THE INSTITUTES FOR ENVIRONMENTAL RESEARCH

The mission of the Institutes is to study the oceans, and inland waters, the lower and upper atmosphere, the space environment, and the earth, seeking the understanding needed to provide more useful services. These research Institutes are:

- The Institute for Earth Sciences
  conducts exploratory and applied research in geomagnetism, seismology, geodesy, and related earth sciences.

- The Institute for Oceanography
  works to increase knowledge and improve understanding of the ocean and its interaction with the total physical environment of the globe.

- The Institute for Atmospheric Sciences
  seeks the understanding of atmospheric processes and phenomena that is required to improve weather forecasts and related services and to modify and control the weather.

- The Institute for Telecommunication Sciences and Aeronomy
  supports the Nation's telecommunications by conducting research and providing services related to radio, infrared, and optical waves as they travel from a transmitter to a receiver. The Institute is also active in the study and prediction of periods of solar activity and ionospheric disturbance.

Otto Neall Strand

Abstract

The theory of radiative transfer in the microwave region is discussed. A method for the numerical solution of a Fredholm integral equation of the first kind is derived and illustrated. The method employs an \textit{a priori} constraint vector together with covariances of both the constraint vector and the measurement errors. The method automatically incorporates an optimum amount of smoothing in the sense of maximum-likelihood estimation. The problem of obtaining optimum basis vectors is discussed. The trace of the covariance matrix of the error in the solution is used to estimate the accuracy of the results. This trace is used to derive a quality criterion for a set of measurements and a given set of constraint statistics. Examples are given in which the behavior of the solution as obtained from a specific integral equation is studied by the use of random input errors to simulate measurement errors and statistical sampling. The quality criterion and behavior of the trace of the error covariance matrix for various bases are also illustrated for the equation being considered. A least-squares analysis of microwave absorption data to determine line width for water vapor and oxygen is presented. Calculations of the error covariance matrix and quality-criterion values to be expected when probing for the tropospheric temperature structure from microwave emission measurements are presented.
1. Introduction

The general subject of passive probing of the atmosphere by electromagnetic means has recently received attention by several authors: Fleming and Wark, [1]; Kaplan [2]; and King, [3]. In spite of the wide differences in the specific techniques applied to each spectral region, several elements are common to all passive probing schemes. The first of these elements is the sensor, which measures relevant properties of the radiation emanating from the spatial region being probed. Secondly, detailed knowledge is required concerning the mechanisms by which radiation is generated at the region being probed and by which the radiation is propagated to the sensor. The last, but certainly not the least, is the manner by which information concerning the physical property of interest is derived from the set of radiation measurements, the so-called "inversion process".
The probing methods discussed here attempt to derive information about the temperature distribution of the troposphere by measuring the microwave brightness temperature of the atmosphere from the ground looking up. The propagation and emission of this radiation are determined for the most part by the absorption coefficients of oxygen and water vapor.

The inversion method we derive here is illustrated for the physical situation of ground-based upward probing; however, the inversion equations are applicable to more general situations. This technique extends methods given by Phillips [4], Twomey [5],[6], and Twomey and Howell [7] for the solution of integral equations of the first kind. These methods use a controlled amount of smoothing in solving the matrix system derived from a quadrature approximation, but give no systematic method of determining the required amount of smoothing. In this paper, we derive and illustrate a general least-squares process for estimating the solution and show that it contains Twomey's method of weighting an a priori constraint vector as a special case. The optimum amount of smoothing (in the sense of maximum-likelihood estimation) depends on certain covariance matrices describing the measurement process. In a manner similar to that of the more recent work [8],[9],[10], and [11], we derive and use statistically orthogonal basis vectors.
Certain other bases are also used and numerical comparisons are made for a particular kernel. In our method, the covariance matrix of the error in the resulting solution is calculated and its trace is used as a measure of the error in the final results. It is shown in this paper that the trace of the error covariance matrix is minimized when the number of basis vectors equals the number of quadrature points. We use the resulting minimum trace as a quality criterion describing the effectiveness of a given matrix equation (with specified accuracy of observation and a specified distribution of the constraint vector) in reducing the variance of the a priori constraint vector. We also derive and discuss the condition for an optimum basis and present numerical examples using random input errors to simulate the measurement process. We discuss and present a least-squares analysis of line width and absorption data for both water vapor and oxygen. We also present numerous calculations of the solution quality criterion and indicate how this criterion could be used to determine both experimental feasibility and optimum choice of probing frequencies.

2. Theory of Radiative Transfer in the Microwave Region

The equation of transfer in a steady field of radiation in the case of local thermodynamic equilibrium is given by Kondrat'ev [12]
\[
\frac{\cos \theta}{\rho} \frac{\partial I_v}{\partial h} = k_v B_v + \frac{\sigma_v}{4\pi} \int I_v(h, r') p_v(h, r', r) d\omega' - (k_v + \sigma_v) I_v, \quad (1)
\]

where \( I_v \) is the intensity of radiation, \( \theta \) is the zenith angle, \( h \) is the height above the surface, \( k_v \) and \( \sigma_v \) are the mass absorption and mass scattering coefficients respectively, \( \rho \) is the density of material absorbing the radiation, \( B_\infty \) is the Planck intensity function, and \( \frac{d\omega'}{4\pi} p_v(h, r', r) \) is the fraction of energy incident upon the scattering volume in the direction \( r' \) which is scattered in the direction \( r \).

The integration over \( d\omega' \) extends over all directions of \( r' \). For a cloudless atmosphere and for microwave frequencies, the scattering coefficient is zero and the equation of transfer for a purely absorbing atmosphere is obtained

\[
\frac{\cos \theta}{\rho} \frac{\partial I_v}{\partial h} = k_v (B_v - I_v). \quad (2)
\]

This can be integrated to give

\[
I_v(h) = I_v(\infty) e^{-\tau_v(h, \infty)/\cos \theta} + \int_k^\infty \left\{ k_v \rho \right\} B_v e^{-h/\cos \theta} \frac{dh'}{\cos \theta}, \quad (3)
\]

for the intensity received "looking up" at a height \( h \) and at a zenith angle \( \theta \). In (3), \( I_v(\infty) \) is the unattenuated intensity incident outside the atmosphere and \( \tau_v(h, \infty) \) is the total vertical attenuation given by
The Planck function, $B_ν$, multiplied by the absorption coefficient is proportional to the power flux density emitted per unit bandwidth and may be approximated by the Rayleigh-Jeans law in the microwave region [13]:

$$B_ν = \frac{2ν^2}{c^2} k T,$$  \hspace{1cm} (5)

where $k$ is the Boltzmann constant, $c$ is the speed of light, and $T$ is the absolute temperature. The intensity, $I_ν$, may be related to the brightness temperature, $T_b$, by the defining relation

$$I_ν = \frac{2ν^2}{c^2} k T_b.$$  \hspace{1cm} (6)

It follows immediately from (3), (5), and (6) that

$$T_b(ν) = T_b^{(∞)} e^{-\tau(ν, ∞)/\cos θ} \int_{h'}^{h' ∞} \int_{h'}^{h''} \int_{h''}^{h'} \int_{h''}^{h'''} \int_{h'''}^{h''''} \int_{h''''}^{h''''' \cos θ} \rho dh'/\cos θ.$$

The apparent sky temperature, as measured by an antenna immersed in a radiation field, will be the contribution of (7) from
each direction seen by the antenna multiplied by the appropriate antenna gain factors and integrated over the antenna pattern.

