ABSTRACT

Underwater explosions at great depth have been simulated by detonating small spherical pentolite charges in vessels hydrostatically pressured to 4000 psi. An increase in hydrostatic pressure is found to have no effect on the peak magnitude of the primary shock wave, but the impulse per unit area and the duration of the positive phase of the initial pressure pulse are observed to decrease with an increase in hydrostatic pressure. The magnitude of the negative phase of the shock wave increases as the hydrostatic pressure increases. Although little difficulty is encountered in studying primary pressure pulses in pressure vessels, secondary pressure pulses created by expansion and contraction of the gas bubble formed by the detonation are difficult to observe due to the large displacement of the water particles at close-in distances and the associated acceleration of the piezoelectric pressure transducer at the times of interest. Also, the myriad of reflections from the gauge positioning devices and the vessel walls and the inconsistency usually exhibited by bubble pulses under seemingly identical conditions complicate analysis of the secondary pulses. The magnitude of the bubble pulse appears to increase as the hydrostatic pressure increases, and, at moderately high hydrostatic levels, the frequency of the bubble oscillation is such that the bubble pulse is recorded as a vibration.

I. INTRODUCTION

In full-scale ocean tests, pressure measurements close to the detonation center of deep explosions are both expensive and technically difficult. Consequently, theoretical studies\(^{(1,2)}\) of underwater explosions at great depths have been based on pressure recordings taken at relatively long distances from the center of the explosion but conveniently close to the surface. The use of pressure vessels to study shock waves from charges detonated under high hydrostatic pressure has facilitated observations of the pressure pulses at close-in distances.

The measurement of the initial shock pressures from a detonation contained within a pressure vessel is rather straightforward. Secondary pressure surges, such as the pulses created by the swelling and contraction of the gas bubble formed by the detonation, are difficult to observe, however, due to reflections within the vessel. This report is concerned with summarizing measurements of the characteristics of the primary shock wave under increasing hydrostatic pressures, summarizing observations of the effect of hydrostatic pressure on the bubble pulse at close-in distances and discussing the utility and difficulties associated with the use of pressure vessels for studying the effects of underwater explosions superposed on high hydrostatic pressures.
II. SUMMARY AND CONCLUSIONS

Primary pressure pulses from small charges are readily observed in vessels hydrostatically pressured to 4000 to 5000 psi. It is expedient that the vessel diameter be large enough to prevent reflection from the walls prior to the end of the pulse. Some difficulty is encountered with small, eight-gram charges in that observed values more often deviate from anticipated or calculated values than do 13-gram charges. This is perhaps due to the fact that the blasting cap used to initiate detonation is a greater percentage of the charge weight and the pressures it generates are more directional than the main spherical charge. With both size charges, however, it is observed that hydrostatic pressure does not alter the peak pressure of the initial shock wave. It is further noted that both the duration and impulse per unit area of the positive pressure phase decrease with an increase in hydrostatic pressure. The magnitude of the negative phase of the initial pressure pulse increases as the hydrostatic pressure increases.

Bubble pulses from small charges are difficult to produce with any degree of consistency. Measurement of their characteristics in a pressure vessel is impeded by vibration and reflection, and it is necessary to compare peak to peak pressure values from bubble pulses at high hydrostatic pressures. The bubble pulse period agrees rather well with the predicted value for all levels of hydrostatic pressure to 3000 psi. At
the higher pressures (even 500 psi), the bubble pulses appear as a continuous damped vibration, which is the reason for the peak to peak comparison. This peak to peak value increases as the hydrostatic pressure increases.

