant heat transfer mode and a more accurate prediction is needed.

Absorption and emission of radiant energy in air depend on temperature, density and frequency. Thus, radiation energy from a particular element of volume will have a spectral distribution of intensity which is characteristic of the temperature and density of that element. The amount of energy reabsorbed along a particular
path will depend on the path length and also on the absorption characteristics (hence temperature and density) of each volume element along the path. A complete solution of the radiation heat transfer problem with self-absorbing gas therefore requires detailed knowledge of the radiation characteristics of air plus calculation for all volume elements (or a representative sample if advantage can be taken of symmetry), all possible paths for each volume element and all frequencies for each path.

As a practical matter some approximations are necessary. By means of the method described in this report, sufficiently tight upper and lower bounds can be placed on the effect of self-absorption that the calculation of radiant flux density is limited in accuracy by the state of knowledge of radiation properties, and of arc column temperature profiles.
SECTION II
ANALYSIS

2.1 THE ARC COLUMN MODEL

Consider an infinite cylindrical column of radiating gas at constant pressure with a known or assumed radial temperature profile. Let the column boundaries be cold and non-reflecting because, for structural reasons, the wall must be kept sufficiently cool that re-radiation can be neglected and, while cold compared with the arc plasma, it is still too warm to retain a high reflectivity. A correction for the effect of non-black walls is discussed in Section 2.7.

Complete equilibrium cannot be attained in the arc column, which exists only because of continuous energy transfer processes. However, a considerable body of evidence, both experimental and theoretical (Refs. 3, 4, 5, 6 and 7), indicates that local thermal equilibrium among electrons, ions, atoms and molecules can be assumed, with certain restrictions, so that equilibrium properties may be used in the computation.

Finkelnburg (Ref. 3) has indicated that according to existing analytical and experimental evidence, local thermal equilibrium exists to a good approximation in the plasma of all arcs operating at one atmosphere or greater except near the electrodes where strong electric fields (hundreds of volts per centimeter) are present. Lochte-Holtgreven (Ref. 4) concluded from his theoretical studies of the arc column that, at atmospheric or higher pressures, both the temperature of excitation and the "temperature" of ionization are for practical purposes equal to the electron temperature, with the possible exception of constricted arcs having an electric field intensity of 300 volts/cm or more. Cobine (Ref. 5) has shown that bulk gas temperature and electron temperature are essentially identical for a constant current discharge whenever the pressure is above 17 mm hg. Maecker's (Ref. 6) experimental studies support these conclusions.

The arc heater used in this study was designed to isolate completely the constricted region from electrode contamination (a major source of column and flow perturbation). The only part of the arc column used for this study was the constricted region, well separated from the electrodes, with a voltage gradient less than one hundred volts/cm (Ref. 8).
A given temperature distribution implies the existence of a steady state; each element of volume, dV, has presumably struck a balance among heat generated, radiated, absorbed and conducted in and out. Each such element within the column radiates in all directions with an intensity which is a known function of temperature, density and frequency. The assumptions of cylindrical symmetry and constant pressure make temperature and density dependent on radius only, so that intensity and transmissivity reduce to functions of radius and frequency only.

The arc column was divided into a constant temperature core and a series of constant temperature annuli with radiant heat flux originating in the core and in each annulus considered separately in terms of equivalent surface emissivities. Radiant flux densities for each surface are given by an equation of the form

\[ q/A = \int_0^\infty \epsilon_n W_{B,n} \, dn \]  

(2.1)

where \( W_{B,n} \) is the monochromatic emissive power of a black body at the radiator temperature and \( n \) is the wavenumber.\(^*\) Over a small but finite wavenumber interval the flux density is of the form

\[ (q/A)_{\Delta n} = \sigma T^4 \epsilon_n \eta_n \]  

(2.2)

where \( \epsilon_n \) is the average emissivity within the wavenumber interval and \( \eta_n \) is the fraction of the total energy radiated by a black body at temperature \( T \) which is radiated within the interval \( \Delta n \).

\(^*\) Each annulus was denoted by the index number \( j \) assigned to its exterior surface, counting from the outside surface of the arc column inward to the core.

\(^*\) Wavenumber is the reciprocal of wavelength and is therefore proportional to frequency. Tabulation of properties by wavenumber proves convenient so the term will be used interchangeably with frequency in the sense of frequency dependence.
Upper and lower limits were placed on the fraction of emitted radiant energy which actually leaves the arc column by considering two assumed sets of absorbing paths. One set of paths was so chosen that absorption is always less than or equal to the true absorption while along the other set of paths radiation absorption was always greater than or equal to the true value.

2.2 INFINITE HALF CYLINDER ABSORPTIVITY

The basic element from which the absorption model was built up is an infinite half-cylinder of gas, of radius R, absorbing radiation from an element of area on its axis. Associated with the cylinder is a linear absorption coefficient k which is a function of radial distance only. The angles shown in Fig. 2.1 (a) are related by

\[ \cos \gamma = \sin \theta \cos \psi \]  

(2.3)

From Fig. 2.1(b), the solid angle d\omega can be written

\[ d\omega = \frac{R}{L} \ d\theta d\psi \]  

(2.4)

If the surface element dA is radiating with an intensity I (energy flux per unit solid angle) and absorption takes place along the path according to Beer's law, then

\[ d^2 q = (I \cos \gamma dA) \ d\omega \ \exp \left( - \int_0^L k \ dl \right) \]  

(2.5)

Integration of Eq. (2.5) over the half cylinder would yield the total radiant flux originating from dA and escaping the half cylinder. With the further definition

\[ (kR) = \int_0^R k \ dr = \frac{1}{\sin \theta} \int_0^L k \ dl \]  

(2.6)

the radiant flux density from dA which escapes the half cylinder is

\[ \text{5} \]
Figure 2.1 Absorption by an Infinitely Long Half Cylinder.

a) Geometry

b) Typical Absorption Path.
\[
\frac{d\sigma}{dA} = 4I \int_0^{\pi/2} \cos \psi d\psi \int_0^{\pi/2} \exp \left( -\frac{KR}{\sin \theta} \right) \sin^2 \theta \ \ \ \ \ (2.7)
\]

For the case of no absorption

\[
\frac{q}{A} = \pi I \ \ \ \ \ \ (2.8)
\]

Therefore if \( kR \neq f(\psi) \) transmissivity and absorptivity are given by

\[
\tau_n = 1 - \alpha_n = \frac{4}{\pi} \int_0^{\pi/2} \cos \psi d\psi \int_0^{\pi/2} \exp \left[ -\frac{(kR)_n}{\sin \theta} \right] \sin^2 \theta d\theta \ \ \ \ (2.9)
\]

where subscript \( n \) denotes dependence on wavenumber. Equation (2.9) cannot be integrated inclosed form but numerical evaluation is straightforward and the result is shown in Fig. 2.2. Note that \( \alpha_n \) and \( \tau_n \) depend only on \( (kR)_n \) hereafter called the absorption length. When \( k_n \) is assumed to undergo a series of step changes with radius, Eq. (2.6) is replaced by an appropriate summation but Eq. (2.9) is unchanged.

2.3 ABSORPTION OF EXTERIOR RADIATION

An element of the exterior surface of any annulus but the outermost "sees" the annuli exterior to it as a segment of a cylinder. The segment was approximated by two or more sectors of cylinders centered at the radiating surface element is shown in Fig. 2.3. In this way, calculation of absorption became simply a matter of determination of absorption lengths plus application of Eq. (2.9).

The boundaries of a typical sector are at angles \( \psi \) and \( \psi + \Delta \psi \) from the normal to the radiating surface element. It is clear from Fig. 2.3 that an upper limit transmission approximation -- all absorption lengths less than or equal to the true absorption lengths -- corresponds to the case where sector coincides with segment at the \( \psi \) boundary. Likewise, a lower limit on transmissivity corresponds to sector-segment coincidence at the \( \psi + \Delta \psi \) boundary.
Figure 2.3 Absorption of Exterior Radiation. The $j=3$ Annulus is shown as a Typical Example.
The absorption geometry calculation must be done separately for all but the outermost ($j = 1$) annulus. Referring to Fig. 2.4 there are $q = j - 1$ sector radii $R_{j}, \phi_{q}$ exterior to the $j^{th}$ annulus within each sector. Calculation of each $R_{j}, \phi_{q}$ is straightforward trigonometry since $r_{j}$ and $r_{q}$ are known and $\phi$ is equal to either $\psi$ for the upper limit calculation or $\psi + \Delta \psi$ for the lower limit calculations. Absorption lengths are then

$$
(kR)_{n, j, \phi} = \sum_{q=1}^{j-1} k_{n, q} \left( R_{j, \phi_{q}} - R_{j, \phi} \right) \tag{2.10}
$$

The magnitude of $\Delta \psi$ depends on the number of sectors into which the quadrant $0 \leq \psi \leq \frac{\pi}{2}$ was divided. Let $s$ be the number of sectors, so that

$$
\Delta \psi = \frac{\pi}{2s} \tag{2.11}
$$

Transmissivity is then given by

$$
\tau_{n, j} = \frac{4}{\pi} \sum_{i=1}^{s} \left[ \sin(i \Delta \psi) - \sin \left( (i-1) \Delta \psi \right) \right] \int_{0}^{\pi/2} \exp \left[ \frac{-(kR)_{n, j, \phi}}{\sin \theta} \right] \sin^{2} \theta \, d\theta \tag{2.12}
$$

*Subscript $j$ on sector radius, absorption length and transmissivity refers to the respective quantities as "seen" from the $j^{th}$ annulus. Subscript $q$ is used to denote annuli absorbing radiation from the $j^{th}$ annulus, again counting inward from the outermost radius. Capital $R$ is used to distinguish sector radii from annulus radii and the angle $\psi \leq \phi \leq \psi + \Delta \phi$ designates the angle at which absorption lengths for a particular sector were calculated.
Figure 2.4 Sector Radius, $R_j$, $\phi$, $q$ for Calculation of Exterior Radiation Absorption Length.
Upper and lower limits on transmissivity depend on choice of \( \phi \)

\[
\phi = i \Delta \psi; \quad \tau = (\tau_{n,j})_{E, LL} \\
\phi = (i-1) \Delta \psi; \quad \tau = (\tau_{n,j})_{E, UL}
\]

where subscripts E, LL and UL refer to exterior, lower limit and upper limit respectively.