If it is desired to determine the brightness temperature of the atmosphere from directions confined to a narrow solid angle, it is necessary to have a highly directional antenna with low side lobes such that the contributions from the desired direction are maximized. The noise temperature of the antenna can be measured directly by comparing the received signal with that of a known source.

In using (7) to deduce $T(h)$ from measurements of $T_b$, one may vary either zenith angle, $\theta$, or frequency, $\nu$. In ground-based probing, however, there are reasons to avoid the angular scheme. First, an assumption of horizontal homogeneity of the atmosphere is necessary. It is also probable that some of the space swept out by the observing antenna will include discrete cloud structures whose emission is not easily taken into account. Finally, it is very difficult to take account of ground emissions and reflections because of uncertainties in antenna gain patterns. We will therefore only consider inversion using measurements at different frequencies. This scheme reduces, but does not eliminate, the above difficulties. Henceforth, it will be assumed that no clouds are present in the main beam of the observing antenna.
Equation (7) is non-linear in the temperature because the absorption coefficient depends on temperature and pressure. As discussed by Westwater [14], this non-linearity can be handled by assuming a mean temperature profile to determine a first approximation to the absorption, solving the resulting Fredholm equation of the first kind, and iterating. The next section presents a method of solving the linearized equation in the presence of measurement error by statistically weighting a priori knowledge of the temperature profile against information given by the integral equation. Because of the nature of the constraint, it is presumed that convergence of the iteration sequence will cause no problem, even in the presence of large experimental errors. This has not yet been verified.

3. Inversion Method

Let \( \{f(y), a \leq y \leq b\} \) be a Gaussian random process having continuous sample functions. If \( K(x, y) \) is a continuous function of \( x \) and \( y \) and if

\[
\int_{a}^{b} K(x, y) f(y) \, dy = g(x)
\]

(8)
then \( g(x) \) is also a Gaussian process with continuous sample functions. The main idea is to estimate \( f(y) \) by measuring \( g(x) \) at various values of \( x \), say \( x = x_i, \ i = 1, \ldots, n \). Introducing a quadrature formula of the type \( \int_a^b h(y)dy = \sum_{j=1}^m w_j h(y_j) \) gives a matrix equation

\[ Af = g \]  

where

\[ A = (A_{ij}) \ i = 1, 2, \ldots, n; \ j = 1, 2, \ldots, m, \]

\( m \) is the number of quadrature abscissas,

\( n \) is the number of observations of \( g(x) \),

\( y_j \) are the quadrature abscissas,

\( x_i \) are the specific values of \( x \) for which \( g(x) \) is observed,

\( w_j \) are the weights associated with \( y_j \),

\( f_j = f(y_j) \),

\( g_i = g(x_i) \),

\( A_{ij} = w_j K(x_i, y_j) \),

\( f = [f_1 f_2 \ldots f_m]^T \) is the column vector of unknown functional values, (the superscript \( T \) denotes matrix transposition throughout this paper),

and \( g = [g_1 g_2 \ldots g_n]^T \) is the column vector of values of \( g(x) \).

We assume that the mean vector \( E(f) = f_o \) and the covariance matrix, \( \Sigma_f \), of \( f \) are known. \( (E(\cdot) \) denotes the expected-value operator and \( \Sigma_v \) denotes the covariance matrix of any vector \( v \) throughout this paper).

By the linearity of \( E \) and the propagation rule for covariance matrices, respectively, we have \( E(g) = g_o = Af_o \) and \( \Sigma_g = \Sigma_f A^T \). In the cases
of interest here $g$ is a vector of measurements subject to error.

Thus one observes

$$g_e = g + \varepsilon$$

(10)

instead of $g$. In addition to the assumptions already made, we assume:

a) the errors $\varepsilon_i$ are independent of $f$, hence independent of $g$;
b) the errors $\varepsilon_i$ are normally distributed with zero mean and known covariance matrix $S_e$;
c) the quadrature errors are negligible with respect to $\varepsilon$;
d) $S_e$ and $S$ are both nonsingular with dimensions $n \times n$ and $m \times m$, respectively.

It is convenient in practice to represent the solution in terms of a small number of basis vectors. We let $U = [U_1 \mid U_2 \mid \ldots \mid U_k]$ (lines denote matrix partitions throughout this paper) be a matrix of $k$ linearly independent $m$-component basis column vectors and $C = [C_1 C_2 \ldots C_k]^T$ be a vector of coefficients to be determined where $k \leq m$.

The inference problem to be solved is the following. Given the observed vector $g_e$ and the covariance matrices $S_f$ and $S_e$, estimate $f$ and $\varepsilon$ under the constraint $g_e - Af = \varepsilon$. Putting

$$\eta = f - f_0, \ h = g - g_o = A(f - f_0) = A\eta$$

$$h_e = h + \varepsilon = A\eta + \varepsilon,$$

(11)
where $\eta$ is to be approximated by UC gives an equivalent problem: given $h_e$, estimate $\eta$ and $\varepsilon$ in the form $[\begin{bmatrix} UC \\ \varepsilon \end{bmatrix}]$ subject to the constraint $h_e - AUC = \hat{\varepsilon}$. First, note that the maximum-likelihood estimate of $\eta$ in the absence of measurements $g_e$ is $\eta = 0$. The estimate $\eta = 0$ may be coupled with the set of measurements, $g_e$, to form an "effective" measurement vector $[\begin{bmatrix} 0 \\ h_e \end{bmatrix}]$. From this vector and the Gauss-Markov least-squares principle for correlated variables [15], a maximum-likelihood estimate of $[\begin{bmatrix} \eta \\ \varepsilon \end{bmatrix}]$ can be obtained. Since the covariance matrix of $[\begin{bmatrix} \eta \\ \varepsilon \end{bmatrix}]$ is $[\begin{bmatrix} S & 0 \\ 0 & S_e \end{bmatrix}]$, the desired estimate $[\begin{bmatrix} UC \\ \varepsilon \end{bmatrix}]$ must be such that $R(C, \varepsilon)$ is rendered stationary, where

$$R(C, \varepsilon) \equiv (UC)^T S^{-1}_f (UC) + \varepsilon^T S^{-1}_e \varepsilon + \mu^T (AUC - h_e + \varepsilon),$$

and $\mu^T$ is a row matrix of Lagrange multipliers. Differentiating with respect to $C$, $\varepsilon$, and $\mu$ and equating to zero gives the solution

$$UC = UD^{-1} U^T A^{-1}_e S^{-1}_e h_e$$

and

$$\hat{\varepsilon} = h_e - AUD^{-1} U^T A^T S^{-1}_e h_e,$$

where

$$D = U^T X U \text{ and } X = S^{-1}_f + A^T S^{-1}_e A.$$
We may also rewrite (13) in the equivalent form

\[
U_C = U(U^T S_f^{-1} U) -1 U^T A^T [S_\varepsilon + A(U^T S_f^{-1} U)^{-1} U^T A]^{-1} h_e. \quad (16)
\]