The apparent limitation of pressure vessels for studying secondary pulses from underwater explosions at great depth may be overcome with a technique for damping reflection at the vessel walls. Appropriate wire mesh adjacent to the wall may not only dissipate the impinging shock and prevent reflection but may also afford some protection to the vessel. A method for bubbling air adjacent to the wall prevents shock reflection, but it also disturbs the primary pulse at the point of interest. It is recommended that this method be investigated further to provide greater utility in the use of pressure vessels for studying secondary pulses at distances close to the detonation center.
III. DESCRIPTION OF FACILITY AND INSTRUMENTATION

Testing was accomplished in two pressure vessels, one with a two and one-half-foot inside diameter and the other with a four-foot inside diameter. The 30-inch vessel was used primarily for studies of the initial shock pulse while the four-foot vessel was utilized for observations of the bubble pulse.

Spherical pentolite charges cast by Naval Ordnance Laboratories, White Oak, Silver Spring, Maryland were used in all of the tests. All charges had a cap well and detonation was initiated with Hercules J-2 Engineers Special EB caps, which have a pentolite equivalent of 1.1 gms. The 13.5-gm charges had a diameter of one inch, and the 7.5-gm charges had a diameter of five-sixths inch. Plastic pipe with a plastic steel filler was used to reinforce the blasting cap for high pressure shots, as shown schematically in Figure 1. The reinforcing was used in all shots to insure consistency in charge configuration for all shots. It was necessary to immerse the pentolite charge about one-sixteenth inch into the plastic steel filler to obtain detonation at pressures above 2,500 - 3,000 psi. This immersion was not necessary for the low pressure shots.

Pressures were measured with 1/4" diameter tourmaline piezoelectric crystals manufactured and calibrated by Crystal Research, Inc., Cambridge, Massachusetts. Voltages generated by these gages were
FIGURE 1. SCHEMATIC OF CHARGE ASSEMBLY
transmitted from the pressure vessel by an uninterrupted length of one-half-inch diameter low noise coaxial cable. (Specifically, the cables were Simplex Antimicrophonic Cable, two conductors No. 18 AWG.)

A continuous cable through the pressure vessel wall was deemed desirable to prevent an added problem of electrically insulating a connector at a high pressure seal. Several types of seals were investigated, all of which operated successfully to around 1000 psi. An O-ring type seal allowed the cable to be extruded with no visible damage after a couple of shots at 1000 psi. A wedge type teflon seal appeared to be satisfactory to about 2000 psi, but with an increase in pressure it was necessary to tighten the wedge to a point where the twinnex leads were parted. It was also determined that an appropriate wedge could not be vulcanized as an integral part of the cable without extreme difficulty.

A suitable seal, as shown in Figure 2, was finally obtained by using Devcon plastic steel diluted with a softening agent. When a thinner was used to insure complete penetration to thin parts of the wedge, adequate stiffness and strength were not achieved. The desired flexibility of the filler approximated that of a rubber tire.

To achieve proper bonding between the neoprene surface of the cable and the plastic filler, it was necessary to roughen the neoprene with sandpaper and clean it with toluene. The seal assembly operates on the principal of pressure induced friction, and it is important to insure slight
NOTES:
MATERIAL: MILD STEEL
TOLERANCE: ± 1/32 UNLESS NOTED

FIGURE 2: HIGH PRESSURE COAXIAL CABLE SEAL
flexibility of the plastic filler to prevent relative motion between various layers of the coaxial cable. There should not, however, be relative motion between the Devcon filler and the steel housing.

Calibrating capacitors of .01 microfarads were placed in parallel with the piezoelectric crystals at the terminus of the low noise simplex cable. This capacitance was large relative to the transducer and cable capacitance (of around 0.0007 microfarads) and minimized any effect of impinging shock on the cable capacitance and its consequent effect on the transmitted signal.

Signals from the tourmaline transducers were displayed on Tektronix 502 oscilloscopes. The differential amplifiers internal to the scopes were used on all tests after the initial three shots. Displays were recorded on Polaroid Type 37 film through the use of a Dumont Type 302 Oscillograph Record Camera with an f/1.9 lens.

