COUNTRY: USSR
The article presents theoretical principles for calculating the vibration period of clock escapement regulators without natural vibrations, taking into account the effect of dynamic factors on the magnitude of the period. The formulas obtained contribute to an understanding of certain laws governing the operation of these regulators (slight dependence of the balance's vibration range upon the moment of the motive force, the negligible influence of great changes in the moment of inertia of the train upon the magnitude of the vibration period etc.) and may be useful in the designing of clockworks and the calculation of vibration periods.
CERTAIN PROBLEMS IN THE DYNAMICS OF ESCAPEMENT REGULATORS WITHOUT NATURAL VIBRATIONS OF THE BALANCE

The article sets forth the principles of the theory for calculating the vibration period of regulators without natural vibrations, taking into account the effect of dynamic factors on the magnitude of the period. The dependences here obtained contribute to an understanding of the laws governing the operation of these regulators and may be of use in designing and analyzing them.

Various branches of present-day engineering make extensive application of simplified clockwork using regulators without natural vibrations (Figure 1).

Vibrations of the balance in systems with such regulators take place exclusively by virtue of the interaction of the teeth of the escape wheel with pallets of one form or another, situated immediately on the balance or on a separate anchor rigidly connected with the axis of the balance. In character these vibrations are discontinuous auto-oscillations.

A balance has no fixed equilibrium position. Therefore, amplitude is in significant measure an arbitrary parameter here, depending on where one's reckoning starts.

Only the double amplitude (range of vibrations) of the balance is completely definite. It is equal to a complete angle of rotation of the balance in one direction and if the magnitude of amplitude has to be established, it can be deemed equal to half this angle.
The vibration range of a balance ordinarily does not exceed 15-20°.

The chief parameter of the regulators here under consideration is the vibration period. For a balance which is not subject to the action of any restoring force the cycle of motions performed by the balance between two adjacent identical positions is said to be a complete vibration. The vibration period determines the duration of this cycle. The magnitude of the balance's vibration period depends considerably upon the angular momentum on the escape wheel.

The theory here proposed for determining a balance's vibration period and angles of rotation is based on the concept of impulse angles depending not only on the design of the escapement, but also upon moments of inertia of the balance and the entire wheelwork transmission, as well as the correlations between moments on the anchor and the escape wheel during impulses, and upon a number of other factors. It also contains a method for finding the period and fundamental angles with correction for the effect of the impacts of the teeth of the escape wheel with the pallets on their contact at the beginning of each impulse.

By taking these factors into account, we can explain certain laws, here noted in practice, governing the operation of these regulators: the slight dependence of the balance's vibration range upon the moment of the motive force; the
negligible influence of great changes in the moment of inertia of the train upon the magnitude of the vibration period; etc.

The formulas obtained here make it possible to assess the role of dynamic factors in the operation of regulators without natural vibrations and to make a more valid selection of design parameters in the design and planning of clockwork, as well as to obtain more accurate results in the calculation of vibration periods.

Positions of the Contact Points of Balance and Escape Wheel

In the vibrational steady state the pallets of the balance meet with the teeth of the escape wheel at strictly defined points, the positions of which on each pallet serve as the reference point for the angles of rotation of the balance during the operation of the regulator.

In order to find the angular coordinates of the elements of an escapement during contact, let us examine the free rotation of the balance and wheel (Figures 2 and 3).

The beginning of free rotation coincides with the end of an impulse, and the position of the escape wheel and the balance at this moment is established by the appropriate plotting or calculation.

Part of the angle of free rotation \( \beta_c \), which we shall designate \( \beta_{ck} \), will be traversed by the wheel; the other part, which we shall designate \( \beta_{co} \), will be traversed by the balance. Thus, the angle of free rotation of the balance is

\[
\beta_{co} = \beta_c - \beta_{ck}.
\]

[Translator's Note]: The subscripts here and hereinafter are Russian letters. A summary list of symbols with Russian-letter subscripts -- together with expansion, translation and notation of first occurrence -- is given below at pages 22-24.

The second condition for finding the angles \( \beta_{co} \) and \( \beta_{ck} \) is that the time during which the balance and the escape wheel are in motion without contact is identical and can be
found not only from the equation of balance rotation but also from the equation of wheel rotation.