We apply the propagation rule for covariance matrices to UC-\eta, where UC is given by (13):

\[
U_C - \eta = UD^{-1} U^T A^T S_\varepsilon^{-1} (\alpha \gamma + \varepsilon) - \eta
\]

and

\[
S_{UC} - \eta = [UD^{-1} U^T A^T S_\varepsilon^{-1} A - I] S_f [UD^{-1} U^T A^T S_\varepsilon^{-1} A - I]^T
\]

\[
+ [UD^{-1} U^T A^T S_\varepsilon^{-1}] S_f [UD^{-1} U^T A^T S_\varepsilon^{-1}]^T,
\]

so that

\[
S_{UC} - \gamma = TYS_f YT - (TYS_f + S_f YT) + S_f - TYT, \quad (17)
\]

where

\[
Y = A^T S_\varepsilon^{-1} A \text{ and } T = UD^{-1} U^T. \quad (18)
\]

Substituting \( Y = X - S_f^{-1} \) into (17) and noting that \( TXT = T \) gives

\[
S_{UC} - \eta = S_f + T + T (XS_f) T - TXS_f - S_f XT, \quad (19)
\]

and

\[
S_\varepsilon - \varepsilon = AS_{UC} - \eta A^T. \quad (20)
\]
Expressions (13), or (16), and (14) give the desired statistical estimates of the solution for any given basis \( U \). Equations (19) and (20) give the error covariance matrices by which the quality of the results may be estimated, as will be seen in the next section. In the work reported in this paper no use has been made of the estimate (14) of \( \hat{e} \) of the expression (20) giving \( S_{\hat{e}-e} \).

Various special cases may be noted. If \( k=m \), that is, if \( U \) is a nonsingular \( mxm \) matrix, (13), (16), (19), and (20) become, respectively,

\[
UC = \tilde{\eta} = X^{-1}A^TS_{\hat{e}}^{-1}h, \quad (21)
\]

\[
\tilde{\eta} = S_fA^TH^{-1}h, \quad (22)
\]

\[
S_{\hat{\eta}-\eta} = X^{-1} \quad , \quad (23)
\]

\[
S_{\hat{e}-e} = AX^{-1}AT \quad , \quad (24)
\]

where

\[
H = S_{\hat{e}} + AS_fAT .
\]

From (22), a result equivalent to (23) is

\[
X^{-1} = S_{\hat{\eta}-\eta} = S_PS_PS_f - 2S_fPS_f + S_f + S_fA^TH^{-1}S_{\hat{e}}H^{-1}AS_f , \quad (25)
\]

where

\[
P = A^TH^{-1}A.
\]
The study of special cases will be confined to the case \( k = m \) here. If \( S_{e}^{-1} \to 0 \), i.e., if the measurements have large errors, we obtain

\[ \hat{\eta} = 0 \text{ or } f = f_{0} \text{ and } S_{\hat{\eta}} = S_{\hat{\eta}}. \]

If \( S_{f}^{-1} \to 0 \), then \( X \) will be nonsingular if and only if \( \text{rank } A = m \). Then

\[ \hat{\eta} = (A^{T}S_{e}^{-1}A)^{-1}A^{T}S_{e}^{-1}h \text{ and } S_{\hat{\eta}} = (A^{T}S_{e}^{-1}A)^{-1}. \]

If \( S_{e} \to 0 \), i.e., if the measurements of \( g \) are perfect, and if \( \text{rank } AU = n \) then \( n \leq m \) and (22) and (23) become respectively,

\[ \hat{\eta} = S_{f}A^{T}[AS_{f}A^{T}]^{-1}h \text{ and } S_{\hat{\eta}} = S_{f} - S_{f}A^{T}(AS_{f}A^{T})^{-1}AS_{f}. \]

In computational practice the latter situation will not occur since the quadrature errors will invalidate the assumptions as \( S_{e} \to 0 \). Finally, if \( S_{f} \to 0 \), then (22) and (25) give, respectively,

\[ \hat{\eta} = 0 \text{ or } f = f_{0} \text{ and } S_{\hat{\eta}} = 0. \]

We may show the correspondence of the present method with that of Twomey [6] as follows: for \( k = m \), let \( S_{e} = \sigma_{e}^{2}I, S_{f} = \sigma_{f}^{2}I, \gamma = \frac{\sigma_{e}^{2}}{\sigma_{f}^{2}}, f_{0} = \bar{p}, f_{0} + \hat{\eta} = \bar{f}, \text{ and } g_{e} = \bar{g} \) in (21) to correspond with Twomey's notation [6]. Then

\[ \bar{f} = \left[ A^{T}A + \gamma I \right]^{-1} \left[ A^{T}g + \gamma \bar{p} \right], \tag{26} \]

which is identical to Twomey's equation (6), p. 105. Thus, if the covariance matrices \( S_{f} \) and \( S_{e} \) are both scalar, the optimum choice of \( \gamma \) (in the sense of maximum-likelihood estimation) is given by the ratio of variances. However, in commonly occurring physical situations \( S_{f} \) has substantial off-diagonal elements.
The basis $U = I$ with $m = k$ gives an adequate solution via (21), (23), and (24). However, it is often convenient to represent the solution in terms of $k$ parameters, where $k < m$, using (13), (19), and (20). The quality of such a representation depends on the choice of basis. In the next section we discuss the problem of basis optimization.

4. Determination of Optimum Basis Vectors

Previous solutions by Wark and Fleming [10], and Twomey [11] have employed basis vectors (i.e., columns of $U$) which were obtained to fit the data in an optimum manner without reference to the integral equation to be solved. It will be shown below that the integral equation (as represented by the matrix $A$ which is an ingredient of $S_{UC - \eta}$) plays a part in obtaining the optimum matrix $U$, but (see section 5) the use of an exactly optimum basis $U$ is often not critical, so that $U$ as employed in earlier solutions should suffice. This classical determination of $U$ (as exemplified by Obukhov's paper [16], for example) is presented here and interpreted in terms of the covariance matrix of the residuals. The criterion which must be satisfied for an optimum basis for the integral equation is then easily seen.

Consider the quadratic form

$$(d - UC)^T (d - UC) \equiv q(U, C).$$

(27)
Here $U$ and $C$ have the same meaning as in section 3 and $d$ is a sample vector from a population having a multivariate $m$-dimensional normal distribution, say, with zero mean and covariance matrix $S_d$.

For any specified basis $U$, $q(U, C)$ is minimized when

$$UC = U(U^TU)^{-1}U^Td,$$  \hspace{1cm} (28)

as can be seen by differentiation. Thus the minimum value of $q(U, C)$ for any given basis $U$ is given by

$$q_{\text{min}}(U) = d^T[U(U^TU)^{-1}U^T - I]U(U^TU)^{-1}U^Td.$$  \hspace{1cm} (29)

Various criteria may be used to determine what is meant by "smallness" of $q$. In the classical case the optimum $U$ is that which minimizes the expected value of $q_{\text{min}}(U)$. Let $\text{Tr}B \equiv \text{trace } B$ denote the sum of the diagonal elements of any matrix $B$. By expanding and employing the linearity of the operator $E$ we may show that

$$E[d^TQd] = \text{Tr}S_dQ$$  \hspace{1cm} (30)

for any real symmetric matrix $Q$. Applying (30) to (29) gives $U$ as that basis which minimizes

$$\text{Tr}[S_d[I - U(U^TU)^{-1}U^T]] = \text{Tr}S_d - \text{Tr}U^TS_dU(U^TU)^{-1}.$$  \hspace{1cm} (31)
In the last expression we have used the relation \( \text{Tr } AB = \text{Tr } BA \), which holds whenever \( AB \) is square. Expression (31) is invariant with respect to replacement of \( U \) by \( UB \), where \( B \) is any nonsingular \( k \times k \) matrix.