The oscilloscopes were triggered with a breakwire activating the single pulse circuit shown in Figure 3. This device was successful in limiting the scopes to a single sweep. It also served as a calibration unit for scope deflection by generating a one-volt instantaneous step with a 30-microsecond decay.

A 100-KC marker generator (Figure 4) was used as a timing calibrator in several shots through the use of the Z-axis of the oscilloscopes. Every ten microseconds, the accelerating potential of the electron beam
was turned off. This method was abandoned, however, since it interfered with the clarity of the recorded trace.
IV. MEASUREMENT OF SHOCK WAVE CHARACTERISTICS

The pressure-voltage relation for tourmaline gauges is given by

\[ p = \frac{c}{ka} v \]  \hspace{1cm} (1) \]

where

- \( p \) = pressure, psi
- \( c \) = capacitance, farads
- \( ka \) = gauge constant, coulombs/psi
- \( v \) = scope deflection, volts

An empirical relation from which the peak overpressure can be predicted is \(^{(4)}\)

\[ P_c = k \left( \frac{w^{1/3}}{R} \right)^{\alpha} \]

where

- \( P_c \) = calculated peak overpressure, psi
- \( w \) = charge weight, lbs.
- \( R \) = distance from charge, ft.
- \( k, \alpha \) = empirical constant

For the spherical 50/50 pentolite charges used in these tests, \( k = 22,500 \), \( \alpha = 1.13 \). The J-2 caps used as initiators were equivalent to 1.1 gms of pentolite.

In the initial tests in the 30-inch tank, the gage-charge suspension assembly was such that an early reflection from the gauge mount was
possible. Results of the first three tests, during which an external amplifier was used, are shown in Appendix A (Figures 1A, 2A, and 3A). Even though drift in the amplifier precluded accurate calibration, peak overpressures at static pressures of zero and 500 psi are seen to be equivalent. It is to be noted that area measurements for unit impulse were not always possible in the initial shots. After the first three shots, the oscilloscope differential amplifiers were used to magnify the tourmaline response. Data from Shots 7 through 10 are shown in Figures 4A through 7A.

Prior to Shot 12, the suspension assembly was modified as shown in Figure 5 so that the gages could be positioned with tape on small wires to alleviate the problem of early reflection. Also, epoxy seals were implemented for the first time. In order to avoid systematic increase or decrease in hydrostatic pressure and any associated drift in tourmaline response due to such a procedure, a pressure of 3500 psi was randomly chosen for Shot 12. At 2900 psi, however, the seal on Gauge 527 could not contain the pressure. The pressure had leaked to around 1540 psi before the charge could be detonated. At around 800 psi, the seal again functioned properly. From Figure 8A, it is seen that pressures were higher than anticipated at three locations. Shot 13 (Figure 9A) was made at zero pressure for purposes of calibration. Again the measured pressures exceeded calculated values. Another attempt was made to shoot in a 3500-psi medium, but at 3200 psi the firing line broke. The seal on Gauge 527
FIGURE 5. SCHEMATIC OF SUSPENSION FRAME
failed at 2700 psi upon repressurization. Shot 14 was finally accomplished at 2000 psi, after the lead-through to Gauge 527 had been blanked. Figure 10A shows that the response again was high.

It was noted that the high pressures in Shots 12 through 14 corresponded to pressures that should be obtained one-half inch closer to the charge. Distances were predicated on the basis of length from center of charge to gauge tip, and errors in measurement were probably less than one-eighth inch. Also the consistency of above average pressures in corresponding to distances a charge radius closer to the gauge indicated that spatial configuration was probably at fault. That is, the alignment of the gauges relative to the charge was such that the gauges were on (or nearly on) the blasting cap side of the charge. The rod holding the charge was shortened so that the gauges would be on the side of the charge away from the cap. This introduced the difficulty of aligning the gauges to point straight at the charge. Shot 15 (Figure 11A) was accomplished at 3000 psi, but a higher than anticipated pressure was measured at one of the positions. Again the positioning device for the charge was shortened. The charge was detonated at 1500 psi for Shot 16 (Figure 12A), during which a timing mark was superposed on the recorded signal. Unfortunately, the peak response could be distinguished only when the original recording was placed on a light table.

