TECHNICAL NOTE 1965-15

30 SEPTEMBER 1965
ABSTRACT

This paper describes a technique for obtaining high aperture efficiency in the Haystack 120-foot diameter Cassegrain antenna system. The approach used seeks to maximize the percentage of power intercepted by the hyperboloidal subreflector of the Cassegrain antenna system by shaping its primary feed radiation pattern. The primary feed configuration is a linearly polarized waveguide feed illuminating a specially shaped reflector. A number of theoretical antenna models were calculated and one of these antennas (a 30 wavelength diameter shaped reflector at 7750 Mcps) was fabricated and evaluated. Calculated estimates of percentage of primary feed power intercepted by the subreflector and Cassegrain aperture efficiency are presented.

A Shaped Reflector as a Primary Feed for Haystack

INTRODUCTION

An effort is made to maximize the percentage of power intercepted by the subreflector of a Cassegrain antenna system. The technique employed seeks to improve the beam efficiency of the primary feed by shaping its radiated pattern in such a way as to illuminate the hyperboloidal subreflector with a pattern whose chief characteristics are a flat top and steeply sloped sides. The accompanying phase is also calculated at a distance $R_0$ which represents the separation between the primary feed and the subreflector.

This paper will describe the method used to design a feed with the characteristics stated above. A number of theoretical antenna models are calculated; one of these antennas was built and its measured data compared with the theory. A technique for correcting the primary feed phase deviation is also described. In addition, calculated estimates of percentage of primary feed power intercepted by the subreflector and the Cassegrain aperture efficiency are presented.

I. DESCRIPTION OF PRIMARY FEED

A series of Clavin$^{1,2}$ waveguide feeds, linearly polarized, used for illuminating paraboloids have been built as primary feeds for the Haystack Cassegrain antenna system. Although these feeds are compact and versatile, such as providing 1.0 Gcps bandwidth, low cross polarized energy and continuous rotation of polarization capability; the beam efficiency defined as that percentage of primary feed power intercepted by the subreflector measures 70 percent. A well designed horn$^{3,4}$ can be constructed to allow the
subreflector to intercept approximately 90 percent of the incident power.

In an effort to approach this efficiency and still maintain the aforementioned advantages of the Clavin feed it was considered feasible to shape a reflecting surface to the Clavin feed radiation in order to obtain a highly efficient flat-topped secondary radiation pattern.

A paraboloid aperture diameter of ten wavelengths was used to illuminate Haystack's subreflector with an average 12 db edge illumination. It was realized that in order to maintain sufficient gain after reshaping a reflector, the aperture diameter would need to be greatly increased. Thirty wavelengths was arbitrarily chosen as a new reflector diameter. The focal length of the feed was set such that the shaped reflector subtends an angle of 180° at the feed to obtain a maximum interception of incident power by the reflector.

The expression for determining the shape of a line to be used in designing the reflector configuration is found as follows.5

---

Fig. 1. Ray Geometry at reflector surface.
The relationships of the angles $\psi$ and $\theta$ and the curve shape is seen from the figure to be

$$\frac{dp}{d\psi} = \tan \frac{\psi + \theta}{2} \quad (1)$$

and the integral is

$$\ln \frac{p}{p_0} = \int_0^\psi \tan \left[ \frac{\psi + \theta(\psi)}{2} \right] d\psi \quad (2)$$

The angle $\theta(\psi)$ must be determined before the above expression can be used.

Referring to Fig. 2 and utilizing the energy balance principle of geometric optics the power within an angular segment defined by $\psi$ and $\psi_1$ is equal to the power within the angular segment defined by $\theta$ and $\theta_1$. As it is desired
to include all of the power within an angular segment defined by $\theta_2$ and $\theta_1$, the following relationship is established

$$\frac{\theta - \theta_1}{\theta_2 - \theta_1} = \frac{\int_{\psi_1}^{\psi} I(\psi) d\psi}{\int_{\psi_1}^{\psi_2} I(\psi) d\psi}$$

$I(\psi)$ is the illumination power function of the primary feed. (3)

setting $\theta_1 = 0$

$\psi_1 = 0$

$\psi_2 = \text{angle at edge of reflector}$

$$\theta(\psi) = \frac{\int_{0}^{\psi} I(\psi) d\psi}{\int_{0}^{\psi_2} I(\psi) d\psi}$$

It is the parameter $\theta_2$ which is used to determine $\theta(\psi)$.