In fact, the matrix \( S_d U (U^T U)^{-1} U^T \) is unaffected by such a transformation. Furthermore, let \( J \) be an \( m \times m \) symmetric positive definite matrix and let \( V \) be any \( m \times k \) basis matrix. Since \( V^T JV \) is positive definite, there exists \( [M] \) a real nonsingular upper triangular \( k \times k \) matrix \( B^{-1} \) such that \( V^T JV = (B^{-1})^T (B^{-1}) \). Let \( U = VB \). Then \( U^T JU = B^T (V^T JV) B = I \). Thus any normalization of the form \( U^T AU = I \) may be assumed without loss of generality. We suppose

\[
U^T U = I. \tag{32}
\]

Hence \( U \) must be found which maximizes \( \text{Tr } [U^T S_d U] \) subject to the constraint (32). By partitioning \( U \) into individual columns of basis vectors and considering the maximization process involved, it can be shown [18] that the columns of \( U \) must be chosen as those eigenvectors corresponding to maximal eigenvalues \( \lambda_1 \geq \ldots \geq \lambda_k > 0 \) of \( S_d \). Thus \( U \) must satisfy

\[
S_d U = U \Lambda, \quad \tag{33}
\]

where

\[
\Lambda = \text{diag } [\lambda_1, \lambda_2, \ldots, \lambda_k].
\]
Substituting (32) and (33) into (31) gives

$$E\{q_{\min}(U)\} = \text{Tr}S_d - \text{Tr} \Lambda = \sum_{i=k+1}^{k} \lambda_i \text{ for optimum } U.$$  

$$\alpha = \frac{\sum_{i=1}^{k} \lambda_i}{\text{Tr}S_d}$$  

The ratio (34) is sometimes called [8] the fraction of the total variance "explained" by the basis U.

It follows from (28) and (31) by use of the propagation rule for covariances, with \(\text{Tr}AB = \text{Tr}BA\), that

$$E\{q_{\min}(U)\} = \text{Tr}S_{UC} - d'$$

Thus \(E\{q_{\min}(U)\}\) may also be given another interpretation. As a criterion of the size of the errors resulting from a distribution having zero mean and second moments defined by a given covariance matrix \(S\), we may choose \(\text{Tr}S\). Since the trace is equal to the sum of the eigenvalues of a matrix, this interpretation is geometrically equivalent to defining the "size" of an \(m\)-dimensional ellipsoid as the sum of the squares of its semi-axes. The interpretation of \(E\{q_{\min}(U)\}\) as the trace of the covariance matrix will be freely used throughout the remainder of the report. Note that \(E\{q_{\min}(U)\}\) is also equal to \(m\) times the expected overall mean-square error of the approximation \(d \sim UC\).
Although no use is made of the result in what follows, it is interesting that the minimum of the quadratic form

\[ q_d(U, C) = (d - UC)^T S_d^{-1} (d - UC) \]

has the expected value \( m - k \) for any choice of \( U \), and therefore cannot be used to determine an optimum basis.

From the preceding discussion it follows that an optimum basis \( U \) for use with the integral equation would be that which minimizes

\[ \text{Tr} S_{UC}^{-1} \eta^T \{ S_I + T + T (X S_I X)^T S_I^{-1} - S_I X T \} \]  \[ (35) \]

From the definition of \( T \) we see that, even with the normalization \( U^T X U = I \), expression (35) is of fourth degree in the elements of \( U \).

Since minimization of (35) is difficult, and since classical basis vectors seem to suffice in practice, the determination of \( U \) from (35) will not be pursued farther in this paper.

5. Quality Criterion

The quantity \( \text{Tr} X^{-1} \) can be used as a measure of the accuracy to be expected from a given integral equation with given covariance matrices \( S_I \) and \( S_X \) and a given set \( \{ x_i \} \) of values of \( x \). For \( k = m \), i.e., for a non-singular \( m \times m \) matrix \( U \), \( S_{UC}^{-1} \eta \) reduces to \( X^{-1} \) by (23). Furthermore, as demonstrated below, \( \text{Tr} S_{UC}^{-1} \eta \geq \text{Tr} X^{-1} \) for any basis \( U \). Thus, \( \text{Tr} X^{-1} \) is a measure of the best that can be done for a given problem. Calculating \( \text{Tr} X^{-1} \) and comparing with \( \text{Tr} S_I \) indicates the amount of improvement over the \textit{a priori} statistical knowledge that can be expected in a given case.
Theorem: \( \text{Tr} S_{\text{UC}} - T - \text{Tr} X^{-1} = 0 \), where, as previously defined,

\[
X = S_f^{-1} + A^T S_z^{-1} A,
\]

\[
D = U^T X U,
\]

\[
T = U D^{-1} U^T,
\]

\[
\text{Tr} S_{\text{UC}} - T - \text{Tr} X^{-1} = \text{Tr} \left[ S_f - T + T X S_f X T - T X S_f - S_f X T - X^{-1} \right]
\]

\[
U = \begin{bmatrix} U_1 | U_2 | \ldots | U_k \end{bmatrix}^T \text{m where the } U_i \text{ are linearly independent}
\]

and \( m \geq k \).

Lemma: \( \text{Tr} B^T S_f B = \text{Tr} B^T X^{-1} B \) where \( B \) is any real \( m \times m \) matrix.

Proof: Let \( S_f = (S_{ij}) \), \( X^{-1} = (X_{ij}^{-1}) \), and \( B = (B_{ij}) \). By direct calculation,

\[
\text{Tr} B^T S_f B = \sum_{i,j} B_{ij} S_{ij} B_{ij} = \sum_{i=1}^m \left( \sum_{p=1}^m \sum_{q=1}^m S_{pq} B_{qi} B_{pj} \right) = \sum_{i=1}^m B_i^T S_f B_i,
\]

where \( B_i \) is the \( i \)-th column vector of \( B \). By an extension \([19]\) of Bergstrom's inequality we have, for any real column vectors \( y \) and \( z \),

\[
(y^T S_f y)(z^T S_f^{-1} z) \geq (y^T z)^2.
\]

Since \( X = S_f^{-1} + A^T S_z^{-1} A \) so that \( z^T X z \geq z^T S_f^{-1} z \), we have
\[(y^T S_i y)(x^T x) \geq (y^T z)^2\]. Putting \(y = B_i\), \(z = X^{-1} B_i\) gives 

\[(B_i^T S_i B_i)(B_i^T X^{-1} B_i) \geq (B_i^T X^{-1} B_i)^2\]. If \(B_i = 0\), dividing out the positive quantity \(B_i^T X^{-1} B_i\) gives \(B_i^T S_i B_i \geq B_i^T X^{-1} B_i\). (If \(B_i = 0\), the inequality is trivially true.) Therefore, 

\[\text{Tr} B_i^T S_i B = \sum_{i=1}^{m} B_i^T S_i B_i \geq \sum_{i=1}^{m} B_i^T X^{-1} B_i = \text{Tr} B^T X^{-1} B\]. This proves the lemma. It can now be applied to prove the theorem. Note that 

\[S_{UC} \cdot X^{-1}\] may be written as \(S_{UC} \cdot X^{-1} = (XT - I)^T S_i (XT - I) + T - X^{-1}\). By the lemma 

\[\text{Tr} \{S_{UC} \cdot X^{-1}\} \geq \text{Tr} \{(XT - I)^T X^{-1} (XT - I) \} + \text{Tr} T - \text{Tr} X^{-1}\]

\[= \text{Tr} \{TXT - 2T + X^{-1} - T - X^{-1}\}.\] Since \(TXT = T\) we have 

\[\text{Tr} \{S_{UC} \cdot X^{-1}\} \geq \text{Tr} 0 = 0\]. q.e.d.