Shots 17 and 18 (Figures 13A and 14A) were calibration shots at zero pressure. Shot 19 (Figure 15A) was made at 3500 psi. Gauge 529 was
replaced after it leaked at low pressure. Unfortunately, the seal on the
gauge used to replace Gauge 528 extruded prior to detonation.

In Shot 20 (Figure 16A), the cable seals successfully contained
4500 psi, even after detonation. The spherical pentolite charge did not
detonate, however, as evidenced by both explosion noise and charge frag-
ments remaining in the vessel.

Shot No. 21 (Figure 17A) was a calibration shot at ambient pressure.
Prior to Shot 22 (Figure 18A) a leak developed in one of the cable seals,
and the eight-inch air blanket normally maintained at the top of the pres-
sure vessel for each shot was lost; but a pressure of 1,000 psi was achieved
with little difficulty and the charge was detonated. The lack of an air
blanket did not appear to affect the characteristics of the shock wave,
however.

Shot 23 was made at 500 psi (Figure 19A). In Shots 24 and 25, the
electric blasting caps failed at 2400 and 2800 psi. Shot 26 (Figure 20A)
was a calibration shot, and Shot 27 (Figure 21A) was made under a hydro-
static pressure of 4000 psi. During a subsequent attempt to shoot at 4500 psi,
the blasting cap failed at 3950 psi.

Peak pressures achieved from detonation of the 13.7-gm charges
are shown in Table I. In Figure 6, the ratio of the peak measured pres-
sure, $P_p$, to the peak calculated pressure, $P_c$, is plotted against hydro-
static pressure. This ratio stays close to unity and indicates that an in-
crease in hydrostatic pressure does not affect the magnitude of the peak

overpressure. The duration of the positive phase of the pressure pulse is summarized in Table II. For zero hydrostatic pressure, it was difficult to assess the time required for the shock pressure to return to zero, but, as shown in Figure 7, an increase in hydrostatic pressure definitely decreased the duration of the overpressure.

The area under the positive pressure phase is equivalent to the impulse per unit area. A summary of these measurements is shown in Table III and Figure 8, where it is seen that the impulse decreases as the hydrostatic pressure increases.

Table IV and Figure 9 show the magnitude by which the pressure pulse goes below the hydrostatic pressure. It is evident that the negative pressure (relative to the original hydrostatic pressure) increased as the hydrostatic pressure was increased.

It is sometimes convenient to use semi-log plots to compare the characteristics of shock waves. Representative curves for shock waves from 13.7-gm charges detonated at 1, 1500, 3000, 3500, and 4000 psi are shown in Figures 22A through 26A, respectively. These curves are summarized in Figure 10 for the pressure at 12 inches and in Figure 11 for the pressure at 8 inches. The summaries show that the slope of the decay is more rapid for the higher hydrostatic pressures.

FIGURE 9. NEGATIVE PRESSURE AT 8 INCHES AND 12 INCHES FROM 14.7 TO 14.8-GM PENTOLITE CHARGES DETONATED AT VARIOUS HYDROSTATIC PRESSURES
FIGURE 10. SUMMARY OF SHOCK OVERPRESSURES 12 IN. FROM CENTER OF 14.7 TO 14.8 CM PENTOLITE CHARGES DETONATED UNDER VARIOUS HYDROSTATIC Pressures AS A FUNCTION OF TIME
FIGURE 11. SUMMARY OF SHOCK OVERPRESSURES 8 INCHES FROM CENTER OF 14.7 TO 14.8-GM PENTOLITE CHARGES DETONATED UNDER VARIOUS HYDROSTATIC Pressures AS A FUNCTION OF TIME
A series of tests was made with seven and one-half-gm spherical Pentolite charges to determine whether or not the trends noted on pulse duration, impulse per unit area and negative pressure magnitude could be obtained with a smaller charge as the hydrostatic pressure varied. Data from these shots are shown in Appendix B, except for bubble pulse observations which are grouped in Appendix C. Figure 12 shows again that the peak shock overpressure is not noticeably affected by an increase of hydrostatic pressure. In Figure 13, the duration of the positive pressure phase is seen to decrease as the hydrostatic pressure increases. The same is true for the impulse per unit area, as is indicated in Figure 14. The negative pressure increases, however, as the hydrostatic pressure increases (Figure 15). It should be remembered that the negative pressure indicates the amount by which the shock pulse decreases below the hydrostatic level. To summarize, it is seen that the data in Figures 12 through 15 reinforce the observations presented in Figures 8 through 11.