### 2.4 Absorption of Interior Radiation

The parts of annuli "visible" to a radiating element of interior surface are no longer segments, but similar sector approximations can be applied. Calculation of absorption lengths is somewhat complicated by the fact that, depending on \( \phi \), a radiation path can cross an annulus boundary twice, once, or not at all, corresponding to the existence of two, one, or no solutions to the triangle specified by \( r_{j+1} \), \( r_q \) and \( \phi \), Fig. 2.5. Sector radii* are given by

\[
R_{j, \phi, q}^+ = \frac{r_q}{\sin \phi} \left\{ \sin \left[ \phi + \sin^{-1} \left( \frac{r_{j+1}}{r_q} \sin \phi \right) \right] \right\}
\]

(2.14a)

when

\[
r_{j+1} \sin \phi \leq r_q
\]

and by

\[
R_{j, \phi, q}^- = \frac{r_q}{\sin \phi} \left\{ \sin \left[ \phi + \pi - \sin^{-1} \left( \frac{r_{j+1}}{r_q} \sin \phi \right) \right] \right\}
\]

(2.14b)

when

\[
r_{j+1} \sin \phi < r_q \leq r_{j+1}
\]

*Sector radii equal to or larger than \( r_{j+1} \) are designated \( R^+ \) while those smaller than \( r_{j+1} \) are designated \( R^- \).
Figure 2.5 Geometry of Absorption of Interior Radiation Illustrated for Radiation from the Outermost Annulus (j=1) with q=j+2.
Defining \( q' \) as the maximum value of the index \( q \) (corresponding to the smallest \( r_q \)) for which two solutions exist, the absorption lengths are given by

\[
(kR)_{n,j,\phi} = \sum_{q=2}^{q'} k_{n,q-1} \left[ \left( R^+_{j,\phi,q-1} \right) - \left( R^+_{j,\phi,q} \right) \right] + k_{n,q'} \left[ \left( R^+_{j,\phi,q} \right) - \left( R^-_{j,\phi,q'} \right) \right] + \sum_{q = j+2}^{q'} k_{n,q-1} \left[ \left( R^-_{j,\phi,q-1} \right) - \left( R^-_{j,\phi,q} \right) \right]
\] (2.15)

Because absorption coefficient is not necessarily a monotonically increasing function of temperature, the extremals of absorption length within any sector do not always correspond to the values at sector boundaries \( \psi \) and \( \psi + \Delta \psi \). Therefore, a third computation of \((kR)_{n,j,\phi}\) was made within each sector at \( \phi = \psi + \Delta \psi/2 \). The smallest and largest of these were used for computing interior transmissivities \((\tau_{n,j})_{\ll} I, (\tau_{n,j})_{\ul} I\) respectively from Eq. (2.12).

### 2.5 EMISSIVITY CALCULATIONS

Radiation from the exterior and interior surfaces of each constant temperature annulus was also considered separately. Emissivity of the exterior surface was obtained by modifying the limits on the absorptivity integral for a complete cylinder. At the interior surface emissivity was obtained using a modification of the transmissivity calculation already discussed.
The basis for calculating emissivity of the exterior surface is the integral expressing absorptivity of an infinitely long gaseous cylinder relative to an element of its surface. The integral is given by Jakob (Ref. 9) as

\[
\alpha = \frac{k}{\pi} \int_{-\pi/2}^{\pi/2} \int_{-\pi/2}^{\pi/2} \cos^2 \chi \cos \psi \left( \int_0^L e^{-kr} \, dr \right) \, d\chi \, d\psi
\]

(2.16)

where \( \psi \) is defined in Fig. 2.6 and \( \chi \) is the angle between the vertical and \( L \) measured in a plane passing through the surface element normal to the plane of Fig. 2.6.

Instead of evaluating the complete double integral, a closed form solution was obtained for the case where \( kL \) is sufficiently small that the inner integral reduces to

\[
\int_0^L e^{-kr} \, dr \approx L \quad kL << 1
\]

(2.17)

This solution was extended to optically denser conditions using the mean beam length concept (Ref. 10).

Replacing the cylinder by a cylindrical annulus, Fig. 2.6, only the unshaded part of the annulus is considered because radiation which passes through the hollow is included in the emissivity of the interior surface. The integration of Eq. (2.16) over \( \psi \) must therefore be performed in two steps:

1. \( 0 \leq \psi \leq \beta : \quad L = \frac{r}{\cos \chi} \left[ \cos \psi - \sqrt{\sin^2 \beta - \sin^2 \psi} \right]

(2.18a)

2. \( \beta \leq \psi \leq \frac{\pi}{2} : \quad L = \frac{2r \cos \psi}{\cos \chi}

(2.18b)

where \( \beta \) is the angle at which \( L \) is tangent to the inner surface and is related to the ratio of annulus radii by
Figure 2.6  Absorption Paths for Calculation of Exterior Emissivity from an Infinitely Long Cylindrical Annulus. Only the Unshaded Part of the Annulus is Directly Visible to the Surface Element.
Combining Eqs. 2.16, 2.17 and 2.18 the absorptivity of an annulus can be expressed by

\[ \alpha_j = \frac{2kr_j}{\pi} \left[ \int_{-\frac{\pi}{2}}^{\frac{\pi}{2}} \cos \chi d\chi \right] \]

(2.20)

\[
\int_{0}^{\beta} \left( \cos \psi - \sqrt{\sin^2 \beta - \sin^2 \psi} \right) \cos \psi d\psi + 2 \int_{0}^{\beta} \frac{\cos^2 \psi d\psi}{\beta} \\
\]

Integrating and dividing by \(2kr_j\), which is the limiting absorptivity of a cylinder of radius \(r_j\)

\[
\frac{\alpha_j}{2kr_j} = \left[ \frac{1}{\pi} - \frac{\sin^2 \beta}{2} - \frac{\beta}{\pi} - \frac{\sin 2 \beta}{2\pi} \right] \\
\]

(2.21)

Equation (2.21) is plotted in Fig. 2.7. If the factor 2 is changed to 1.9, the mean beam length of a cylinder is obtained and the absorptivity over the range from optically thin to black body is given within \(\pm 5\%\) (Ref. 10) by

\[
\alpha = \left[ 1 - \exp \left( -1.9 kr_j \right) \right] \\
\]

(2.22)

Combining Eqs. (2.21) and (2.22) and noting that the assumption of local equilibrium implies \(\alpha = \epsilon\), the following expression for "exterior" emissivity \(\epsilon_j, n\) results
Figure 2.7 Absorptivity of a Cylindrical Annulus Relative to Absorptivity of a Cylinder (both infinitely long).
\[ (\epsilon_{j, n})_E = 1 - \exp \left[ -1.9 k \frac{r}{n} j \left( 1 - \frac{\sin^2 \beta}{2} - \frac{\beta}{\pi} - \frac{\sin 2\beta}{2\pi} \right) \right] \]  

Equation (2.23) includes the emissivity of the cylindrical core as the special case \( \sin \beta = 0 \).

The interior emissivity of an annulus is identical with the absorptivity of a single annulus relative to a radiating element at its inner surface. The sum of absorptivity and transmissivity is unity so transmissivity of a single annulus can be calculated from Eq. (2.12) using absorption lengths given by

\[ \overline{kR} = \left\{ \frac{k_{n, j}}{n} \right\} (R_{j+1}, \phi, j) \]  

(2.24)

The arithmetic mean of the upper and lower limits on \( \tau \) was used to calculate interior emissivity

\[ (\epsilon_{n, j})_E = 1 - \frac{\tau_{UL} + \tau_{LL}}{2} \]  

(2.25)

2.6 COMPLETE EXPRESSION FOR RADIANT HEAT FLUX

Radiant heat flux, expressed as power per unit surface area of arc column boundary, may now be written as a double summation of terms like Eq. (2.2), each multiplied by the appropriate transmissivity

\[ q/A = \sigma \sum_{n} \left\{ \left[ \sum_{j=1}^{m} T_{j}^{4} \left( \frac{r_{j}}{\delta} \right) \left( \eta_{n, j} \right) \left( \tau_{n, j} \right)_{E} \left( \epsilon_{n, j} \right)_{E} \right] \right. \]

\[ + \left[ \sum_{j=1}^{m-1} T_{j}^{4} \left( \frac{r_{j+1}}{\delta} \right) \left( \eta_{n, j} \right) \left( \tau_{n, j} \right)_{I} \left( \epsilon_{n, j} \right)_{I} \right] \right\} \]  

(2.26)
The radius of the arc column is $\delta$, $m$ is the number of constant temperature subdivisions (core plus annuli) and $T$ and $\epsilon$ are given by Eqs. (2.13), (2.23) and (2.25). Black body energy fraction, $\eta$, is proportional to the integral of the Planck radiation function over each wavelength interval $\Delta \lambda$. Methods used for calculation of $\eta$ are discussed in Appendix A.

2.7 CONSTRICTED ARC WITH NON BLACK WALLS

As pointed out in Section 2.1 the arc chamber wall will have a low reflectivity (high emissivity). However, wall emissivity will not be unity as has been assumed thus far, and a means of evaluating its effect on the magnitude of the radiant heat flux actually absorbed by the wall is desirable.

A complete calculation of the radiant interchange between the arc and the constrictor walls adds a very substantial complication to the analysis already presented and, in addition, requires data on the frequency and angular dependence of wall surface emissivity. Fortunately the effect of a non-black wall can be accounted for quite closely in the following way.