These equations have the form

\[ I \ddot{\beta} - M_\theta + M_f = 0, \]  
\[ I \ddot{\alpha} - M_\theta + M_{x\theta} = 0. \]

where \( \beta \) and \( \alpha \) are the current angles of rotation of the balance and the escape wheel;

\( I \) and \( I_x \) are respectively the moment of inertia of the balance and that of the wheel transmission reduced to the axis of the escape wheel;

\( M_\theta \) and \( M_{x\theta} \) are respectively the momentum acting upon the balance, and the momentum from the balance acting upon the escape wheel;

\( M_x \) is the angular momentum on the axis of the escape wheel;

\( M_T \) is the friction torque on the pivots of the balance.

In impulse sectors elements of the motion of the balance and the escape wheel are found by common solution of these equations. During free rotation the equations are solved separately with moments \( M_\theta \) and \( M_{x\theta} \) equaling zero in this case.

Since in order to determine free-rotation time we must know the velocity of the balance and wheel at the end of the impulse, let us turn our attention to the common solution of equations (2) and (3).

If we say that

\[ M_\theta = M_{\theta\theta} \varphi(\beta), \]

we shall obtain

\[ \left[ I + I_x \frac{\ddot{\varphi}(\beta)}{\dot{\beta}} \right] \ddot{\beta} - M_x \varphi(\beta) + M_f = 0. \]
Figure 2. Diagram for determination of angles of free rotation in case of pin pallets.

[Translator's Note]: The Russian subscript "о" refers to the balance, "x" to the escape wheel. For symbols with other Russian-letter subscripts see summary list below at pages 22-24.

In view of the relative smallness of the impulse angles for the regulators here under consideration, we shall assume [1]

$$\frac{z}{a} = \frac{3}{a} = i.$$  \hspace{1cm} (4)

If in view of its poor variability throughout an impulse we replace $\varphi(\beta)$ with mean value

$$\varphi(\beta)_{tp} = k.$$

Key: $\varphi = \text{mean}$
we shall obtain the following equation of motion for the "balance-escape wheel" system

\[ I_0 \ddot{\gamma} - M_\nu k + M_\nu = 0, \]

where

\[ I_0 = I + \frac{I_x k}{i} \]

is the reduced moment of inertia of the balance.

If we assume the velocity of the balance at the beginning of the impulse generally to be terminal velocity owing to post-impact reflection and equal to \( \psi_0 \), and if we integrate (5), we shall find its velocity at the end of the impulse

\[ \psi_n = \sqrt{\frac{2(M_\nu k - M_\nu)}{I_0}} \beta_\nu + \psi_0, \]

where \( \beta_\nu \) is angle of rotation of the balance during an impulse.

If we then consider free rotation and integrate equations (2) and (5) separately, we shall obtain expressions of the time of free motion.

From (2) given \( M_\nu > 0 \)

\[ t_c = \frac{I}{M_\nu} \left( \psi_n - \sqrt{\frac{2(M_\nu k - M_\nu)}{I_0} \beta_\nu} \right). \]

Given \( M_\nu = 0 \)

\[ t_c = \frac{\beta_\nu}{\psi_n}. \]

From (3), given velocity of the escape wheel at the end of the impulse \( \xi_n \),

\[ t_c = \frac{I_x}{M_x} \left( \sqrt{\frac{2(M_\nu k - M_\nu)}{I_x}} \alpha_n + \xi_2 - \xi_n \right), \]

it being given that

\[ \xi_n = \frac{2M_\nu}{I_x} \psi_n = \frac{\psi_n}{i_k}. \]
where \( r_{\lambda \mu} \) and \( r_{\lambda \nu} \) are the distances from the centers of the escape wheel and the balance to the general normal to the surfaces of the impulses of the tooth and pallet at the moment when impulse transmission ceases, and \( \alpha \) is the angle of free rotation of the escape wheel.

Let us establish the relation between angle of rotation of wheel \( \alpha \) and angular displacement of impulse surface of tooth relative to axis of balance \( \beta \).