FIGURE 15. NEGATIVE PRESSURES FROM 7.4-GM PENTOLITE CHARGES DETONATED AT VARIOUS HYDROSTATIC PRESSURES.
V. BUBBLE PULSE MEASUREMENTS

Measurement of bubble pulse characteristics as affected by increasing hydrostatic pressure is considerably more difficult than observations of the primary pressure pulse under similar circumstances, especially within pressure vessels. Even under "free field" conditions in the open ocean, close-in measurements of pressures from bubble pulsations are difficult to perform, and reproducible results under supposedly identical conditions are seldom achieved\(^ {4}\).

The Willis formula for bubble pulse period\(^ {4}\) is

\[
T = \frac{k w^{1/3}}{(D + 33)^{5/6}}
\]

where

- \(T\) = period, sec.
- \(W\) = charge weight, lbs.
- \(D\) = depth, ft.

From this, the period of bubble oscillation for 7.4-gm Pentolite charge initiated by a J-2 electric blasting cap at a depth of five feet in a pressure tank is estimated to be about 56 milliseconds. In Figure 1C, the time from detonation until the first positive bubble pulse arrives at a distance of eight inches is about 40 milliseconds for two gauges. The time between the first and second oscillation is 54 milliseconds for both gauges. The magnitude of the peak pressure was overestimated, however,
so that the vertical deflection (indicating pressure magnitude) was not easily measured. Shots 1B through 5B were then made in the 30-inch tank. A third oscilloscope was used to record piezoelectric response at times corresponding to anticipated bubble pulse arrival for both the eight-inch position and the twelve-inch position. The shock pressures from these tests are shown in Appendix B and the bubble pulses are shown in Appendix C.

In Shot 1B the primary pressure pulse was lower than anticipated at all four gauge positions. The bubble pulse was also weaker than it should have been (Figure 2C). A second shot was made at zero confining pressure (Figure 3C), but again the peak bubble pressure was not even as high as indicated in Shot 1A.

In a third shot made in a 2,000-psi environment, the oscilloscope displaying the bubble pulse characteristic did not trigger. At 1,500 psi (Figure 4C), the peak pressure of the bubble pulse had increased to about 350 psi at 12 inches and 250 psi at 8 inches. It should be noted, however, that Gauge No. 3 at 8 inches was giving a low reading for the shock pressures in Shots 1B through 5B. The indication was, however, that the magnitude of the bubble pulse increased as the hydrostatic pressure increased.

Shot 5B was made at 3,000 psi and an allowance was made for an increase in bubble pressure on the third oscilloscope. As shown in
Figure 5C, the magnitude of the bubble pulse appeared to increase again with a further increase in pressure. To compare Figures 4C and 5C, it was necessary to estimate peak to peak deflection from Figure 5C. The recurring pressure peaks occur at intervals that agree with the calculated bubble period for the respective pressures. In both figures, however, the initial portion of the sweep is unreadable. This is due in part to the overshoot caused by the high shock pressure arriving immediately after detonation. Other spurious signals were probably caused by gauge accelerations and pressure reflections.