As an initial approximation, the angle $\theta_2 = 6.7^\circ$ was chosen because it was desired that all of the power in the secondary pattern be included within a cone whose half angle is $6.7^\circ$. The illumination function used in the calculation is the power distribution of the Clavin feed. With the $\theta(\psi)$ calculation completed it is now possible to insert these values into the equation
for \( \rho/\rho_0 \) and compute the line shape. When this line is rotated about the focal axis through \( 360^\circ \) the surface of the specially shaped reflector is generated.

II. CALCULATION OF CURVED REFLECTOR RADIATION PATTERN

The scattered field \( E \) will be calculated starting with the expression derived in Silver\(^6\)

\[
E = \int_{S_0} \frac{[G_F(\theta, \phi)]^2}{\rho} \left[ \eta \times (\vec{\rho} \times \vec{e}_1) \right] e^{-jk[-(\vec{\rho} \cdot \vec{R}_1)]} ds. \tag{5}
\]

\( \vec{e}_1 \) is a unit vector defining the polarization of the electric field intensity. The polarization will be assumed constant and will be neglected. The expression reduces to

\[
E = \int_{S_0} \frac{[G_F(\theta, \phi)]^2}{\rho} e^{-jk[-(\vec{\rho} \cdot \vec{R}_1)]} ds. \tag{6}
\]

To evaluate the phase term in the near field the distance \( R_0 \) and \( R_1 \) to a point \( P \) in the near field must be considered. Referring to Fig. 3

\[
\vec{R}_1^2 = [\rho \sin \phi \sin \psi]^2 + [\rho \cos \phi + R_0 \cos \theta]^2 + [R_0 \sin \theta - \rho \sin \phi \cos \psi]^2. \tag{7}
\]

The total distance to point \( P \) from phase reference point \( O \) by way of point \( A \) on the reflector is \( \rho + R_1 \)

\[
\rho + R_1 = \rho + R_0 \left[ 1 + 2 \frac{\rho}{R_0} (\cos \phi \cos \theta - \sin \theta \sin \phi \cos \psi) + \left( \frac{\rho}{R_0} \right)^2 \right]^{1/2}. \tag{8a}
\]
and the phase difference is:

\[ \rho + R_1 - R_0 = \rho + R_0 \left[ 1 + 2 \frac{\rho}{R_0} \left( \cos \phi \cos \theta - \sin \theta \sin \phi \cos \psi \right) \right] + \left( \frac{\rho}{R_0} \right)^2 \frac{1}{2} \]  

\[ - R_0 \]  

(8b)

which can be simplified to

\[ \rho + R_1 - R_0 = \rho \left[ 1 + \cos \theta \cos \phi - \sin \theta \sin \phi \cos \psi + \frac{\rho}{2R_0} \right] \].

(8c)

Fig. 3. Geometry used for determining near field phase expression.
The expression for the field is:

\[ E = \int_{S_0} \frac{G_f(\theta, \phi)}{\rho} \left[ -jk \frac{1}{2} \left( 1 + \cos^2 \Theta \cos^2 \phi - \sin \theta \sin \phi \cos \psi + \frac{\rho}{2R_0} \right) \right] \text{e}^{-j \phi} \text{ds}. \quad (9) \]

To evaluate \( \text{ds} \), the elemental area, refer to Fig. 4.

![Elemental projection on reflector surface](image.png)

Fig. 4. Elemental projection on reflector surface.