From Figure 2 for escapement with pin pallets, if we disregard the curvature of arcs \( AB \) and \( AA' \) in view of the smallness of the angles of free rotation of the balance and the wheel, in considering \( AA' \) we shall have

\[
AA' = Rz, \quad AB = r_\beta \gamma & \quad \frac{r_\beta}{\sin \gamma} = \frac{Rz}{\sin \alpha}.
\]

From \( \Delta O_5 O_6 A \)

\[
\mu = \pi - (\nu + \gamma),
\]

where

\[
\tau = \frac{\pi}{2} - \nu; \quad \nu = \pi - \gamma; \quad \gamma = \pi - \arccos \left( \frac{l^2 - R^2 - r_\beta^2}{2Rr_\beta} \right).
\]

[Translator’s Note]: The subscript “\( \delta \)” refers to the balance.

Angles \( \lambda, \gamma \) and \( \delta \) do not depend on the position of the escapement and that is why angle \( \mu \) remains unchanged during free motion. Consequently, if we rewrite (\( \nu \)) in the form

\[
\gamma = \frac{R \sin \gamma}{r_\beta \sin \mu} \quad \alpha = D \gamma,
\]

coefficient \( D \) will be constant and the sought relation between angles \( \alpha \) and \( \beta \) will be linear.

If we reason similarly with reference to a balance with flat pallets on the anchor, it is easy to prove the correctness of dependence (12) in this case too, but angles \( \gamma \) and \( \mu \) are more simply taken directly from the sketch of the escapement (Figure 3).
If we substitute $\alpha_{ck} = \frac{\beta_{ck}}{D}$ into (10), if we replace $\xi_n$ by $\psi_n$ (11) and $\beta_{ck}$ by $\beta_{c6}$ in accordance with (1), and if we equate expressions (8) and (10) given $M_T > 0$, we shall obtain

$$\frac{I_t}{M_t} \left( 1 - \sqrt{1 - \frac{2M_T}{\psi_n I} \beta_{c6}} \right) = \frac{I_t}{I_x M_x} \left[ \sqrt{\frac{2I_x^2 M_x}{\psi_n^2 I_x D} (\beta_c - \beta_{c6}) + 1} - 1 \right].$$

(13)
If we equate (9) and (10) given $M_T = 0$, with allowance for the fact that

$$\beta_n = \beta_0 + \beta_n,$$  \hfill (14)

where $\beta_0$ (Figure 2) is the angle determining the position of the pallet at the beginning of free rotation and, further, with allowance for the fact that, given $M_T = 0$ and $\psi_0 = 0$, from (7)

$$\psi_n = \sqrt{-\frac{2h}{l_0} \lambda \sqrt{M_v}},$$  \hfill (15)

we shall have

$$\beta_0 = \frac{2T_e (\psi_0 - \beta_0)}{l_0 l_k} \sqrt{\frac{l_0}{l_k} D_k (\beta_0 + \beta_n)^{-1} - 1}.$$  \hfill (16)

From the last equation it can be seen that in the absence of friction on the pivots of the balance and in the absence of balance repercussion during impacts with the wheel the position of the contact point of balance and escape wheel and, consequently, the magnitude of the balance's amplitude of vibrations will not be dependent upon the magnitude of the angular momentum on the escape wheel.

O. M. Bautin [6] also arrived at the same conclusion, using for his investigation the method of point transformations on a phase plane.

The friction on balance pivots and the velocities of the balance at the beginning of impulses $\psi_0$ are usually small. Therefore we can consider the above-indicated law to be characteristic in significant measure of all regulators of the type here under study.

If we solve (16) relative to $\beta_n$, we shall obtain the following expression for impulse angle
\[
\beta_n = \frac{c_1 + \sqrt{c_2^2 - 4c_1c_3}}{2c_1},
\]

where

\[
c_1 = Da + 4D + 4\beta_0; \quad c_2 = 2(Da\beta_0 + 2D\beta_0 + 2\beta_c + 2\beta_v) \quad c_3 = aD\beta_0^2 \quad a = \frac{1}{k}.\]

In formula (17) only a plus stands in front of the root since, given \(\beta_0 = 0\) and \(c_3 = 0\), \(\beta_n\) cannot equal zero.