In an attempt to improve the bubble pulse detail, additional tests were performed in a larger vessel with a four-foot diameter. Hydrostatic levels in this tank were limited to 500 psi due to the shock pressure anticipated at the vessel wall. The charge and one gauge were positioned as nearly as possible on the vessel centerline. For the first few tests, a second gauge was positioned four inches from the centerline gauge and at the same distance from the charge as the first gauge. The output from the centerline gauge, which was above the charge and positioned with wires, was transmitted to two oscilloscopes, one of which was on a slow sweep rate so as to display secondary pressure pulses. As shown in Figure 6C, the bubble period corresponded fairly closely to the anticipated period. Maximum bubble pressure was about 465 psi, peak to peak. The primary pressure pulse indicated a peak pressure of about 8000 psi when the record was illuminated by light.
In Shot 7B (Figure 7C), the bubble pulse period again was in close agreement with the calculated value; but the peak to peak value of the pressure pulse appeared to be about 290 psi. If the thin, faint spike of the bubble pulse in Figure 6C is neglected, the bubble pulse values obtained in the two shots agree reasonably well. The peak values of the initial shock wave were larger than would be anticipated, but the reflection from the vessel wall was lower than it previously had been.

Prior to Shot 8B, a two-foot wide section of flat steel mesh was placed two inches from the vessel wall symmetrically around the charge. The arrangement is shown in Figure 16. One gauge was placed on the vessel centerline, while a second gauge was placed between the vessel wall and the mesh. In Shot 8B (as shown in Figure 8C), the reflection was minimized and the pressure outside the mesh was about 1690 psi; whereas it was calculated to be 2280 psi. Similar results were obtained in Shot 9B (Figure 9C).

Shot 10B (Figure 10C) was made at 500 psi. In this instance the peak shock pressure was lower than anticipated at eight inches, but the bubble pulse period was reasonably close to the expected value. Equivalent results were again obtained in Shot 11B (Figure 11C), which was made at 500 psi.

To try to reduce the vibrations, it was decided to move the center-line gauge farther from the charge. Shot 12B (Figure 12C), also made
at 500 psi, indicated that some reduction in random vibration was achieved. A final pressurized shot, No. 13B (Figure 13C) was accomplished with the bubble pulse gauge positioned 15 inches from the charge. A slight improvement in clarity of detail was achieved, but it was still necessary to compare the results with zero pressure shots on a peak to peak basis. Shot 14B (Figure 14C) was made at 20 psi with instrument positions the same as they were in Shot 13B except for the sweep speed of the oscilloscope displaying the bubble pulse. This shot was made at 20 psi to provide a bubble pulse under near-zero psi conditions but with enough pressure to provide some of the stability afforded the tank under the higher pressure shots. The spike of the bubble pulse indicated a pressure of 240 psi, which is somewhat greater than the bubble pressures measured at zero confining pressure.

From the above discussion of the data presented in Appendix C, it is obvious that measurement of bubble pulse characteristics at high pressures within a pressurized tank is impeded by reflections from the tank walls and vibration of the gauge positioning device, which is usually a cantilevered rod or two wires spanning the distance between two pipes. At zero confining pressure, the bubble pulse arrives after much of the random vibration has ceased, even at the close-in distances of interest. At higher pressures, however, the pulses occur so quickly that random vibrations do not have time to dissipate. Apparently, bubble pulses are
difficult to observe close to the charge even under free-field conditions at shallow depths \(^{(4)}\), but at greater depths and pressures, water motion and random agitation from the primary shock wave compounds the problem.

Two qualitative trends appear to emerge from the data: (a) the peak to peak magnitude of the bubble pulse seemingly increases as the hydrostatic pressure increases and (b) the bubble pulse appears as a continuous vibration at greater depths.
VI. ADVANTAGES AND LIMITATIONS OF PRESSURE VESSELS FOR STUDYING UNDERWATER EXPLOSIONS

For small charges detonated at great depths, pressure vessels offer an economic advantage over free-field tests in the ocean. Also, a technical advantage is achieved in the shorter leads used to transmit the pulse characteristics from the sensing device within the vessel to a recording system. Further, there is a convenience factor in having a fixed site for experimentation.