The projection on the reflector surface is \( \text{ds} \)

\[ \text{ds} = [(\rho \phi)\rho^2 + (d\phi)^2] \rho \sin \phi \text{ d}\psi \quad (10) \]

\[ \text{ds} = \rho d\phi \left( 1 + \left( \frac{d\phi}{\rho d\phi} \right)^2 \right) \rho \sin \phi \text{ d}\psi \quad (11) \]

\[ = [1 + \tan^2 \xi] \frac{1}{\cos^2 \xi} \text{ dA} \quad (12) \]

\[ = \sec^2 \xi \text{ dA}. \quad (13) \]
\[ ds = \sec \varphi \rho^2 \sin \varphi \, d\varphi \, d\psi \]  

rewriting the equation and noting that the radiation pattern is invariant with \( \psi \).

\[
E = \int_0^\phi \int_0^{2\pi} \frac{1}{\rho(\phi)} \rho^2 \sec \varphi \sin \varphi 
\]

\[
- j \kappa \rho(\phi) [1 + \cos \theta \cos \phi - \sin \theta \sin \phi \cos \psi + \frac{\rho}{2R_o}] 
\]

\[
\cdot e^{-j k \rho(\phi) [1 + \cos \theta \cos \phi - \sin \theta \sin \phi \cos \psi + \frac{\rho}{2R_o}]} \, d\phi \, d\psi \]  

(15)

and for a circular aperture

\[
E = \int_0^\phi \int_0^{2\pi} \frac{1}{\rho(\phi)} [1 + \left( \frac{\partial \rho}{\partial \phi} \right)^2]^{\frac{1}{2}} \sin \varphi \, J_0(k \rho \sin \theta \sin \phi) 
\]

\[
- j \kappa \rho(\phi) [1 + \cos \theta \cos \phi + \frac{\rho}{2R_o}] 
\]

\[
\cdot e^{-j k \rho(\phi) [1 + \cos \theta \cos \phi + \frac{\rho}{2R_o}]} \, d\phi \]. 

(16)

**Phase Correction:** The phase front of a spherical wave at the subreflector is a locus of constant phase described by a radius \( R_o \). The Cassegrain antenna system transforms the primary spherical wave illumination over the subreflector into a spherical wave illumination over the paraboloid which appears to originate from the common paraboloid and hyperboloidal focii. In this way the reflector system produces a collimated wave front whose rays are parallel to the focal axis. The shaped reflector phase front is not spherica\(.

Figure 5 and Fig. 6 consider two different shaped reflectors and plot.
the phase distribution over the main reflector as a function of its radius r. A similar phase distribution which could be produced by an axial displacement, $S_0$, of the apparent feed point is also shown. Combining these two distributions it is possible to obtain a nearly spherical wave illumination of the main reflector, as shown in Figs. 5 and 6. This could be accomplished by moving the subreflector along the focal axis. It is seen in Fig. 5 that a half-wave displacement could result in a maximum resultant phase error of 0.11λ at the edge of the paraboloid. Figure 5 indicates the phase relationship for the parameter $\theta_2$ in Eq. (4) equal to 4.5°. Figure 6 indicates the same for $\theta_2 = 3.5°$.

Results of Theoretical Calculations:— The significant parameters for consideration are the percentage of power intercepted by the subreflector and the resultant Cassegrain aperture efficiency. Calculations were performed to determine this percentage of power for various shape reflectors.

The expression for gain and the method used for calculating the beam efficiency is as follows. Assuming circular symmetry about the axis of the beam, the gain of the feed, G, is given by:

$$G = \frac{4\pi}{2\pi \int_0^\pi E^2 \sin \theta d\theta}$$

where $E$ is the field illumination obtained from Eq. (16) and the fraction of power, $\xi$, intercepted by the hyperboloid is given by
where $6.7^\circ$ is one-half the angle subtended by the subreflector at the feed.