Radiant interchange between a non-black wall and a radiating gas can be expressed, following Eckert (Ref. 10)

$$
(q/A)_i = -B_i + \sum_k F_{i-k} (1 - \alpha_{i-k,g}) B_k + (q/A)_g
$$

(2.27)

where $(q/A)_i$ is the net radiant flux density absorbed at surface $i$, $B_i$ and $B_k$ are the total radiant flux densities leaving surface $i$ and surface $k$ respectively, $F_{i-k}$ is a view factor between surface $i$ and each surface $k$, $\alpha_{i-k,g}$ is the absorptivity of the gas between surface $i$ and each surface $k$ as determined by integration over the solid angle corresponding to the particular $F_{i-k}$, and $(q/A)_g$ is the radiant flux density from the gas incident on surface $i$. Equation 2.27 expresses the net radiant flux density to surface $i$ as the algebraic sum of radiant flux density leaving surface $i$, radiant flux density arriving from surfaces $k$ and radiant flux density from the gas.

*McAdams (Ref. 17) gives a total normal emissivity of 0.57 for a copper "plate heated at 1110°F".*
Let surface \( i \) be an infinitesimal element of the chamber wall and consider as a single surface \( k \) the remainder of the infinitely long cylindrical arc chamber wall. Then

\[
\frac{(q/A)_g}{(q/A)_a} = \frac{\delta}{R_c}
\]  \hspace{1cm} (2.28)

where \((q/A)_a\) is the radiant flux density from the arc as given by Eq. 2.26 and \(R_c\) is the constricted radius. Also

\[
B_i = B_k = B_w
\]  \hspace{1cm} (2.29)

\[
F_i - k = 1
\]  \hspace{1cm} (2.30)

\[
\sum_k F_i - k(1 - \alpha_{i-k, g}) B_k = (1 - \alpha_{w, g}) B_w
\]  \hspace{1cm} (2.31)

where \(B_w\) is the radiant flux density leaving the wall at any point and \(\alpha_{w, g}\) is the "average" absorptivity of the gas between surface element \( i \) and all other parts of the wall surface. Further, defining \(B'_w\) as the total radiant flux density incident on the wall at any point we can write, where \(\epsilon_w\) is the emissivity of the wall

\[
B_w = \epsilon_w \sigma T_w^n + (1 - \epsilon_w) B'_w
\]  \hspace{1cm} (2.32)

By definition

\[
(q/A)_w = B'_w - B_w
\]  \hspace{1cm} (2.33)

so that, neglecting radiation at wall temperature,

\[
B_w = \frac{1 - \epsilon_w}{\epsilon_w} (q/A)_w
\]  \hspace{1cm} (2.34)

Combining eqs. 2.27, 2.28, 2.31 and 2.34 we obtain

\[
\frac{(q/A)_w}{(q/A)_a \left( \frac{\delta}{R_c} \right)} = \frac{1}{1 + \alpha_{w, g} \left( \frac{1 - \epsilon_w}{\epsilon_w} \right)}
\]  \hspace{1cm} (2.35)
which has been plotted as Fig. 2.8.

The quantity \( \alpha_{w,g} \) is an "average", over all frequencies and angles, of the absorptivity of the gas relative to radiation which has been reflected one or more times from the constrictor wall. Reflection may itself vary with frequency and angle, and multiple reflection will be more likely at those frequencies at which gas absorption is relatively low. However, if the arc fills the constrictor, \( \alpha_{w,g} \) cannot differ greatly from the average emissivity of the arc column and, as arc radius becomes small compared to wall radius, \( \alpha_{w,g} \) approaches zero. A reasonable estimate of \( \alpha_{w,g} \) and Fig. 2.8 shows that the correction is relatively insensitive to the precise value of \( \alpha_{w,g} \), particularly for the relatively high values of emissivity expected in practice.

All results in Sections 3, 4, and 5 are presented in terms of heat flux from the arc and a wall emissivity correction may be applied as required.
Figure 2.8  Influence of Arc Chamber Emissivity on Radiant Heat Transfer.
SECTION III
DIGITAL COMPUTATION

3.1 PROGRAM ARCRAD

The FORTRAN computer program which enabled an IBM 7090 digital computer to produce solutions to Eq. 2.23 is called ARCRAD and is included as Appendix B. It requires as input information the temperature, density and inner and outer radii of each annulus, absorption coefficient data and some programming data discussed in Appendix B. Its standard output includes

1. A repeat of the temperature-density-radius input.

2. Radiant flux density based on upper and lower limit transmissivities tabulated by wavenumber interval and also summed over all wavenumbers.

3. Radiant flux density with all transmissivities set equal to unity, again both tabulated by wavenumber interval and summed.

4. Optionally, an output tape which can be converted automatically to a graph of tabulations 2) and 3) above.

3.2 LIMITS ON FREQUENCY RANGE OF CALCULATIONS

Although radiant energy is distributed throughout the electromagnetic spectrum, all but a negligible fraction is contained within rather narrow limits which are a function of temperature. These limits are conveniently expressed in terms of a parameter \( v \) defined as

\[
v = \frac{c_2 n}{T}
\]

(3.1)

where \( c_2 \) is Planck's second radiation constant and is equal to 1.4380 cm\(^{-2}\) K. For a black body radiating at a given temperature, only 0.25\% of the total energy is radiated at frequencies corresponding to \( v < 0.3 \) or to \( v > 13 \). Therefore the only energy considered was that at frequencies (wavenumbers) bracketed by the above values of \( v \). Figure 3.1 shows these limits, along with the curve \( v = 1 \), which was the dividing line for application of two different methods for calculating \( \eta \) (see Appendix A).
Figure 3.1 Frequency and Temperature Ranges of Spectral Absorption Coefficient Data. The Solid Outline Represents Available Data.
The solid outline of Fig. 3.1 represents the range of temperature and frequency of the Breene and Nardone results (Refs. 1, 2) plus additional as yet unreported work. Data above 61,500 cm\(^{-1}\) are not precise but are known to provide an upper bound within a factor of 2. Temperatures near the centerline on the measured profiles exceeded the 15000°K upper limit on available high frequency data. An upper bound on the possible contribution in the high frequency range was therefore established by considering annuli at temperatures above 15000°K to be black bodies in the wavenumber range for which data was not available.

\[
\frac{(q/A)_{HF}}{T} = \sigma \sum_{j=16,000}^{m} \frac{(r_j)}{\delta} (D_{61,500})
\]

where \(D\) is defined by Eq. A.2 and is here the fraction of black body energy above 61,500 cm\(^{-1}\). The dependence of \(D_{61,500}\) on temperature is shown in Fig. 3.2. Both \(D\) and \(r/\delta\) are generally small in this case so use of the upper bound does not greatly increase the uncertainty of the results.

3.3 PRELIMINARY PROCESSING OF ABSORPTION COEFFICIENT DATA

The Breene and Nardone data from 1300 cm\(^{-1}\) to 62,000 cm\(^{-1}\) is recorded on magnetic tape but the tape contains much information extraneous to this study and the absorption coefficients are tabulated at unnecessarily fine frequency intervals. A preliminary processing of these tapes was therefore necessary to obtain a data tape containing linear absorption coefficients tabulated at 500 cm\(^{-1}\) intervals.

Data above 62,000 cm\(^{-1}\) was available only in printed form so punched cards were prepared which were then converted to magnetic tape. The wavenumber interval was increased to 1000 cm\(^{-1}\) because at higher frequencies a given increment represents a smaller fraction of the total energy.

3.4 TEMPERATURE AND DENSITY PROFILES USED IN COMPUTATION

As has been stated, temperature distribution in the arc column is presumed known. With the assumption of local thermal equilibrium
Figure 3.2  Fraction of Black Body Energy Emitted at Wave Numbers Greater Than 61,500 cm\(^{-1}\).
and a given pressure level, the density distribution can then be determined from a table or chart of thermodynamic properties. A limited amount of temperature profile data was available from direct spectroscopic measurement (see Section 5.2 for further discussion) which provided a basis for comparison of results with direct measurements of radiant heat flux.

Based on the results of direct measurements plus application of reasonable boundary conditions, a series of simple analytic (polynomial) profiles were also used for computation. These profiles were chosen to provide a systematic comparison of the effect on radiant heat flux of temperature level and fullness of the temperature profile. These analytic profiles, shown in Fig. 3.3 along with a profile measured by Maecker, (Ref. 6) were of the form

\[ \frac{T - T_{ref}}{T_{CL} - T_{ref}} = 1 - \left( \frac{r}{\delta} \right)^x \]  

The spectral absorption coefficient data were tabulated at temperature intervals of 1000°K and decade density intervals. In order to avoid double interpolation for temperature and density, the thickness of each annulus was selected in such a way that the weighted average temperature of each annulus was a tabulated temperature, see Appendix C. Absorption coefficients were then interpolated logarithmically with density. Calculation of weighted average annulus temperatures requires a polynomial representation of the temperature profiles so measured profiles were reduced to this form using a modification of a standard least squares polynomial curve fit program, Appendix D.

3.5 TRANSMISSIVITY APPROXIMATION

Numerical evaluation of the integral appearing in Eq. 2.12 leads to the curve of Fig. 2.2 with \((kR)_{n,j,\phi}\) as a parameter. Rather than perform the numerical integration for each different \((kR)_{n,j,\phi}\) empirical approximations were used in Program ARCRAD which took advantage of the similarity of Fig. 2.2 to a simple exponential decay. The approximations were made over three regions as follows:

1) \(0 \leq kR \leq 1.1\) \(\tau = \exp (-1.206(kR))\)
Figure 3.3  Arbitrary Polynomial Profiles and a Nitrogen Profile Measured by Maecker.
2) $1.1 < \overline{kR} \leq 16 \quad \tau = \{ \exp [-1.206 (\overline{kR})] \} [1.0774 - .09539 (\overline{kR})$

\[ + .055577 (\overline{kR})^2 - .004291 (\overline{kR})^3 \]

\[ + .00020826 (\overline{kR})^4 \} \]

3) $\overline{kR} > 16 \quad \tau = 0$

Introduction of this approximation resulted in roughly halving the computer time per case.
SECTION IV
COMPUTER RESULTS

4.1 WAVENUMBER RANGE OF RESULTS

Because of the limitations on available data discussed in Section 3.2, curves presenting results of calculation are labeled as follows to indicate the wavenumber range they cover.