**Operational Regime of Regulators with allowance for Impacts**

Depending on the combination of different balance and escape-wheel parameters affecting impact results (magnitudes of moments of inertia, mechanical properties of materials, design factors etc.), the following post-impact states can be observed in regulators without natural vibrations after contact of the escape-wheel tooth with the pallet:

1) Withdrawal (recoil) of the wheel and rotation of the balance without reversal;
2) Recoil of the balance and wheel in opposite directions from the contact point;
3) Rotation of the wheel without reversal, and recoil of the balance.

As we enter upon a determination of the vibration period, we must establish the character of the operational regime [See Note] characteristic of a regulator with particular parameters. For this purpose the magnitudes and directions of the post-impact velocities of balance and escape wheel may serve as criteria.

[Note]: In principle different regimes may arise on each of the pallets.

Let us find the expressions determining these velocities.

Let the balance and wheel at the moment of contact have velocities of \(\psi (Y)\) and \(\dot{Y}\) respectively, and after impact \(\psi (B)\) and \(\dot{B}\) respectively. Let us designate the distances from axes of rotation to impact line (Figure 4) \(\rho_\Delta\) and \(\rho_\delta\).
and the total linear velocity of the colliding points at the
end of the first phase of impact $U$.

Figure 4. Diagram of "pallet-tooth" impact.

[Translator's Note]: The Russian subscript "5" refers to the balance, "2" to the escapewheel.
For symbols with other Russian-letter subscripts
see summary list belos at pages 22-24.

Key: 1. Line of impact

Let us take counter-clockwise rotation as positive di-
rection. Then in the first of the above-indicated cases of
regulator operation we shall obtain the following pattern of velocity transformation on impact:

\[
\begin{align*}
\theta_1 \gamma_1 - U - \gamma_2 \gamma_3 \\
- \theta_2 \gamma_2 - U - \gamma_3 \gamma_4
\end{align*}
\]

If we assume the impact of tooth against pallet to be
elastic, in the first phase of impact (equalization of veloc-
ities) we shall have
For the second phase (restoration of velocities)

\[ I(U - \psi_y \epsilon_0) = -S_1 \rho_1, \]
\[ I_x (U + \epsilon_y \rho_1) = S_1 \rho_1^2. \]

If we eliminate from these equations first- and second-phase impulses \( S_1 \) and \( S_2 \) and velocity \( U \), we shall obtain

\[ \psi_y = \epsilon_y \psi_{\text{e}} \frac{I_x}{I} \left( \frac{\epsilon_{\text{e}}}{\epsilon_{\text{e}}} \right) - \psi_y. \]  

(19)

If we introduce coefficient of restitution of impact velocity

\[ K = \frac{S_2}{S_1} = \frac{\epsilon_x \psi_{\text{e}} + \epsilon_y \psi_{\text{e}}}{\epsilon_x \psi_{\text{e}} + \epsilon_y \psi_{\text{e}}}, \]  

(20)

and by means thereof eliminate \( \xi \) in (20), we shall find post-impact velocity of the balance

\[ \psi_y = \frac{(1 + K) \psi_y - \left( \frac{I_x \epsilon_\psi - K}{I_x \epsilon_\psi} \right) \psi_y}{1 + \frac{I_x \epsilon_\psi}{I_x \epsilon_\psi}}. \]  

(21)

According to the data of F. V. Drozdov [3], \( K = 0.5 \) to 0.6. If we know \( \psi_y \), the post-impact velocity of the escape wheel can be computed according to the formula

\[ \psi_e = (\psi_y + \psi_{\text{e}}) \frac{I_x}{I_x} \psi_y - \psi_y. \]

(22)
Analogous expressions for $\psi_B$ and $\xi_B$ are obtained also from a consideration of impact on the discharging pallet.

If $\psi_B$ or $\xi_B$, computed according to (21) and (22), turn out to be negative, this will mean that the balance or escape wheel will not recoil from the contact point as assumed above, but will keep on moving in the pre-impact direction.

In establishing the operational regime of a regulator, or the beginning of an impulse, or initial velocity of a balance according to the velocities $\psi_B$ and $\xi_B$ for which magnitude and direction are known, we can be guided by the following considerations [See Note]:

[Note]: Let us disregard any possible subsequent impacts since they play no significant role in comparison with the first one.