\[ \zeta = \frac{\int_{0}^{6.7^\circ} E^2 \sin \theta d\theta}{\int_{0}^{\pi} E^2 \sin \theta d\theta} \]

\[ \zeta = \frac{G}{2} \int_{0}^{6.7^\circ} E^2 \sin \theta d\theta. \]

Figure 7 shows plots of beam efficiency as percent power vs. angle $\theta$. Of interest is the percentage of power within $6.7^\circ$ which is half the angle subtended by the subreflector at the primary feed. The first approximation of $\theta_2 = 6.7^\circ$ is the poorest at 50 percent power. However, it is seen that curve shapes of $\theta_2 = 4.5^\circ$ and less indicate greater than 80 percent beam efficiency. In fact, the $\theta_2 = 3.0^\circ$ curve indicates that 92 percent of the power would be intercepted by the subreflector. It will be assumed that the remaining 8 percent is lost in the side lobes and in the small cross polarized component (-30 db).

Also calculated was the aperture efficiency $\eta$ which would result from these various shapes by again assuming a circular beam cross section and correct phase.

\[ \eta = 16 \left( \frac{f}{D} \right)^2 N^2 G_f(o) \left| \int_{0}^{6.7^\circ} E(\theta) \tan \frac{\theta}{2} d\theta \right|^2 \]

where
\[ G_f(o) = \text{on-axis gain of primary feed} \]

\[ M = \text{magnification factor of Haystack geometry} \]

\[ \frac{f}{D} = \text{focal length to diameter ratio of Haystack paraboloid} \]

\[ E(\theta) = \text{voltage distribution of primary feed} \]

\[ \theta = \text{primary feed angle taken from focal axis}. \]

Table 1 is a list of results showing the percentage of power intercepted by the subreflector, the on-axis gain of the shaped reflector and the resulting Cassegrain aperture efficiency calculated.

Figure 8 is a plot showing a family of radiation patterns resulting from a change in the parameter \[ \theta_2 \]. The \[ \theta_2 = 4.5^\circ \] curve illuminates the subreflector edge at -4.0 db; however, 81 percent of the power is intercepted by the hyperboloid. The \[ \theta_2 = 3.5^\circ \] radiation pattern illuminates the subreflector edge 6.7 db down from peak and the percentage power intercepted by the subreflector is 89 percent.
III. MEASUREMENTS

A 30 wavelength diameter shaped reflector design of $\theta_2 = 4.5^\circ$ was constructed and evaluated. Antenna patterns and gain measurements were obtained with the conditions simulating the near field relationship of the primary feed and subreflector separation in the Cassegrain antenna system. Results of these measurements are compared with the calculated radiation pattern and are shown in Fig. 9. The principal plane and $45^\circ$ plane patterns which exhibit good symmetry were averaged and the result is shown as a single illumination function in Fig. 10. Figure 11 compares the calculated beam efficiency with the test antenna measured beam efficiency obtained with the measured gain and illumination function. The shaped reflector design frequency was 7750 Mcps.

The following table lists these results.

| TABLE 2 |
|-----------------|-----------------|
|                | Theoretical     | Measured Test Antenna |

| $G(0)$ dB shaped reflector on-axis gain | 25.3            | 25.0               |

CONCLUSION

The 120-foot Haystack Cassegrain antenna aperture efficiency obtained with a series of Clavin-feed paraboloids has been determined to be 60 percent. This aperture efficiency does not take into account losses due to (1) aperture
block, (2) errors in the surface of the surface of the subreflector and the 120-foot paraboloid and (3) the 150-foot radome which is appreciable (≈ 1.2 db at 8.0 Gcps).

A technique has been described for improving this antenna aperture efficiency by reshaping the beam of the primary feed and repositioning the subreflector along the focal axis. Measurements on one shaped reflector antenna agreed closely with the theory. Listed below is a table comparing possible solutions.

Reflector shapes $\theta = 3.0^\circ, 3.5^\circ$ offer the best solutions and would appear to promise the highest Cassegrain antenna aperture efficiency obtainable utilizing the technique described in this paper.