Table 4.1 - Frequency Range of Results

As will be discussed in Section 5.4 the break at 61,500 cm\(^{-1}\) is also convenient from the standpoint of comparisons with experimental measurements since this frequency is just about the cutoff frequency of the fused quartz window used to protect the radiant heat flux gage.

4.2 CONVERGENCE OF UPPER AND LOWER BOUNDS

The computational model described in Section 2 of this report was designed to bracket the effect of self absorption on radiant heat flux from an arc column. The effectiveness of this approach depended on just how close to each other were the upper and lower bounds and this could not be established without actually performing some numerical calculations.

As originally conceived and proposed, the absorption model postulated a lower limit on absorption (maximum radiant heat flux) in which all radiation was considered to be "exterior" in the sense of section 2.3. For this case the absorption paths were represented by half-cylinders whose radii were equal to the difference between annulus outside radii and the arc column boundary radius. The upper limit on absorption (minimum radiant heat flux) was established by assuming
all radiation to be "interior" and absorbed by half-cylinders whose radii were equal to the sums of the annulus radii and the arc column boundary radius. Results with this model gave an upper bound practically indistinguishable from the optically thin case and a lower bound which was lower by an order of magnitude.

A second computational model was then developed, as described in detail in Section 2. Division of the half cylinders into sectors and separate calculation of "exterior" and "interior" radiation for both upper and lower bounds greatly reduced the spread between them. By retaining the number of sectors as variable, more sectors could be used at higher pressures, where the spread is large, than are needed at lower pressures.

The additional flexibility achieved by retaining the number of sectors as a variable can be used in two ways. Figure 4.1 illustrates the effect of varying the number of sectors while keeping all else constant. Within the limits of roundoff error, increasing the number of sectors improves the approximation. A price is paid of course, in additional computer time. The form of convergence indicates that an average of upper and lower bound calculations will give an excellent approximation to the "exact" result.

In addition to justifying an average of the two limit calculations as representative of the "exact" result, Fig. 4.1 is a useful guide to economic choice of the number of sectors. At pressures equal to or greater than 100 atm, s was set equal to 3. Below 100 atm a value of s=2 sufficed.

4.3 RESULTS WITH ASSUMED TEMPERATURE PROFILES

If one starts with the postulate that the arc column is axially symmetric and that the temperature decreases monotonically from a peak at the centerline to some relatively low temperature at the outermost radius, than the general shape of the profile is reasonably well determined. This is true even though local bumps may exist due to changes in ionization level or other phenomena.

Let us define a full profile as one in which arc temperature remains near arc centerline temperature until very near the outer boundary. Fullness is dependent on details of the local energy balance and is therefore certain to change with, for example, changes in the relative importance of the conduction and radiation modes of heat loss to the boundary.
Figure 4.1 Convergence of Upper and Lower Limit Calculations as Number of Sectors Increases.

PROFILE MEASURED AT 1 atm 400 amp
CALCULATION DONE FOR P = 300 atm
* see section 4.1
The family of curves given by Eq. 3.3 satisfies the aforementioned postulates and contains a single parameter, the exponent $x$, to characterize the fullness. The effect of fullness may then be judged by a plot such as Fig. 4.2 which shows radiant flux density vs. $x$ at 3 pressure levels. Fig. 4.2 also shows, for comparison, the asymptotic value which each curve approaches as $x$ becomes very large. The asymptotes were computed assuming a cylinder of gas uniformly at centerline temperature. The limiting case of a black body at centerline temperature is also included. Lacking knowledge of temperature profiles at the higher pressures, these curves help narrow the possible range of radiant flux densities and will be more useful if and when more becomes known about temperature profiles at high pressure.

The sensitivity of radiant heat flux to temperature was investigated for a sequence of profiles of the form of Eq. 3.3 (with $x=3$) in which centerline temperature was varied from 12,000 to 15,000 K, Fig. 4.3. Over the range calculated the radiant heat flux increases approximately as the $8.4$ power of arc column centerline temperature at 100 atm and below.

### 4.4 Sensitivity to Changes in Outer Radius

Weber's estimates of constricted arc column growth (Ref. 12) indicate that the arc may not entirely fill the constrictor of the arc heater used in the experimental work. Temperature could not be measured over the entire column, so for one of the measured profiles, Fig. 5.4, two different outer edge parabolas were matched to the polynomial which was fitted to the data (in this case also a parabola). The part of the profile for which data existed was unchanged and the sensitivity of the calculation to changes in the outer part of the profile was checked in this way. Comparison made on the basis of heat flux at the constrictor wall (0.5 cm radius) indicated that exact arc column diameter made little difference, Table 4.2.

Because only the outer few annuli were changed this result does not contradict Fig. 4.2 where the entire profile was systematically varied.

4.5 QUASI-THIN MODEL AND FREQUENCY DISTRIBUTION

The quasi-thin model was obtained by setting all transmissivities equal to unity in Eq. 2.26. Because the computation of emissivities takes into account self absorption within each annulus, the quasi-thin model will yield a radiant heat flux known to be closer to the true value than the optically thin model. The extent of the difference between quasi-thin and optically thin depends on the magnitude of the dimensionless absorption lengths associated with each annulus, so choice of number of annuli will have an effect on the quasi-thin result. The quasi-thin result, however, is a very simple extra step for the computer and provides a useful indication of the importance of self-absorption.

As mentioned in section 3.1, an option in the program permits automatic plotting of radiant flux density in each wavenumber interval, both quasi-thin and self-absorbing, Fig. 4.4. In general the higher the intensity of radiation the greater the difference between self-absorbing and quasi-thin.
Figure 4.4 Frequency Distribution of Radiant Heat Flux. Arc Profile Measured at 2.4 atm, 455 amp. Computed at 100 atm.
4.6 TWO TEMPERATURE MODEL

In order to gain some idea of the effect of a body of heated plasma in reducing the intense radiation from the arc column proper, a two temperature cylindrical model, which is compatible with that discussed in section 2, was investigated. Figure 4.5 presents results with the arc at 16,000°K and the surrounding plasma at 6,000°K with the dimensions investigated shown in the inset sketch. As pressure is increased, the shielding effect of the lower temperature surrounding plasma may be sufficient to cause the total radiant flux to pass through a maximum and then decrease somewhat. As pressure is increased the energy radiated by the cooler surrounding gas to the walls will continue to increase and the large equivalent radiating surface tends to magnify the increase. However, the fraction of energy reabsorbed from the arc column will also increase and the possibility that the latter effect could result in a net decrease in radiant flux to the walls is confirmed by Fig. 4.5. The calculation was repeated with the arc at 15,000°K in order to include the high frequency radiation, Fig. 4.6.

It must be emphasized that the existence of such an effect is controlled by geometry, operating conditions and arc behavior at high pressures -- all of which affect the temperature distribution and its (here neglected) pressure dependence.

Figure 4.6  Two Temperature Model Including High Frequency Radiation with Arc at 15,000°K.
SECTION V
EXPERIMENTAL STUDY

5.1 OBJECTIVES

The objectives of the experimental work were:

1) measurement of temperature profiles for use as an input to the analysis.

2) measurement of total radiant heat flux to compare with results of the analysis.

5.2 ARC HEATER

The Gerdien type arc heater used for this study is shown in Fig. 5.1. This heater produces a uniform uncontaminated air plasma in a test section (constricted region) instrumented with voltage probes, a spectrographic observation window and a shuttered channel for radiation measurements. The heater has been more completely described in Ref. 8. The constrictor section can be replaced by a somewhat shorter non-constricting section which has a window for photographic observation.

Available power supply voltage limits maximum operating pressure in the unconstricted mode to 15 atmospheres although the heater is capable of withstanding higher pressures. The greater length of the constrictor section reduced the voltage limitation on pressure to about 5 atmospheres.

5.3 TEMPERATURE PROFILES AND CENTERLINE TEMPERATURES

Two temperature profiles were obtained at one atmosphere and one at 2.4 atmospheres. These are shown in Figs. 5.2, 5.3, and 5.4. The reason for two fitted curves in Fig. 5.4 was discussed in Section 4.4.

Relative intensities of several emission lines were used with Abel’s integral equation to establish arc column temperature gradients. A description of the technique is included as Appendix E. Additional measurements of arc centerline temperature were made at 2.2 atmospheres and several current levels as shown in Fig. 5.5. These are based on average intensities in a narrow slice through the center of the arc. Therefore evaluation cannot make use of Abel’s integral

to allow for the cooler gas ahead of and behind the centerline region and the resultant temperatures are slightly lower that the "true" centerline temperature as obtained by measurements over a significant fraction of the profile.

Spectrographic data were not obtained at higher pressures because the measurements depend on observed spectral lines being nearly optically thin. The line reversal technique which is applicable at high pressures requires of the order of 70% absorption and is therefore most applicable at pressures substantially above 5 atm.

5.4 RADIANT HEAT FLUX MEASUREMENTS

Three types of gages were considered for measuring radiant heat flux while avoiding convective heating. The first gage was a cavity type, recessed in a channel 5 cm from the arc column. The channel eliminated convection and conduction without the necessity of a transparent window, but temperature rise of the cavity was barely detectable. At the other extreme a thermopile proved too sensitive.

The gage actually used, Fig. 5.6, was a cylindrical copper slug mounted with one base coated with lampblack and covered by a 1/16" thick quartz window. Remaining surfaces were thermally insulated by a teflon sleeve which also held the window in place. Temperature rise in the slug was measured by a chromel-alumel thermocouple directly connected to a recording oscillograph.

A shutter shielded the gage until the arc had stabilized at the desired conditions. Then the shutter was opened and the gage moved rapidly forward to one of several preselected positions in the channel. In the first position the gage surface was recessed 1/2" from the constrictor wall. Fully extended the gage surface was recessed 1/16" so that the exposed surface of the quartz was tangent to the constrictor wall.

Radiant heat flux to the gage was calculated from the rate of temperature rise of the copper slug, assuming constant specific heat and no heat losses. A typical data trace is shown in Fig. 5.7. Radiation of the constrictor wall can be inferred by plotting heat flux data at several points along the channel and extrapolating to zero distance.