There are conditions for which a basis may be chosen such that 

\[\text{Tr} S_{UC} \cdot \eta\] decreases as \(k\) increases, and approaches \(\text{Tr} X^{-1}\) for \(k\) considerably less than \(m\). Such behavior is illustrated in figure 1, which presents the values of \(\text{Tr} S_{UC} \cdot \eta\) vs. \(k\) for the integral equation (36), given and discussed in section 6. The conditions are: 

\[S_\varepsilon = .01 I, n = 7, m = 15\] with \(\{x_i\}\) and \(\{y_j\}\) as given in section 6. The Obukhov basis resulting from the \(S_\varepsilon\) of table 1 is used. Figure 2 presents the values of
TrSuC - η vs. k under similar conditions using the power basis

\[ U_{ij} = y_{ij}^{j-1} \] and figure 3 presents similar results for the trigonometric basis

\[ U_{ij} = \sin \left( \frac{2\pi y_{ij}}{b-a} \right) i = 1, 2, \ldots 15, j = 1, 2, \ldots 7 \]

\[ U_{ij} = \cos \left( \frac{2\pi y_{ij}}{b-a} \right) i = 1, 2, \ldots 15, j = 0, 1, 2, \ldots 7. \]

Evidently k = 6 will suffice for the power basis and k = 11 will suffice for the trigonometric basis. Figures 1, 2, and 3 are combined for easy comparison in figure 4.

The results of figures 1 through 4 arise from reasonably well-chosen bases. The type of behavior to be expected for ill-chosen bases is indicated in figures 5 and 6. Figure 5 presents TrSuC - η vs. k for a basis consisting of random numbers uniformly distributed between -1 and +1. Figure 6 presents similar results for the basis \( U_{ij} = \delta_{ij} \). Clearly, in these cases nothing less than a full complement of basis vectors (i.e., \( k = m = 15 \)) will achieve the desired accuracy. By noting that TrSuC - η is \( m \) times the theoretical overall mean-square error of the fit, we see that TrSuC - η = 120.407 corresponds to an overall rms error of 2.88 and that TrX -1 = 23.946 corresponds to an overall rms error of 1.26. This shows the extent to which the original statistics of \( f \) may be improved by using the integral equation in this particular case. The analysis presented here serves a similar purpose to the analysis of the "degree of independence" of the measurements of \( g(x) \) as discussed by Twomey [6], [11]. However, in the present
case the actual rms error to be expected is found and the results are necessarily dependent on the statistics $S_e$ and $S_f$, as well as on the kernel of the integral equation.

6. Numerical Inversion Results

For purposes of numerical experimentation the following equation was used:

$$e^{-a(x)H_o} \alpha(x) \int_0^H e^{-y/H_o} f(y) e^{a(x)H_o} e^{-y/H_o} dy = g(x). \quad (36)$$

This equation occurs in remote atmospheric probing work if an exponential atmosphere is assumed. Here $H_o$ is a constant and $\alpha(x)$ is given by

$$\alpha(x) = 1.1x - 1 \quad (37)$$

for the purposes of this section. If $f = f_c = \text{const.}$ is inserted in the left side of (36) and the integrations performed, the resulting right side is:

$$g(x) = f_c \left[ 1 - e^{-\alpha(x)H_o} (1 - e^{-H/H_o}) \right] \quad (38)$$

Substituting (38) into (36) will, of course, give an integral equation whose correct solution is $f = f_c$. In the work reported here, the values $H = 10$, $H_o = 5$, and $f_c = 293.997$ were assumed. To study the

behavior of (36) in the presence of measurement error, random errors distributed in accordance with $S_\epsilon$ were added to $g(x)$ as given by (38) and the mean value $f_0$ was varied randomly from $f_c$ in a manner determined by $S_{f_0}$, which is given in Table 1.

Since the solution $f$ simulates an atmospheric temperature profile, $S_f$ was obtained from radiosonde data from 240 soundings during August at Denver, Colorado. The matrix $S_\epsilon$ was assumed to be scalar and the values assumed will be indicated. The method of constructing random errors is indicated below.

The CDC 3600 computer has a FORTRAN function, RANF (-1), which gives random numbers uniformly distributed between 0 and 1. These numbers are random in the same sense that a table of random numbers is random; that is, if the series of statements $V_i = \text{RANF}(-1)$, $i=1,2,...,M$ is repeated in the same manner, where $i=1$ refers to the first use of RANF (-1) in a given computer run, the same sequence will result, but the sequence itself is random. It follows from the central limit theorem [20] that the variable $\hat{V}_M$, where

$$\hat{V}_M = \frac{\sum_{i=1}^{M} V_i - M/2}{\sqrt{M/12}}$$

(39)

is approximately a random normal deviate (i.e., it has a normal distribution with mean zero and standard deviation 1), the degree of the approximation depending on the size of $M$. A sample of 9,000 values of $\hat{V}_M$ was calculated for $M=1,2,4,8$, and 16.
Histogram frequencies were found and compared with the frequency distribution for random normal deviates. There appeared to be no significant discrepancy between the histogram and the theoretical curve for $M \geq 8$. In all work reported here $M = 10$ was used. To simulate errors having a given covariance matrix $S$, we first determine \[ 17 \] a matrix $W$ such that
\[ S = W^T W . \] \( 40 \)

If $V = (V_1, V_2, \ldots, V_m)^T$ is a sample of independent random normal deviates, we form $\tilde{V} = W^T V$. Then, since $S_V = I$, it follows from the propagation rule for covariance matrices that
\[ S_{\tilde{V}} = (W^T I (W^T)^T = W^T W = S. \] \( 41 \)

This process was used to simulate errors having zero mean and covariance matrix $S_f$.