1. If $\psi_B < 0$ and $\xi_B > 0$, impact does not reverse the rotation of the balance, but causes a withdrawal (recoil) of the escape wheel. After the angle of departure is passed, $\psi_0 = 0$.

The angle of departure is found from the circumstance that the post-impact kinetic energy of the wheel equals the work of the angular momentum at this angle, which yields

$$ x_0 = \frac{1}{2} \xi_0^2 \frac{1}{2M_t} . $$

(23)

Key: OT [othod; departure]

The additional angle of rotation of the balance during withdrawal of the wheel in this case is

$$ \xi_{ot} = x_{ot} \psi_0 . $$

(24)

Key: OT [othod; withdrawal, departure]

and the complete impulse angle is
2. Given \( \psi_B > 0 \) and \( \xi_B > 0 \), on-impact reflection of both balance and wheel takes place. The latter, having certain energy due to the magnitude of velocity \( \xi_B \), initially withdraws at a certain angle (23) and then rotates, catching up with the pallet.

The extreme position assumed by the escape wheel on withdrawal can also be considered as the beginning of an impulse in this particular instance. The initial velocity of the balance must be taken approximately as \( \psi_0 \approx \psi_B \).

3. If \( \psi_B > 0 \) and \( \xi_B < 0 \), only the balance will recoil from the impact point. The position of the parts of the escapement will correspond to the beginning of the impulse, \( \psi_0 = \psi_B \).

The most frequently encountered regime characteristic of \( I > I_k \) is the first.

From (21), (22) it can be seen that in order to compute \( \psi_B \) and \( \xi_B \), we must know the pre-impact velocities of balance and escape wheel \( \psi_y \) and \( \xi_y \) which, in their turn, depend on \( \psi_0 \) and \( \xi_0 \) and the impulse angles with correction for the effect of impacts.

\( \psi_y \) and \( \xi_y \) can be eliminated from (21), (22). However, in this case, complex biquadratic equations are obtained.

In practice it is more practical to find \( \psi_y \) and \( \xi_y \) by successive approximation according to the following procedure.

Assuming \( \psi_0 = 0 \) at the beginning of the preceding impulse (the beginning determined without including the impact), we find the velocities of the balance and the escape wheel at the end of an impulse on one of the pallets and then their velocities at the moment of wheel-tooth contact with the next pallet in turn.
Found in accordance with these velocities are the first approximate values of subsequent velocities, by taking which into account the impulse angle and velocity of wheel and balance on the preceding pallet etc., are refined until subsequent refinements no longer appreciably change results.

Let us note that owing to the degree of approximation of the classical impact theory used by us, as well as the inaccuracy and inconstancy of the coefficient of restitution \( K \), it is quite sufficient to limit refinement to just one approximation.

**Vibration Period of the Balance**

If we designate impulse transmission time, free rotation time and the time required to pass through angle of departure respectively as \( t_n \), \( t_0 \) and \( t_r \), according to the previously given determination of the vibration period we have

\[
T = t_n + t_0 + t_r - t_{or} + t_{or} + 2t_{ir}. \quad \text{(See Note)(26)}
\]

where \( t_{ir} \) is the time the tooth is in contact with the pallet during impact, assumed to be identical on both pallets.

[Note]: Here and henceforth the indexes ' and " designate quantities referring to receiving and discharging pallet respectively.

In view of the comparative smallness of the quantity \( 2 t_{ir} \) (approximately ten-thousandths of a second), given \( T > 0.01 \) sec, it is quite validly disregarded. In case of smaller values of the period, the duration of impacts can be allowed for by making experimental correction.

To find time intervals \( t_{ir} \), let us solve equation (5). By double integration we shall obtain

\[
t_{n} = \frac{1}{c} (\eta_{n} - \eta_{0}). \quad \text{(27)}
\]

where

\[
c = \frac{M_{tk} - M_{1}}{t_{n}}. \quad \text{(28)}
\]
and $\psi_n$ is determined from (7).

Free rotation time is expressed by formulas (8) and (9).