5.4 RADIANT HEAT FLUX MEASUREMENTS

Three types of gages were considered for measuring radiant heat flux while avoiding convective heating. The first gage was a cavity type, recessed in a channel 5 cm from the arc column. The channel eliminated convection and conduction without the necessity of a transparent window, but temperature rise of the cavity was barely detectable. At the other extreme a thermopile proved too sensitive.

The gage actually used, Fig. 5.6, was a cylindrical copper slug mounted with one base coated with lampblack and covered by a 1/16" thick quartz window. Remaining surfaces were thermally insulated by a teflon sleeve which also held the window in place. Temperature rise in the slug was measured by a chromel-alumel thermocouple directly connected to a recording oscillograph.

A shutter shielded the gage until the arc had stabilized at the desired conditions. Then the shutter was opened and the gage moved rapidly forward to one of several preselected positions in the channel. In the first position the gage surface was recessed 1/2" from the constrictor wall. Fully extended the gage surface was recessed 1/16" so that the exposed surface of the quartz was tangent to the constrictor wall.

Radiant heat flux to the gage was calculated from the rate of temperature rise of the copper slug, assuming constant specific heat and no heat losses. A typical data trace is shown in Fig. 5.7. Radiation of the constrictor wall can be inferred by plotting heat flux data at several points along the channel and extrapolating to zero distance.
Figure 5.6 Copper Slug Gage for Total Radiant Heat Flux Measurement Shown in Retracted Position.
Figure 5.7 Typical Recording Trace for Determination of Radiant Heat Flux.
Allowances must be made for losses through the window and at the gage surface. The percentage of light reflected by a glass surface of refractive index 1.55 (about that of quartz) is tabulated as a function of angle of incidence in Ref. 13 and a graphical integration based on this tabulation indicates that approximately 92% of the incident energy is transmitted when the gage is fully in. Taking the absorptivity of lampblack as .95, the radiant energy measured by the gage at the arc chamber wall must be increased by a factor of 1.14. This correction is approximate but extrapolation to the arc column wall leads to considerable uncertainty in any event. The transmission characteristic of type 101 fused quartz, Fig. 5.8, coincides very nearly with the Low Frequency Range computer output so comparison will be made with LF curves.

An additional uncertainty introduced by the quartz window is the possible change in transmission characteristic when the glass is exposed to the high temperature arc. The transmission characteristic in the visible range was checked for a few windows using a standard lamp and photomultipliers. The ratio of photomultiplier outputs with and without the window inserted gave the fraction of energy transmitted (i.e., energy neither reflected nor absorbed). A clean window gave values from .89 to .90. Transmission of windows which has been exposed to the arc ranged from .40 to .79. The time at which the changes took place is unknown so no correction has been made for this effect.

Results are shown in Table 5.1 and Fig. 5.9. For the first series the insulator used to jacket the copper slug was melamine, and the quartz window was fastened to the melamine with an adhesive. This was not entirely satisfactory since the glass did not always remain in place. In the second series tabulated the teflon sleeve arrangement shown in Fig. 5.6 proved to be much more reliable.

The effect of the quartz window in shielding the gage from conduction is evident in the comparison of table 5.2.

Figure 5.10 is a comparison of calculations based on two measured profiles and the results of direct measurement. Complete confirmation of the calculation model and absorption coefficient data requires measurements at substantially higher pressures but at least the magnitude and trend are consistent.

Table 5.2 - Comparison of Total and Radiant Heat Flux at a Pressure of Two Atmospheres
SECTION VI
APPLICATION TO ARC HEATER CONFIGURATIONS

6.1 GENERAL

A variety of configurations for heating plasma by means of an electric arc are in use today. Two of the more common basic arc heater geometries are the constricted arc and the ring electrode rotating arc. Application of the model developed in Section 2 applied fairly well to the constricted arc since axial symmetry is maintained in most of the heater and some measurements of arc column temperature profiles are available.

Analysis of the ring electrode rotating arc is considerably more difficult because arc temperature measurements are not available and arc behavior is influenced by such new factors as the ratio of ring diameter to separation distance, the magnitude and direction of self-induced or externally applied magnetic driving fields, and the magnitude and direction of cold air flow transverse to the arc column.

Under some circumstances for instance, the rotating arc may bow inward to the extent that, except near the electrodes, it is stationary on the axis of symmetry, Fig. 6.1. Fastax films taken of a rotating arc between ring electrodes separated by a distance of about 4 ring radii tend to bear out this possibility. The column was photographed through a 3/8" wide x 1/8" high port midway between electrodes. At pressures above approximately 10 atmospheres the column was visible and stationary, centered in the port. At lower pressures, down to about 2 atmospheres, changes in brightness indicated that the column was moving past the port. At 2 atmospheres pressure light from the port was uniform. These observations fit the hypothesis that at the highest pressure only the parts of the arc near the electrodes are moving, while the body of the column is aligned with the axis, while at low pressure the entire column may be moving too fast for the Fastax camera to "stop" the motion.

If the magnetic field which causes the arc to rotate is sufficiently strong, of the order of 20 kilogauss, the arc can be magnetically diffused (Ref. 14) thus radically altering its geometry and radiation characteristics. A transverse flow created by a rapidly moving arc column may destroy the axial symmetry of the column, probably tending to create a turbulent If this tail merges with the leading "edge" of the column a diffuse operating mode also results.
Figure 6.1  Ring Electrode Rotating Arc With Separation Distance of 4 Ring Radii.
6.2 SPECIFIC CONFIGURATION

An outline sketch of the arc heater of immediate interest is shown in Fig. 6.2. It is designed to operate at high pressure on 3 phase, 60 cps, alternating current with the arcs kept in rapid motion by a steady, externally applied, magnetic field. Cold air flows radially inward through the arcs, then axially to the nozzle.

Magnetic field strength is 5 kilogauss, which is probably not sufficient to cause magnetic diffusion, so the arc will be treated as a cylindrical column. Arc length cannot easily be established because, while electrode separation is only about one fourth that in the observations described in Section 6.1, pressure can be higher and there is a radially inward velocity component which will probably cause the arc to bow inward. Some estimated operating conditions at two pressures are shown in Table 6.1.

Figure 6.2 Outline of AEDC 20 MW Arc Heater Interior (based on drawing furnished by Westinghouse Electric Co.)
6.3 ARC COLUMN MODEL

Arc size and temperature distribution are not known, so some admittedly crude assumptions were made in order to arrive at an estimate. The arc was assumed to be cylindrical at a uniform temperature with air flow through it limited by aerodynamic choking or by the total flow, whichever was least. The choked flow function for flow through an arc has been computed by Weber (Ref. 15) and is shown in Fig. 6.3. For a known or assumed voltage gradient and current there is then a unique combination of arc radius and temperature which satisfies both an energy balance and Ohm's Law. In view of the approximate nature of the data and model, electrode drops (of the order of tens of volts) and back EMF due to interaction with the externally applied magnetic field (a few volts) were neglected in the estimates of voltage gradient. A further implicit assumption is that an AC arc may be treated by DC methods and that the RMS value of current gives acceptable mean values. In brief, both space and time variation of arc temperature (and bulk gas temperature too) were ignored.

6.4 LOW PRESSURE OPERATION

The gas is nearly optically thin at 5 atmospheres so that total radiance, \( J \), as computed by Breene and Nardone (Ref. 2) was used to compute radiant heat fluxes. The energy balance for a unit length of arc column was written

\[
\frac{I^2}{\sigma_e \pi \delta^2} - \left( \frac{W}{Ap} \right)^* p(2\delta) (h_a - h_o) - (4\pi J_a) (\pi \delta^2) = 0 \quad (6.1)
\]

where \( p \) is pressure, \( h_o \) is the enthalpy of the incoming air, \( h_a \) is enthalpy at arc temperature, \( \delta \) is arc radius and \( \left( \frac{W}{Ap} \right)^* \) is the choked flow function, Fig. 6.3. Peng and Pendroh (Ref. 16) were the source for electrical conductivity \( \sigma_e \). Equation 6.1 can be considered a function of radius and arc temperature, Fig. 6.4, since, at a given pressure, \( \sigma_e, J_a, \left( \frac{W}{Ap} \right)^* \) and \( h_a \) are all functions of temperature. Ohm's law in the form

\[
E = \frac{I}{\sigma_e \pi \delta^2} \quad (6.2)
\]

is also shown on Fig. 6.4 for several values of \( E \). The values selected are reasonable at the low pressure. Experience with rotating arcs indicates that the column radius should be less than about 0.5 cm and
Figure 6.3  Choked Fully Developed Flow (Ref. 15)
Figure 6.4  Energy Balance and Ohm's Law at 5 Atmospheres Chamber Pressure.
that 60 v/cm is a reasonable maximum voltage gradient. This is a
local column gradient which cannot be obtained by simply dividing the
voltage between electrodes by electrode spacing. Turbulence locally
twists and turns the column extending its actual length to several
times the distance between electrodes. The arc length used for
calculations at 5 atm is then obtained by dividing the applied voltage
by the voltage gradient.

Bulk enthalpy, $h_b$, of plasma leaving the arc chamber, was
estimated from another energy balance. Consider 3 arcs, each of
length $L_a$, in a cylindrical chamber of length $L_c$ and radius $R_c$ and
assume that the only loss is the bulk gas radiation at bulk (exit)
enthalpy. Then

$$\left(\frac{W}{Ap}\right)^* p (2\delta) (3L_a) h_a - Wh_b = 4\pi J_b (\pi R_c^2 L_c)$$

(6.3)

where subscript $b$ refers to bulk gas and $L_a$ is the length of a single
arc. The choked flow function and the total radiance are known
functions of bulk enthalpy (or, equivalently, bulk temperature) so
Eq. 6.3 uniquely determines $h_b$. Results are presented in Section
6.6 along with those for the high pressure case.

6.5 HIGH PRESSURE OPERATION

Essentially the same analysis was applied to the 255 atmosphere case except that the gas can no longer be considered optically
thin and program ARCRAD was used to calculate radiation. For the
conditions given, the entire flow can pass through the arc column
without choking, so the arc column energy balance analogous to
Eq. 6.1 was written

$$\frac{I^2}{\sigma_e \pi \delta^2} - \frac{W(h_a - h_0)}{3L_a} - (q/A)_a 2\pi \delta = 0$$

(6.4)

where $(q/A)_a$ is the radiant flux density at the arc column boundary,
Fig. 6.5.