In the simulation of errors the mean vector $f_0$ was varied rather than the sample vector $f$ because the integration to give the right side of \(36\) could then be obtained in closed form as \(38\), and a check on the accuracy of quadrature could also be obtained. A total of 15 quadrature abscissas were chosen; these consisted of 5 Gass-Legendre values for each of 3 intervals: 0 to 1, 1 to 3, and 3 to 10 respectively. Intervals of different length were needed because of
the general decaying-exponential character of the kernel. The interval enclosing the $x_i$ was taken as $1 \leq x_i \leq 1.98$, for $i = 1 \ldots n$. The $x_i$ were evenly spaced, and the values used will be indicated. Under these conditions a numerical integration with Gaussian quadrature was compared (for $f = f_c$) with (38) and the maximum quadrature error was found to be .0011 in the right side, for which the actual value varied from about 103 to 292. All solutions used the classical Obukhov basis. In table 2 results are shown for $x_i = 1(.0544 \ldots) 1.98$, where the $x_i$ are rounded to four decimal places. Here $n = 19$, $a(x_i)$ is given by (37), $S_i$ is as given in table 1, $S_c = 0_c^2 I = 10^{-4} I$, and $f_c = 293.997$ as indicated. The solutions were run with $\kappa_c = 5.1$. Under these conditions $S_{uc}^{-1} \eta = TrX^{-1} = 12.8$. There was some loss of accuracy in the computation, so that trace values are good only to one decimal place. These were the only trace computations for which the computation errors were noticeable; most other trace values were computed using double precision. The overall rms error corresponding to $TrX^{-1} = 12.8$ is .92. The solution of table 2 and two others are shown graphically in figures 7, 8, and 9. The three solutions were selected at random from a "run" of 40 solutions.

The index $\text{Tr}X^{-1}$ was computed for exactly the same conditions as for the solutions of figures 7, 8, and 9 except that $S_\varepsilon = \sigma_\varepsilon^2 \cdot I = (.01) \cdot I$. Under these conditions it was found that $\text{Tr}X^{-1} = 21.44$. Next every second and third value of $x_i$ was removed to give the set $x_i = 1 (.1633\ldots) 1.98$ where the resulting $x_i$ are rounded to four decimals. In this case $n = 7$ and $\text{Tr}X^{-1} = 23.95$. This is the case shown in figure 1.

Decreasing $n$ from 19 to 7 had very little effect on the expected error. The effect of changing $n$ is summarized in table 3. For this kernel, the theoretical rms error is not strongly influenced by $n$, as long as the interval $(1, 1.98)$ remains fixed.

Figures 10, 11, 12, and 13 present results for the conditions of table 3 with $n = 7$ and $k = 4$. These solutions were selected at random from a "run" of 40 solutions. The improvement of the solution over the statistical values is not as pronounced, because of the increase of $\sigma_\varepsilon$ from .01 to .1.

</table>
The 40 solutions of which figures 10 through 13 are a sample were also run for \( k = 1, 2, 3, 5, 6, 9, 12, \) and 15. The same sequence of random errors was used for each run of 40. A typical solution is shown in table 4 for various values of \( k \). Table 4 shows typical behavior of the solution as \( k \) is varied. In this case, any value of \( k \) from 3 through 15 would have given essentially the same solution.
7. Absorption of Microwaves in the 10-150 GHz Frequency Band.

The Van Vleck-Weisskopf theory [21] was applied by Van Vleck [22],[23], to the absorption of microwave by oxygen and water vapor.

The formula obtained by Van Vleck [22] for the absorption of $O_2$ is

$$\gamma = 10^6 \left( \log_{10} e \right) \frac{8\pi^3 \nu N_d R_{O_2} B}{c(3kT)^2}$$

$$\sum_{N} \left[ \frac{2|\nu_{N+} f(\nu_{N+}, \nu)||\mu_{N+}|^2 + 2|\nu_{N-} f(\nu_{N-}, \nu)|}{|\mu_{N-}|^2 + F(\nu)|\mu_{N_0}|^2} \right] e^{-EN/kT},$$

where the following notation has been introduced:

a) $N_d$ is the total number of molecules per cubic centimeter

and $R_{O_2}$ is the fraction of the total which is $O_2$;

b) $c$, $k$, and $\nu$ are the speed of light, Boltzmann's constant, and

the frequency of the imposed microwave, respectively;

c) $f$ and $F$ are form factors for the line shapes given below;

d) $\nu_{N+}$ and $\nu_{N-}$ are resonant frequencies of the transitions;

$(N_0$ labels the so called zero frequency transition)$^*$

e) $\gamma$ is the absorption in decibels per kilometer and is numerically

equal to the product of the mass absorption coefficient times the dens

f) $N$ runs over odd integers labeling certain rotational quantum states;

g) $|\mu_{N_0}|^2$ is the square of the matrix element dipole moment evaluated

between appropriate angular momentum states;

h) $P$ is a rotational constant whose magnitude is $1.44 \text{ cm}^{-1}$, and

*The transition frequencies for oxygen can be calculated with sufficient accuracy for the purposes of this report from the formulas in Townes and Schawlow [24].
i) $E_N$ is the energy level of the $N^{th}$ quantum state.

In (42) the expression of Van Vleck has been translated into the more modern notation and two of these equations are consolidated. Furthermore, Van Vleck's expression is for pure oxygen. The fraction, $R_{O_2}$, of oxygen in the dry atmosphere is about 0.2. In the actual atmosphere, $R_{O_2}$ varies slightly since the mixing ratio of water vapor also varies.

The form factors in (42) are given by

$$f(v', v) = \frac{\nu}{\pi \nu_1} \left[ \frac{\Delta \nu}{(\nu_1 - \nu)^2 + (\Delta \nu)^2} + \frac{\Delta \nu}{(\nu_1 + \nu)^2 + (\Delta \nu)^2} \right], \quad (43)$$

and

$$F(v) = \lim_{v_1 \to 0} [\nu_1 f(v_1, v)] = \frac{2 \nu \Delta \nu}{\pi [\nu^2 + (\Delta \nu)^2]}, \quad (44)$$

The matrix elements of the dipole moment can be calculated from formulas in Townes and Schawlow [24].

The formula for the absorption by water vapor at the 22.235 GHz resonant line in decibels per kilometer is given by Van Vleck [23] as

$$\gamma_{6-5} = 10^6 (\log_{10} e) \frac{8\pi^3 \nu_n R_{H_2O}}{3 G kT} \frac{2^{E_{5-1}/kT}}{|\mu_{6-5}||5-1| e}$$

and $G$ is the rotational partition function given by

$$G = \sum_{J=0}^{\infty} \sum_{\tau = -J}^{J} \left( \frac{2 - (-1)^\tau}{2J + 1} \right) e^{-E_{J\tau}/kT} \quad (46)$$
The dipole moments and transition frequencies of $\text{H}_2\text{O}$ may be calculated from formulas in the Appendices of Strandberg [25]. These are much more complicated than the corresponding calculations of $\text{O}_2$.

Equation (46) implies that other transitions are possible for the $\text{H}_2\text{O}$ molecule. If the form factor in (43) were valid for these, then the absorption of each of these lines would have the same form as (45). These frequencies are much higher, in general, than the highest frequency of interest for this paper. Thus, an approximate formula for these contributions $\gamma$ can be written as $\gamma_{\text{Res.}}$ given by

$$\gamma_{\text{Res.}} = K \rho \nu^2 \Delta \nu.$$  \hfill (47)

The total $\gamma$ due to $\text{H}_2\text{O}$ is the sum of the contributions of (45) and (47).

The experimental values appropriate for the $K$ and $\Delta \nu$'s for the Van Vleck equations will be discussed in the next section. The $\Delta \nu$ is derived in the Van Vleck-Weisskopf theory from considering broadening to arise from the finite extension of the time between collisions. In fact, $2\pi \Delta \nu$ is the reciprocal of the mean time between collisions in the Van Vleck-Weisskopf theory.