These advantages are rather straightforward for observations of pressure pulses which occur prior to the arrival of wall reflections at the point of interest. Of course, the larger the vessel diameter, the less the depth that can be simulated for a given vessel wall thickness. Pulses which occur at a relatively long interval after the arrival of the initial shock wave do not appear to be distorted by the previously occurring reflections; but these reflections can conceivably distort the bubble source which gives rise to the later pulsations.

At higher pressures, the bubble pulses arrive while the gauge positioning devices are still vibrating and accelerating the tourmaline transducers. Also, reflections have not completely died out upon the arrival of the first pulse. Correction of the observed pressures for the myriad of reflections and vibrations would be both complex and questionable.

In the current study two attempts were made to reduce the reflected pressure and protect the vessel wall. The wire mesh shown in Figure 16
was used in several shots, but the results were erratic, both with respect to the pressure transmitted through the mesh and the reflected pressure. The center gauge was positioned with a cantilevered rod for Shots 11B through 14B. In Figures 10C and 11C, the reflections and pressure transmitted through the mesh were equivalent, so that no effect was introduced by removing the wire previously used to hold the gauges. In subsequent tests, however, the reflected pressure was unusually large and the pressure transmitted through the mesh appeared to increase.

Another attempt to dampen the reflection involved the use of air bubbles adjacent to the tank wall. A ring of copper tubing with one-eighth-inch holes every two inches was placed around the inside of the vessel at the bottom, and air was bubbled up the tank walls prior to and during detonation. Unfortunately, a small circulation was introduced in the tank, so that the pressure pulses (shown in Figure 17) were distorted; but reflection from the tank wall was not observed.

To summarize, it appears that a means for minimizing shock reflection from the vessel wall is possible but needs further investigation. Different types of mesh and bubble arrangements should be investigated. Also, gauge positioning devices in pressure vessels are critical for studying secondary pulses in that they must be small so as not to interfere with the primary shock wave but must be sturdy so as to resist vibrations and reflections occurring prior to or during the arrival of secondary pulses.
Comments: Air bubbled around vessel wall.

APPENDIX B

OSCILLOSCOPE RECORDS OF TESTS WITH 7.4-GM PENTOLITE CHARGES

Note: The suspension frame shown in Figure 5 was used for all tests noted in Appendix B. The two top gages were 12 inches from the charge center and the bottom gages were at a distance of 8 inches.
Comments: Bubble pulse shown in Figure 2C.

Charge Weight: 7.4 gms Pentolite + J-2 cap = 8.5 gms

Figure 14C, Shot 14B, 20 psi, Bubble Pulse
Underwater explosions at great depth have been simulated by detonating small spherical pentolite charges in vessels hydrostatically pressured to 4000 psi. An increase in hydrostatic pressure is found to have no effect on the peak magnitude of the primary shock wave, but the impulse per unit area and the duration of the positive phase of the initial pressure pulse are observed to decrease with an increase in hydrostatic pressure. The magnitude of the negative phase of the shock wave increases as the hydrostatic pressure increases. Although little difficulty is encountered in studying primary pressure pulses in pressure vessels, secondary pressure pulses created by expansion and contraction of the gas bubble formed by the detonation are difficult to observe due to the large displacement of the water particles at close-in distances and the associated acceleration of the piezoelectric pressure transducer at the times of interest. Also, the myriad of reflections from the gauge positioning devices and the vessel walls and the inconsistency usually exhibited by bubble pulses under seemingly identical conditions complicate analysis of the secondary pulses. The magnitude of the bubble pulse appears to increase as the hydrostatic pressure increases, and, at moderately high hydrostatic levels, the frequency of the bubble oscillation is such that the bubble pulse is recorded as a vibration. (U)
Underwater Explosions, Effect of Depth Upon