Again a unique combination of a radius and arc temperature
exist which simultaneously satisfy Eq. 6.4 and Ohm’s law (Eq. 6.2)
for an established value of $E$.

Raezer, et al., Ref. (17) indicate that voltage gradient varies
as the 0.28 power of the pressure. Applying this to the 60 v/cm
gradient at 5 atmospheres gives 174 v/cm and an arc length of 4.5
Figure 6.5 Radiant Flux Density at the Boundary of a Uniform Temperature Air Arc at 255 Atmospheres.
inches. The resulting arc radius is quite large, probably much too large, and the arc temperature and enthalpy are therefore low since the general trend of the curve is similar to Fig. 6.4. For this reason results are also included for an arbitrarily assumed arc length of 2 inches.

Exit enthalpy was again estimated from a simplified arc chamber energy balance. The bulk gas was taken to be a cylinder of arc chamber dimensions at a uniform temperature corresponding to exit enthalpy, with a smaller cylinder, the arc column, moving rapidly around its circumference. Both the bulk gas and the arc column radiate to the arc chamber wall but a part of the arc radiation is now re-absorbed by the bulk gas.

In cross section this geometry corresponds very closely to radiation of a surface element into a cylinder, so the Nusselt solution for absorptivity of a cylinder can be applied. By Lambert's cosine law the equivalent arc surface area per unit length radiating inward is equal to the arc column diameter so that \( q_{ab} \), the power reabsorbed by the bulk gas, is given by

\[
q_{ab} = 2\pi (3L_a) \sigma T_a \frac{4}{\pi} \sum n \epsilon_{a,n} \eta_{a,n} \alpha_{b,n} \tag{6.5}
\]

Program ARCRAD was adapted to the computation of \( q_{ab} \).

Neglecting all losses but radiation and assuming, optimistically, that radiation from the bulk gas takes place at bulk exit enthalpy, the equivalent of Eq. 6.3 is

\[
W(h_a - h_b) + q_{ab} = q_b \tag{6.6}
\]

where power radiated by the bulk gas, \( q_b \) is given by

\[
q_b = \frac{(q/A)_b}{(2\pi R_c)(R_c + L_c)} \tag{6.7}
\]

and \((q/A)_b\) was computed using program ARCRAD. Strictly speaking, absorption lengths for radiation from the ends of the cylinder are slightly different than for the cylindrical surface, but the difference is of the order of 5% and the ends are only a small fraction of the total surface anyway so no distinction is made. It was convenient to solve for \( T_b \) graphically, Fig. 6.6, plotting Eqs. 6.6 and 6.7 as functions of temperature because both \( q_b \) and \( h_b \) are non-analytic.
Figure 6.6  Arc Chamber Energy Balance at 255 atmospheres with an Input power of 19 megawatts.
Two curves are shown for \( q_b \), one assuming that the chamber walls are black and the other applying the correction factor discussed in Section 2.7. The arc itself is small compared to the chamber so no correction is needed, but reabsorption by the bulk gas can be significant. In evaluating the correction factor for the bulk gas \( \alpha_w \), \( g \) was taken as the ratio of \( (q/A)_b \) to black body radiation, both at 7500 °K.

If \( P_{\text{loss}} \) is defined as that part of the input power which is absorbed by processes other than net heating of the incoming air and \( P_{\text{in}} \) is the total input power then

\[
P_{\text{loss}} \leq P_{\text{in}} - W(h_b - h_o)
\]

A curve representing the equality is also plotted in Fig. 6.6 and its intersection with the radiation loss curve places an upper bound on bulk temperature.

6.6 RESULTS AND DISCUSSION

Results of calculations are summarized below.

* at 7500°K

** Based on a cylinder 17.5 inches long by 4 inches diameter.

At 5 atmospheres the bulk gas radiation loss is relatively small and the decrease in enthalpy from arc to bulk gas is primarily the result of mixing with cold gas which did not pass through the arc.

At 255 atmospheres bulk gas radiation alone can consume practically all of the power input. Results presented in Fig. 6.6 and Table 6.2 tend to be optimistic in that conduction losses have been neglected and bulk gas radiation has been assumed to take place at exit temperature rather than somewhere between arc temperature and bulk temperature.
Total radiation to the wall includes radiation directly from the arcs. The arcs would tend to create local hot spots except that they are in rapid motion -- making about 10 revolutions for each half cycle of input voltage -- so the heat flux per unit length from the arc was considered as uniformly distributed around the arc chamber periphery.
SECTION VII

CONCLUSIONS

At high pressures there is no simple way to predict the radiant heat transfer from an arc column. The computational model described herein provides very tight upper and lower limits if the basic geometry assumptions of the model are satisfied and if the temperature distribution is known. Reasonable limiting assumptions about temperature profiles can be useful in bracketing the desired answer but one must know the temperature level either by measurement or calculation.

Incorporation of radiation including self-absorption into a solution of the energy equation such as Weber has done (Ref. 11) for the optically thin case, is the next logical step in the study of this problem. The temperature profile would then be a part of the result rather than a required input. A coordinated experimental program to measure radiant heat flux and/or temperature profiles at high pressure would also be very desirable.
REFERENCES

APPENDIX A

CALCULATION OF ENERGY FRACTION

For a given wavenumber interval, \( \Delta n = n_2 - n_1 \), let \( \eta \) be the fraction of the total energy flux radiated by a black body at a given temperature which falls within this interval

\[
\eta = D_1 - D_2 \quad \text{(A.1)}
\]

where

\[
D = \frac{\int_{n_1}^{n_2} W_{B,n} \, dn}{\int_{0}^{\infty} W_{B,n} \, dn} \quad \text{(A.2)}
\]

The function \( D \) is available in tabular form, (Ref. 18) but, for computer application, direct generation of \( \eta \) by series expansion was desired. Two series were used.

1. Pivovonsky and Nagel (Ref. 18) gives a series expansion for \( D \) as

\[
D = 1 - \frac{15}{\pi^4} v^3 \left( \frac{1}{3} - \frac{v}{8} + \frac{v^2}{60} - \frac{v^3}{5040} + \frac{v^4}{272160} - \cdots \right) \quad \text{(A.3)}
\]

where

\[
v = \frac{c_2 n}{T} = \frac{1.4380n}{T} \quad \text{(A.4)}
\]

This series converges for \( v < 2\pi \) but convergence is slow when \( v > 1 \). Defining
\[
\bar{v} = \frac{v_2 + v_1}{2}; \quad \Delta v = \frac{v_2 - v_1}{2}
\]  

Equation A.3 was transformed to

\[
\eta = \frac{15}{\pi^4} \left\{ \Delta v \left( \frac{-v}{2} - \frac{v^3}{2} + \frac{v^4}{12} - \frac{v^6}{720} + \ldots \right) + (\Delta v)^3 \left( \frac{1}{12} - \frac{v}{8} + \frac{v^2}{24} - \frac{v^4}{576} + \ldots \right) \right. \\
+ (\Delta v)^5 \left( \frac{1}{960} - \frac{v^2}{3840} + \ldots \right) \left. + 0 \left[ (\Delta v)^7 \right] + \ldots \right\}
\]

and used to calculate \( \eta \) when \( \bar{v} \leq 1 \). Inclusion of the terms shown through order \((\Delta v)^3\) results in a value of \( \eta \) accurate to \( \pm 0.1\% \).

2. While \( D \) itself cannot be expressed in closed form, its derivatives can be. Since \( \eta \) is the difference between two values of \( D \), the zero order term of a Taylor expansion of \( \eta \) vanishes. Expansion about \( \bar{v} \) eliminates all even order derivatives, thus

\[
\eta = \left[ (v_1 - \bar{v}) - (v_2 - \bar{v}) \right] \left[ \frac{\partial D}{\partial v} \right]_{v=\bar{v}} + \frac{1}{3!} \left[ (v_1 - \bar{v})^3 - (v_2 - \bar{v})^3 \right] \left[ \frac{\partial^3 D}{\partial v^3} \right]_{v=\bar{v}} + \ldots \]  

(A.7)

Since

\[
\frac{\partial D}{\partial v} = -\frac{15}{\pi^4} \frac{v^3}{(e^1 - 1)}
\]  

(A.8)
the energy fraction becomes

\[
\eta = \frac{15}{\pi^4} \left\{ (\Delta \nu) \left[ \frac{-3}{v^3 e^{v-1}} \right] + (\Delta \nu^3 \frac{v}{3!(e^v-1)^3} \left[ (6+v^2+6v-12) e^v + (v^2-6v+6) e^2v \right] + \ldots \right\}
\]

(A.9)

Retaining only the term of order \( \Delta \nu \), Eq. (A.9) was used to calculate \( \eta \) to \( \pm 0.6\% \) when \( \nu > 1 \). The curve \( \nu = 1 \) on Fig. 3.1 separates the region of application of the two methods.
APPENDIX B

PROGRAM ARCRAD

B.1 PURPOSE

The purpose of this program is the calculation of radiation heat flux from a cylindrical air arc based on spectral emission-absorption characteristics of air and a measured or assumed temperature profile.

B.3 INITIALIZATION AND INPUT, PROGRAM NOTES

B.3.1 Initialization

1. General Initialization

   The Initial sequence sets aside 86 locations in the BUFFT array for the I-O buffer. Input requires 39 locations - output 47 locations.

2. Input Initialization

   Call ABUF1 sets up input buffer on A5. To read BCD, decimal tape number is 645. To read BIN, decimal tape number is 661. Logical tape number is 15.

3. Output Initialization

   BUFFS sets up output buffer on A6 to write labeled and blocked tape. To read BIN, decimal tape number is 662. Logical tape number is 16.

4. Header for File of LBT on A6

   Call LBID, specifies a BCD file name for label of a labeled and blocker tape to be written on A6. Call LBID for each file.