If one had hard spherical molecules, the mean time between collisions could easily be calculated from kinetic theory [26]. However, molecules interact in a much more complicated way than can be described by the simple hard-sphere collision picture. A better approximation can be made by considering the molecular interactions to be more complicated functions of the separation than the hard-sphere approximation. This at least improves the temperature dependence of $\Delta \nu$. 

34
The classical theory described above does not explain why different lines have different widths. One could account for this in the classical approximation by ascribing a different interaction between each state. No a priori knowledge from classical theory can supply this sort of information and it must be introduced as an additional set of assumptions if one is to proceed further via a classical mechanical calculation of line widths.

A partial quantum mechanical approach to the problem was given by Anderson as quoted in Tsao and Gurnutte, [27]. The translational motion in this calculation is treated as a classical mechanical problem, whereas the internal state transitions are treated as a quantum mechanical problem. In this picture $\Delta v$ is given by

$$\Delta v = n v \sigma ,$$

where

$$\sigma = 2\pi \int b \, db \, f(I, b).$$

In (48), $n$ is the number density of perturbers, $v$ is the average relative velocity, $b$ is the separation of the molecules at closest approach and $f(I, b)$ is the distribution function for cross section as a function of the internal coordinates, $I$, and $b$. 

35
8. Least-Squares Analysis of Line Width Data

The absorption equations given in the last section, as developed by VanVleck and Weisskopf [21], contain essentially one undetermined parameter, the line width constant, $\Delta \nu/c$. Calculations of this quantity are laborious and many uncertainties are present in such calculations. Examples of such uncertainties are lack of knowledge of the exact form of the molecular interaction, imprecise knowledge of molecular constants (such as quadrupole moments) which enter into the theory of line broadening, and the effect of higher order corrections to the perturbation expansions.

As a check on theory, there are fortunately many experimental results on line broadening and absorption coefficients for a variety of conditions of pressure and temperature. For low pressures (around 10 to 20 mm of Hg), direct measurements of line widths can be made since unresolved lines are well separated and there is very little line shape asymmetry from the "negative frequency" portion of the VanVleck-Weisskopf line shape. However, there is danger in extrapolating these low pressure measurements to high pressures, especially if the individual lines are not well resolved at the higher pressures. A notable example of this type of behavior is oxygen.

In the work reported in this section, the absorption data of various researchers have been least-square analyzed to determine line widths
and, in the case of water vapor, line shape factors. A least-squares analysis applied to nonlinear equations (such as the VanVleck-Weisskopf equations) cannot, in general, be solved exactly; the solution must be determined iteratively by use of a reasonable first estimate to insure convergence.

The least-squares method used here may be described as follows. We wish to characterize $N$ data points $d_i$ by a function $f_i$ of $n$ parameters $p_j$ such that

$$
\sum_{i=1}^{N} \left( d_i - f_i(p_1, p_2, \ldots, p_n) \right)^2 w_i = \min ,
$$

where $w_i = \text{positive definite weight of the } i^{\text{th}} \text{ data point}$. It is assumed that "reasonable" first approximations to the parameters $p_j$ are known. If these first approximations are labeled as $p_j^{(0)}$, then the functions $f_i$ may be expanded in a Taylor series about $p_j^{(0)}$:

$$
f_i(p_j) = f_i(p_j^{(0)}) + \sum_{k=1}^{n} \frac{\partial f_i}{\partial p_k} (p_j^{(0)} - p_j^{(0)}) .
$$

Let

$$
J = \begin{bmatrix}
\frac{\partial f_1}{\partial p_1} & \frac{\partial f_1}{\partial p_2} & \ldots & \frac{\partial f_1}{\partial p_n} \\
\frac{\partial f_2}{\partial p_1} & \frac{\partial f_2}{\partial p_2} & \ldots & \frac{\partial f_2}{\partial p_n} \\
\vdots & \vdots & \ddots & \vdots \\
\frac{\partial f_N}{\partial p_1} & \frac{\partial f_N}{\partial p_2} & \ldots & \frac{\partial f_N}{\partial p_n}
\end{bmatrix}
$$

$$
\leftarrow \quad n \quad \rightarrow
$$
and
\[ r = [d_1 - f_{i_1}, d_2 - f_{i_2}, \ldots, d_N - f_{i_N}]^T \] (52)

= vector of residuals.

In (51) and (52), both the function \( f \) and its derivatives are to be evaluated at the original estimate \( p_j^{(0)} \). Then minimizing (49) yields the matrix equation given by Strand [28].

\[ \Delta p \approx p - p^{(0)} = (J^T \Gamma J)^{-1} J^T \Gamma r, \] (53)

where
\[ \Gamma = \text{diag}(w_1, w_2, \ldots, w_N). \] (54)

Equation (53) is then iterated by reevaluating (51) and (52) at each stage of the iteration process.

Equation (53) was applied to the oxygen absorption data of Artman [29] and Crawford and Hogg [30] to determine the values of the line width constants for both the (+) and (-) transitions. The data of Artman were taken under laboratory conditions at \( T = 300^\circ \text{K} \) and pressures of 1 atm, 2 atm, and 4 atm in air. Each of the above samples of data was taken at approximately 25 frequencies covering the range of 50 to 62 GHz.
Each piece of data was weighted with unit weight. The data of Crawford and Hogg were taken from transmission studies through the atmosphere at sea level pressures. As stated in their article, the approximate temperature range during the period of measurement was $0 \pm 3^\circ C$. Hence, as with most data taken in the field, the uncertainty of these data is greater than that of laboratory measurements. The results of the least-squares fit are shown in table 5. As has been discussed previously [31], the numerical values of the normalized line width parameter $(\Delta v/c)/P$ decrease with increasing pressure. A new feature, possibly of significance for line breadth theory, is that the line widths of the + transitions are consistently higher than those of the - transitions for all of the data examined. In addition, the data of Crawford and Hogg give higher values of the line width than a simple extrapolation using the usually assumed temperature dependence would indicate. This fact causes the authors to speculate that the interaction of $H_2O$ with $O_2$ might give rise to the increase in oxygen line widths. Of course, the residual absorption of the 22 GHz and the 183 GHz $H_2O$ lines might also appear in this analysis as an increase in line width, but because of the absence of relative humidity measurements while the absorption measurements were being taken, it was impossible to ascertain if this was the case. In any case, it would be useful if measurements were taken of oxygen line broadening in the presence of water vapor.

The 22-GHz water vapor absorption data of Becker and Autler [32]
were also analyzed, but in a slightly different fashion. For a fixed tem-
perature, the water vapor absorption coefficient may be written [23]:

\[
\frac{\gamma}{\rho} = c_1 \tilde{\nu}^2 \left\{ \frac{\Delta \nu/c}{(\tilde{\nu} - \tilde{\nu}_0)^2 + (\Delta \nu/c)^2} + \frac{\Delta \nu/c}{(\tilde{\nu} + \tilde{\nu}_0)^2 + (\Delta \nu/c)^2} \right\} + c_2 \tilde{\nu}^2 \frac{\Delta \nu}{c},
\]

(55)

where \( \Delta \nu = a(1 + b \rho) \). From 66 measurements of \( \frac{\gamma}{\rho} \) vs. \( \rho \) and \( \nu \), four-
and five-parameter fits to the data were determined. The parameters
determined were \( c_1, c_2, a, b, \) and, in addition, for the five-parameter
fit \( \tilde{\nu}_0 \). The results are tabulated in table 6. The initial estimates in all
cases were taken from accepted values of these constants.