<tbody>
<tr>
<td>1. ORIGINATING ACTIVITY: Enter the name and address of the contractor, subcontractor, grantee, Department of Defense activity or other organization (corporate author) issuing the report.</td>
</tr>
<tr>
<td>2a. REPORT SECURITY CLASSIFICATION: Enter the overall security classification of the report. Indicate whether &quot;Restricted Data&quot; is included. Marking is to be in accordance with appropriate security regulations.</td>
</tr>
<tr>
<td>2b. GROUP: Automatic downgrading is specified in DoD Directive 5200.10 and Armed Forces Industrial Manual. Enter the group number. Also, when applicable, show that optional markings have been used for Group 3 and Group 4 as authorized.</td>
</tr>
<tr>
<td>3. REPORT TITLE: Enter the complete report title in all capital letters. Titles in all cases should be unclassified. If a meaningful title cannot be selected without classification, show title classification in all capital letters in parenthesis immediately following the title.</td>
</tr>
<tr>
<td>4. DESCRIPTIVE NOTES: If appropriate, enter the type of report, e.g., interim, progress, summary, annual, or final. Give the inclusive dates when a specific reporting period is covered.</td>
</tr>
<tr>
<td>5. AUTHOR(S): Enter the name(s) of author(s) as shown on or in the report. Enter last name, first name, middle initial, if military, show rank and branch of service. The name of the principal author is an absolute minimum requirement.</td>
</tr>
<tr>
<td>6. REPORT DATE: Enter the date of the report as day, month, year; or month, year. If more than one date appears on the report, use date of publication.</td>
</tr>
<tr>
<td>7a. TOTAL NUMBER OF PAGES: The total page count should follow normal pagination procedures, i.e., enter the number of pages containing information.</td>
</tr>
<tr>
<td>7b. NUMBER OF REFERENCES: Enter the total number of references cited in the report.</td>
</tr>
<tr>
<td>8a. CONTRACT OR GRANT NUMBER: If appropriate, enter the applicable number of the contract or grant under which the report was written.</td>
</tr>
<tr>
<td>8b, c, &amp; d. PROJECT NUMBER: Enter the appropriate military department identification, such as project number, subproject number, system numbers, task number, etc.</td>
</tr>
<tr>
<td>9a. ORIGINATOR'S REPORT NUMBER(S): Enter the official report number by which the document will be identified and controlled by the originating activity. This number must be unique to this report.</td>
</tr>
<tr>
<td>9b. OTHER REPORT NUMBER(S): If the report has been assigned any other report numbers (other than the originator or by this sponsor), also enter this number(s).</td>

<tr>
<td>11. SUPPLEMENTARY NOTES: Use for additional explanatory notes.</td>
</tr>
<tr>
<td>12. SPONSORING MILITARY ACTIVITY: Enter the name of the departmental project office or laboratory sponsoring (paying for) the research and development. Include address.</td>
</tr>
<tr>
<td>13. ABSTRACT: Enter an abstract giving a brief and factual summary of the document indicative of the report, even though it may also appear elsewhere in the body of the technical report. If additional space is required, a continuation sheet shall be attached.</td>
</tr>
</tbody>
</table>

It is highly desirable that the abstract of classified reports be unclassified. Each paragraph of the abstract shall end with an indication of the military security classification of the information in the paragraph, represented as *(T, S, C, or V).* There is no limitation on the length of the abstract. However, the suggested length is from 150 to 225 words. |
| 14. KEY WORDS: Key words are technically meaningful terms or short phrases that characterize a report and may be used as index entries for cataloging the report. Key words must be selected so that no security classification is required. Identifiers, such as equipment model designation, trade name, military project code name, geographic location, may be used as key words but will be followed by an indication of technical context. The assignment of links, rules, and weights is optional. |