5. Identification of Case

   Call SPGHDR (FMT): page header is written with 12 BCD words of array FMT. Call SPGHDR for every case.

6. Error Initialization

   ERTRP allows printout and transfer to next case

B.3.2 Input

1. Tape

   Binary tape data is input for temperature $3000^\circ{K}$-25000$^\circ{K}$. This is a tape with 23 files, one file per temperature. A description of tape will be given in B.3.3.
2. Cards

a. number of cases (fixed point)

b. Cards per case

1) identification card

2) Radius of cylinder, decrease in wave number, highest wave number - AINC, angle difference in degrees of array ALPHA, divisions of original sectors (ALPHA array) of half cylinder (floating point)

3) number of wave numbers, number of annuli or temperatures, option for writing output tape, NT-1, NT+1, number of angles in ALPHA array, divisions of original sectors of half cylinder (fixed point)

4) temperature array: temperatures of annuli from outermost temperatures must be multiples of thousands in ascending order into core (floating point).

5) radius array: radii of annuli from outermost into core+1 (floating point)

6) radius array: radii of annuli from core to outermost (floating point)

7) log of density ratio array - log of density ratio of annuli from outermost into core (floating point)

B.3.3 Read in Process

Read in linear absorption coefficients for each case, interpolating as necessary.

1. General

A table of absorption coefficient data is interpolated with density selected from input tape and set up as a function of temperature and wave number, f (TEMP, WN)
2. Format

Data is stored in files. Each file corresponds to a temperature. File temperatures range from 3000°K to 25000°K in 1000°K increments. The first file (3000°K) is made up of 5 records. Record 1 is a BCD label. Record 2 is main table heading. The main table headings are: NT, TEMP(1), TEMP(2)... TEMP(23). Record 3 contains the number of words in the data subtable, plus heading: NW, ND, FMIC(1) FMIC(2)...FMIC(NW) DENS(1), DENS(2)...DENS(ND).

Note: NT is number of files

NW is number of wave numbers (21)
ND is the number of densities (5)
FMIC(1) is micron value of WN(1) = 10/WN(1)
FMIC(NW) is micron value of WN(NW)=10/WN(NW)
DENS(1) = -3 (RHO/RHOO)
DENS(ND) = 1 (RHO/RHOO)

Record 4 consists of one word, the temperature of the file. The last record, record 5, is the data subtable and contains linear absorption coefficients for the temperature of the file for all wave numbers for each of the 5 log density ratios. The remaining 22 files are composed of 3 records, corresponding to the format of the last 3 records of file 1: a subtable record, a temperature record, and a data record.

Temperatures (multiples of 1000°K) in array TEMP are stored in ascending order as are the file temperatures. Reading of files is controlled by DO N=1, NT (number of temperatures). Records of files are read up to and including temperature record. If the first and only word of the temperature record is not equal to the indexed TEMP(N), the file is closed and the next file is then read.
in a similar manner. If TEMP(N) and the one word of the temperature record are equal, the following record is read and processed for all wave numbers (61500-1500) to obtain the absorption coefficients. PROP(N, 1) through PROP(N, 121) for TEMP(N) with its associated log of density ratio (RHO(N)). The file is closed, the index for TEMP(N) is increased by 1 and the reading process continued to obtain linear absorption coefficients for all the indexed temperatures. The first file is read as a special case. The BCD record is read by a special instruction and then the 3 following records must be read to include the temperature record. The remaining 22 files are similar in read instructions; 2 records are read, the second being temperature record.

Records are all read in REC(700) which is large enough to include the largest record (the last) of the files.

The data for TEMP(N) is stored as a function of density and wavenumber in the following order: f(d1, NW1), f(d2, NW1), ..., f(d5, NW1), f(d1, NW2), f(d2, NW2), ..., f(d5, NW2), ..., f(d5, NW121). Where d is density and NW is wave number. Thus the data record (last record of each file) can be treated as 121 groups of 5. Each group corresponding to one wave number. The 5 linear absorption coefficients in each group are arranged in ascending order of log density ratio -3, -2, -1, 0, 1.

If the RHO(N) corresponding to TEMP(N) is an integer value between -3 and 1, the value IPST, which is the subscript of array REC is assigned as follows:

IPST = 1 if RHO(N) = -3
IPST = 2 if RHO(N) = -2
IPST = 3 if RHO(N) = -1
IPST = 4 if RHO(N) = 0
IPST = 5 if RHO(N) = -1
Control is then transferred to DO loop - DO I = 1, NW(121). The value REC(IPST) is read directly for linear absorption coefficient for first wave number. IPST is increased by 5 in last step of DO loop. When the DO is satisfied the linear absorption coefficients PROP(N, 1) through PROP(N, 121) are obtained for TEMP(N) with its corresponding RHO(N).

If RHO(N) is not an integer value but within the integer range, the linear absorption coefficient is obtained by logarithmic interpolation between tabulated values. IPST is set corresponding to the next lower RHO(N), e.g. RHO(N) = -2.5, IPST=1, PCNT is the fractional difference between tabulated values, REC(IPST) and REC(IPST+1). PCNT is equal to RHO(N) minus integer values less than RHO(N). Control is then transferred to a DO loop - DO I = 1, NW(121). Linear absorption coefficient for first wave numbers equals antilog of PCNT \( \{\log [\text{REC}(\text{IPST} + 1)] - \log [\text{REC}(\text{IPST})]\} + \log [\text{REC}(\text{IPST})] \). IPST is increased by 5 in last step of DO loop. When the DO is satisfied the linear absorption coefficients to PROP(N, 1) through PROP(N, 121) are obtained for TEMP(N) with its corresponding RHO(N).

If RHO(N) is greater than 1, PCNT is calculated as previously stated, and IPST is set equal to 5. Absorption coefficient is logarithmically extrapolated based on values of REC(IPST) and REC(IPST - 1).

The log difference of REC(IPST) and REC(IPST - 1) is added to REC(IPST) and an antilog is taken to obtain in DO loop similar to the one previously described PROP(N, 1) through PROP(N, 121) for TEMP(N) with its corresponding RHO(N).

This concludes the read in part of the program. Notes related to the remainder of the program are incorporated in the block diagram, section B. 4.

CALL ERROR

CALCULATION OF ABSORPTION LENGTH FOR EXTERIOR TRANSMISSIVITY AND INTERIOR EMISSIVITY

calculate sector radii $R(NQ)=...$

CALL ERROR $N<1$ $N=1$
NA designates angle of which subscript NQ is used counting inward to denote the annulus absorbing radiation from the Nth annulus.

NA=2, NALPHA

AKDR(N) = R(N)×PROP(N, I)
EKDR(NA) = AKDR(N)

EKDR are absorption lengths associated with TEMP(N) for all ALPHA(NA) for the calculation of emissivity inward

AKDR are components of the absorption path

SKDR(NA) = SKDR(NA) + AKDR(NQ)

SKDR are absorption length associated with TEMP(N+1) for all ALPHA(NA) for calculation of transmissivity (exterior)

SKDR(1) = DRK
absorption length at ALPHA(1)
CALCULATION OF INTERIOR EMISSIVITY

FKR(NA) is an empirical approximation to the transmissivity integral; the solution of FKR(NA) varies if EKDR(NA) ≤ 1, or >16.

Interior emissivity of a single annulus is identical to transmissivity of that annulus alone relative to the next interior annulus.

Transmissivity is sum of products of 2 integrals, one being DSINA(NA) the other approximated by FKR(NA).

The lower limit of transmissivity corresponds to sector-segment coincidence at NA=2, ⋯ NALPHA - upper limit at NA=1, ⋯ NALPHA - 1.

Prior to the Do statement EXTRMN and EXTRMX are set equal to 1, and this is the value used when the Do loop index has its initial value (N=1). Later in the loop EXTRMN and EXTRMX are calculated for use when the index is increased by one.

EOUT = 1 - EXPF(•••) 

interior emissivity is the average of upper and lower limit 

Finally, emissivity exterior to annulus 

Prior to the Do statement EXTRMN and EXTRMX are set equal to 1, and this is the value used when the Do loop index has its initial value (N=1). Later in the loop EXTRMN and EXTRMX are calculated for use when the index is increased by one.

APPENDIX C
CALCULATION OF ANNULUS RADII

C.1 ANALYSIS

If one assumes that an individual annulus is optically thin, then there exists a mean value J of total spectral radiance (watts/cm$^3$-steradian) such that

$$4\pi J \left[ \pi (r_j^2 - r_{j+1}^2) \right] = \int_{r_{j+1}}^{r_j} 2\pi r (4\pi J) \, dr$$

(C-1)

where Eq. (C-1) is written for a unit length of arc column. Further assuming that J is proportional to $T^4$ and knowing T as a function of r, Eq. (C-1) can be rewritten

$$T_j = \left\{ \frac{2}{r_j^2 - r_{j+1}^2} \int_{r_{j+1}}^{r_j} [T(r)]^4 \, r \, dr \right\}^{1/4}$$

(C-2)

For measured profiles, the function T(r) was approximated as a polynomial using a standard "least squares" curve fit computer program (Appendix D). Starting at the outer boundary of the arc column, successive values of $r_{j+1}$ were determined such that $T_j$ was a temperature at which absorption data were tabulated (multiples of 1000$^\circ$K).

Since $r_{j+1}$ appears both explicitly and as an integration limit, the following computerized iteration scheme was used. The outside and inside radii of the $j$th annulus are $r_j$ and $r_{j+1}$ respectively and the radius at which $T = T_j$ is $r(T_j)$ (see sketch). The radii $r(T_j)$ and $r(T_{j+1})$ were chosen as trial values of $r_{j+1}$ and the weighted average temperature computed from Eq. (C-2). Additional successive trial values of $r_{j+1}$ were obtained by linear interpolation from the two preceding trials. Typically four trials were needed to match the weighted average temperature to the tabulated $T_j$ within one degree Kelvin.
C.2 DESCRIPTION OF ANALYTIC TEMPERATURE PROFILE COMPUTER PROGRAM

A FORTRAN program called ANALYTIC TEMPERATURE PROFILE was written for the IBM 1620 Digital Computer and used to calculate the successive values of \( r_{j+1} \) satisfying Eq. (C.2). It requires as input data the constants of the polynomial describing the profile (see Appendix D) and a list of the \( T_j \).