If according to (21) and (22) we obtain $\psi_B < 0$ and $\dot{\xi}_B > 0$, we shall find the duration of reverse rotation of the escape wheel from the equation

$$I_0 \ddot{x} + M_x = 0.$$

If we integrate under the initial conditions: $t = 0$; $x = 0$ and $\dot{x} = \dot{x}_0$, and under the conditions at the end of withdrawal: $t = t_{0T}$; $x = x_{0T}$; $\dot{x} = 0$ with allowance for (23), we obtain

$$t_{0T} = \frac{I_x}{M_x} \xi_0.$$

(29)

Taking into account expressions (25), (27), (8) and (29), we shall obtain an expanded expression for determination of the vibration period of a balance without restoring force in the commonest case in the following form:

$$T = \frac{1}{C_1} (\psi_n - \psi_0) + \frac{1}{C_2} (\psi_n - \psi_0) + \frac{I_x}{M_x} \left[ 2 \dot{\psi}_n - \left( \sqrt{\dot{\psi}_n^2 - \frac{2 M_x \psi_n}{I_x}} \right) + \sqrt{\dot{\psi}_n^2 - \frac{2 M_x \psi_n}{I_x}} \dot{\psi}_n \right] + \frac{I_x}{M_x} (\dot{x}_0 + \dot{x}_0) + 2 t_x. \quad (30)$$

where coefficients $C_1$ and $C_2$ are found according to (28).

Given little friction on the balance pivots when one can assume $K_T = 0$,

$$T = \frac{1}{C_1} (\psi_n - \psi_0) + \frac{1}{C_2} (\psi_n - \psi_0) + \frac{\dot{x}_0}{\dot{\psi}_n} + \frac{\dot{x}_0}{\dot{\psi}_n} + \frac{I_x}{M_x} (\dot{x}_0 + \dot{x}_0) + 2 t_x. \quad (30a)$$

If we disregard friction and impacts,
Considered by way of example is an escapement regulator without natural vibrations, having pin pallets, with the following data:

\[
T = \frac{A}{\sqrt{M}},
\]

\[
A = \sqrt{\frac{2\beta}{k'} + \frac{2\beta'}{k''}} + \sqrt{\frac{2\beta}{k''} + \frac{2\beta'}{k'}},
\]

where

\[
A = \sqrt{\frac{2\beta}{k'} + \frac{2\beta'}{k''}} + \sqrt{\frac{2\beta}{k''} + \frac{2\beta'}{k'}},
\]

\[
T = \frac{A}{\sqrt{M}}.
\]

In view of the lack of necessary data the duration of impacts was not computed.

[Note]: Since in escapements with pin pallets, practically speaking, free rotation rather than impulse transmission takes place in sectors of the impulse along the pin, quantities \( k \) and \( i \) for these are determined only within the range of the impulse along the escape-wheel tooth.

Tables 1 and 2 present respectively the results of calculating the vibration period of a balance with and without allowance for the effect of impacts on vibrations. Table 3 shows the post-impact velocities of balance and escape wheel.

**Keys:**

1. Receiving pallet
2. Discharging pallet
3. $\psi_{b, \text{сек}}^{-1}$ given $M_x$ [see summary list of symbols], грам-мм
4. $\psi_{a, \text{сек}}^{-1}$ given $M_x$ [see summary list of symbols], грам-мм
5. $\tilde{\psi}_{a, \text{сек}}^{-1}$ given $M_x$ [see summary list of symbols], грам-мм
6. $\tilde{\psi}_{b, \text{сек}}^{-1}$ given $M_x$ [see summary list of symbols], грам-мм
From the results presented we can draw the following basic conclusions.

1. Impacts and the resultant recoils of the escape wheel if \( I \geq I_x \) cause an increase in the vibration period, but a decrease if \( I < I_x \).

2. The vibration period of the balance is relatively slightly dependent upon the relation between the moment of inertia of the balance and the reduced moment of inertia of the escape wheel, with the greatest magnitude of the vibration period being obtained given \( I \approx I_x \).

3. The vibration period of a balance without restoring force depends in great measure upon angular momentum.

4. The error in the determination of the period if impacts are disregarded amounts to \((25-30\%) \) given \( I \geq I_x \), and may go as high as \( 50\% \) or more given \( I < I_x \). This must be borne in mind in designing clockworks with a bulky wheel system.