Profiles derived from experimental data generally were incomplete. That is, the data extended neither to the centerline nor to the outer boundary. This program therefore automatically completed the profiles with parabolas which joined the curve fit polynomial smoothly and also satisfied the conditions of zero tem-

*From 10,000\(^\circ\)K up, increments of 1000\(^\circ\)K in \( T \); were used to make maximum use of available data. Below 10,000\(^\circ\)K increments were usually 2000\(^\circ\)K because in this temperature range the temperature gradient was generally very steep and the 1000\(^\circ\)K increment would result in annuli unnecessarily thin compared to the higher temperature ones.
temperature gradient at the centerline and a given outer boundary temperature. Next, a calculation of the values of \( r(T_j) \) was necessary. Since the curve fit polynomial was usually at least 3rd order the Newton-Raphson iteration method was used.

Arbitrary profiles of the form of Eq. 3.3 were complete without end parabolas and could be solved exactly for the \( r(T_j) \). A simplified version of the Analytic Temperature Profile program was used with these profiles. The statements in the program listing, Section C. 5, which are bracketed were deleted and four statements were added to compute the \( r(T_j) \).
C.3 DEFINITION OF SYMBOLS FOR COMPUTER PROGRAM

A(N)  Constants associated with curve fit polynomial
B, B2  Constants associated with inner parabola
C, Cl  Constants associated with interpolation of RLLIM
COEF  Coefficient used in calculation of R(N) by Newton-Raphson Method
DELT  Number of intervals for numerical integration
DRAD  Radius increment
E, E1, E2  Constants associated with outer parabola
F(I)  Function of radius \( F(I) = \left[ T(R) \right]^4 \times R \)
FINTG  \( \int FdR \)
FPOW  After some calculation steps FPOW = T(R)
I  Index for integration
UMAX  Maximum value of I
K  Index
L  Index for computing R(N) and for computing \( [RLLIM(L), TAVG(L)] \)
N  Index for temperature
NCST  Number of constants in curve fit polynomial
NORD  Order of curve fit polynomial
NT  Number of temperatures
PRNUM  Profile number
R(N)  Radius associated with Nth temperature
RAD  Radius
RB  Intermediate variable in computing $R(N)$
RD, RE  Radii at which inner and outer parabolas, respectively, join the curve fit polynomial
RDIF  Error in Newton-Raphson calculation of $R(N)$
RJ(N)  Inside radius of annulus having a weighted average temperature $T(N)$
RPOWER  Intermediate variable in computing $R(N)$
RLLIM(L)  Lower limit radius for $TAVG(L)$ integration
RTOL  Tolerance on Newton Raphson calculation of $R(N)$
RULIM  Upper limit radius for $TAVG(L)$ integration
SUM1, SUM2, SUM3  Intermediate variables in $TAVG$ integration
T(N)  $N^{th}$ temperature
TAVG(L)  Weighted average temperature
TD  Temperature at $R = RD$
TDIF  Difference between $TAVG(3)$ and $T(N)$
TDIFA  Absolute value of TDIF
TDP  Slope of temperature profile at $R = RD$
TE  Slope of temperature at $R = RE$
TEP  Slope of temperature profile at $R = RE$
TNR  Temperature as used in Newton-Raphson calculation
TPNR  Slope of temperature profile as used in Newton-Raphson calculation of $R(N)$
TTOL  Tolerance on TDIF
C.4 BLOCK DIAGRAM

1. Read Special Data:

CURVE FIT FOR TEMPERATURE PROFILE DATA

D.1 ARCRAD CURVE FIT PROGRAM DESCRIPTION

Reduction of temperature profile data to analytic form was accomplished by making use of a modification of a standard computer program by W. R. Greaves (Ref. 19) entitled POLYNOMIAL CURVE FITTING, NO CONSTRAINTS.

The following changes were made in Greaves' program.

1. Format statements were added to change from "No Format" FORTRAN to FORTRAN I.

2. The maximum order polynomial was reduced from 50 to 7.

3. Provision for weighting data was eliminated.

4. Control statements were rewritten to the form shown in the accompanying block diagram.

The ARCRAD CURVE FIT program fits a straight line and successively higher order curves to the input data on a "least squares" basis. For each order curve the polynomial constants and the standard error are printed. As the order of the fitted curve increases the standard error at first decreases, then levels off and either increases or oscillates. A curve which is the best compromise between minimum order and minimum standard error is selected as most representative of the data. The program automatically causes a card to be punched for each constant in the polynomial for use as input to the ANALYTIC TEMPERATURE PROFILE program. Finally, for the order selected, the value of the polynomial at each input data point is printed, along with the input data value and the difference.

The number of data points must be at least 2 greater than the order of the maximum order polynomial. The program can handle up to 50 sets of data and computes polynomials up to seventh order but these limits can easily be changed by appropriate changes in the DIMENSION statement.
D.2 SENSE SWITCH SETTINGS

Flexibility in program utilization is made possible by the Sense Switches. Switch 1 OFF causes automatic selection of the 3rd order polynomial. Switch 1 ON causes the computer to pause after printing the constants and the standard error for the preselected maximum order. The desired order polynomial can then be selected and inserted in the machine by on-line typewriter (ACCEPT statement).

Switch 2 ON eliminates automatic card punching of the polynomial constants.

D.3 ARCRAD CURVE FIT DEFINITION SYMBOLS

AM (I, J) Matrix of coefficients of normal equations
DIF Difference between Y(I) and YFLEX(I)
LAST Highest order polynomial to be fitted
NDATA Number of data points
PRNUM Serial number of temperature profile

\[
\begin{align*}
\text{SUMX}(J) & = \sum_{i=1}^{N} (X_i)^{J-1} \\
\text{SUMY}(J) & = \sum_{i=1}^{N} (Y_i)(X_i)^{J-1}
\end{align*}
\]

S1 Same as YFLEX(I)

\[
S2 = \sqrt{\frac{N}{NDATA-NORD-1} \sum_{i=1}^{N} (Y_i - YFLEX_i)^2}
\]

S3 Same as DIF

X(I) \(i^{th}\) value of independent variable (radius)

Y(I) \(i^{th}\) value of dependent variable (temperature)

YFLEX(I) Value of the polynomial at X(I)

APPENDIX E
MEASUREMENT OF TEMPERATURE PROFILES

Conditions required for application of the intensity ratio technique are: (1) steady symmetric source, (2) Boltzmann distribution of the atomic energy levels (i.e., local thermal equilibrium of the plasma particles) and (3) optically thin plasma at the frequency of the emission line. The first condition was checked photographically with a Fastax camera operating at 3000 to 5000 frames per second. In this speed range, which was of the same order as the spectrograph exposures of 1/1000 sec, the source appeared steady and uniform. The existence of local thermal equilibrium is discussed in Section 2.1. Optical thinness is one of the factors governing the choice of suitable lines. At one atmosphere several lines can be used, but at 2 atmospheres only the oxygen pair 7774 A - 7947 A is suitable and it is near marginal. Relative intensity at a given wavelength is related to transition probability $A$, atom number density $N$ and photon energy $h\nu$ by

$$\frac{I_{\lambda 1}}{I_{\lambda 2}} = \frac{A_1 N_1 (h\nu)_1}{A_2 N_2 (h\nu)_2}$$  \hspace{1cm} (E-1)

For spectral lines of the same species, assuming a Boltzmann distribution of energy states

$$\frac{I_{\lambda 1}}{I_{\lambda 2}} = \frac{g_1 A_1 \lambda_1 e^{-\frac{(E_1 - E_2)}{kT}}}{g_2 A_2 \lambda_2}$$  \hspace{1cm} (E-2)

where $g$ is the statistical weight of an energy state and $E$ is the excitation energy of the upper state energy level. Solving for $T$

$$T = \frac{(E_1 - E_2) (1/k)}{\ln(g_1 A_1 \nu_1 / g_2 A_2 \nu_2) - \ln(I_{\lambda 2}/I_{\lambda 1})}$$  \hspace{1cm} (E-3)
The excitation energies and transition probabilities are known, so spectrographic measurement of the intensity ratios establishes an "average" temperature of the column. To determine the temperature distribution the true intensity distribution must be calculated from the "average" observed intensity using Abel's integral equation

\[ I(x) = 2 \int_0^\delta \frac{n(r) \, r \, dx}{\sqrt{r^2 - x^2}} \]  

(E-4)

where \( I(x) \) is observed intensity over radius \( x \) and \( n(r) \) is the number density of emitters in particular radial bands of radius \( r \). This function has been tabulated by Pearce (Ref. 20).

Temperature level can be established because the spectral line intensity goes through a maximum at a unique temperature for a given pressure. This maximum, the so called peaking function, results from the counter-balancing effects of increased excitation of the upper states, which increases the number of emitters per unit volume, and increased ionization which reduces the number of emitters per unit volume. The technique has been described in detail by Sadjian (Ref. 21). For this study the oxygen atom pair, \( \lambda = 7947 \, \text{Å} \) and 7774 \, \text{Å} \) were used as well as the nitrogen atom/ion pair, \( \lambda = 4137 \, \text{Å} \) and 3995 \, \text{Å} \).
STUDY OF RADIATION HEAT FLUX FROM HIGH PRESSURE AIR ARCS

This document has been approved for public release and its distribution is unlimited.

A computational model has been developed and applied for calculating radiant heat flux from an electric arc using real gas properties and taking into account both self absorption and space varying temperature. The model requires knowledge of the temperature profile as an input. Temperature profiles were measured spectrographically using an air arc at one and 2.4 atmospheres. These measured profiles plus some simple analytic ones which satisfied boundary conditions were used to calculate radiant heat flux at pressures from 1 to 300 atmospheres. The experimental program also included measurements of radiant flux density at 2.2 and 5.7 atmospheres for comparison with calculations based on the measured profiles. Estimates were made of radiation losses in the AEDC 20-megawatt arc air heater now under development.