Note that the resonant frequency determined by the five-parameter fit
is very close to the accepted value 0.7417 cm\(^{-1}\), which is determined
by other means. The values of \( c_2 \) and \( b \), which describe respectively
the nonresonant contribution of the 183 GHz and higher lines and the
effect of \( \text{H}_2\text{O-H}_2\text{O} \) line broadening, are both noticeably higher than the
accepted values. Again, these facts could be of theoretical significance.

Surprisingly good consistency was obtained between the four-and-five-
parameter determinations, considering that the data were somewhat
noisy.

9. Application of Quality Criterion to Determine the Reduction of the Variance of \textit{a priori} Temperature Data by Microwave Radiation Measurements

In recent work by Twomey [11] and Mateer [8], the information content of radiation measurements has been discussed. In particular, it was shown that for physically realistic smooth kernels, independent information obtained from separate measurements is severely limited due to ubiquitous measurement error. Twomey [11] goes further in his analysis and determines, from a large number, \( p \), of possible measurements with a given noise level, the number of independent pieces of information, \( t \), which can be found [11], and gives a procedure for determining optimum frequency locations for the \( t \) measurements (\( t < p \)). In many inversion problems, however, certain information about the unknown function is known before any measurements are made. This \textit{a priori} knowledge is embodied in the mean and the covariance matrix, both of which can be estimated from past data.

The information content of radiation measurements should be judged by the improvement over the \textit{a priori} knowledge.

As noted in section 5, the quantity \( TrX^{-1} \) can be used as a measure of the overall accuracy to be expected from a given integral equation with given covariance matrices \( S_f \) and \( S_c \) and a given set \( \{x_i\} \) of \( x \). Calculating \( TrX^{-1} \) and comparing with \( TrS_f \) indicate
the amount of improvement over the a priori statistical knowledge that can be expected in a given case. It is important to realize, however, that $\text{Tr} \mathbf{X}^{-1}$ is not a panacea because no single number can adequately describe $m(m+1)/2$ of them. More detailed information, such as the amount of reduction of variance of the function at various points, can only be obtained by comparison of $\mathbf{S}_f$ and $\mathbf{X}^{-1}$.

The calculations of $\mathbf{X}^{-1}$ in this section have been carried out for ground-based probing "looking up" and for an integral equation determined by the Van Vleck equation (42) for microwave oxygen absorption. The temperature and pressure structure used in calculating the absorption at each height were determined by assuming a constant lapse rate of $6.5 \degree \text{K/km}$ to determine the temperature and by integrating the hydrostatic equation to determine the pressure. The effect of non-linearities in the kernel due to fluctuations of the temperature from the mean value has not been included in this analysis. The water vapor absorption was assumed to be zero, and surface temperature and pressure were taken as $0 \degree \text{C}$ and $850 \text{mb}$, respectively. For simplicity the pressure dependence of the normalized line width constant $(\Delta \nu/\mathbf{P})$ was neglected and the values of $((\Delta \nu/\mathbf{P})_\pm = 0.0341 \text{ cm}^{-1}/\text{atm}$ were used for $+$ and $-$ transitions respectively. The calculations at each frequency have been made assuming
monochromaticity, so that the degradation of information due to finite receiver bandwidth is not accounted for. This effect should be small, however, since the ratio of receiver bandwidth to pressure-broadened linewidth can be made quite small for microwave receivers. Because of the previous assumptions, the calculations involving $X^{-1}$ are meant to be illustrative only.

Before presenting these calculations, we must give one more theoretical extension of the methods of sections 3, 4, and 5. For a ground-based probing scheme, the value of the function at the lower point, $a$, can usually be measured directly. This constrained point should be used to modify the statistical estimation of the function and its uncertainty as given by $X^{-1}$. First, the constraint can be incorporated into the integral equation by using a quadrature formula (such as Gauss-Radau) which uses the value of the function at $a$, $f(a)$, directly:

$$\int_{a}^{b} K(x, y) f(y) \, dy = \sum_{j=1}^{m} w_{j} K(x, y_{j}) f(y_{j})$$

$$= w_{1} K(x, a) f(a) + \sum_{j=2}^{m} w_{j} K(x, y_{j}) f(y_{j}) \quad (56)$$

Thus, by subtracting $w_{1} K(x, a) f(a)$ from the measured quantity, $g(x)$, a matrix equation to be solved for $(m-1)$ components of the
function of $f$ is obtained. Second, knowing $f(a)$ reduces the uncertainty in all the other functional values. The new covariance matrix, $S_f^{(c)}$, of dimension $(m - 1) \times (m - 1)$, has elements

$$
S_{ij}^{(c)} = S_{ij} - \frac{S_{ii} S_{jj}}{S_{11}}, \quad i, j = 2, 3, \ldots, m;
$$

where

$$S_f = (S_{ij}) \quad \text{and} \quad S_f^{(c)} = (S_{ij}^{(c)}). \quad (57)$$

For convenience, the matrix $S_f^{(c)}$ will be referred to in the following as the constrained covariance matrix. Furthermore, instead of the mean, $\bar{f}$, as the best a priori estimate of $f$, the effect of knowing $f_1$ modifies this optimum a priori estimate to $\hat{f}$ where

$$
\hat{f}_i = \bar{f}_i + \frac{S_{11}}{S_{11}} (f_1 - \bar{f}_1), \quad i = 2, \ldots, m. \quad (58)
$$

Equations (57) and (58) may be derived from linear regressions of the $(m - 1)$ functional values $f_2, f_3, \ldots, f_m$ as functions of the surface value $f_1$.

The two temperature covariance matrices and the corresponding means were obtained by ensemble averaging of 5 years of radiosonde data for the 2 months, February and August, at Denver, Colorado. The February and August averages were over 163 and 240 soundings, respectively. The temperatures, given at heights determined by the radiosondes, were interpolated linearly to determine values at the 15
desired quadrature points. (Gauss-Radau quadrature was used for the subinterval 0 to 1 km, while Gaussian quadrature was used in the subintervals 1 to 3 km and 3 to 10 km.) The means \( \overline{T}(h_i) \), and elements of the covariance matrix, \( S(h_i, h_j) = S_{ij} \), were determined from

\[
\overline{T}(h_i) = \frac{1}{N} \sum_{\alpha=1}^{N} T_\alpha(h_i),
\]

and

\[
S_{ij} = \frac{1}{N-1} \sum_{\alpha=1}^{N} \left( T_\alpha(h_i) - \overline{T}(h_i) \right) \left( T_\alpha(h_j) - \overline{T}(h_j) \right),
\]

where \( N \) is the number of soundings, \( \alpha \) is an index for each sounding, and \( T_\alpha(h_i) \) is the temperature of the \( \alpha \)th sounding at the height \( h_i \). The constrained covariance matrix was then calculated using (57). The means of February and August are given in table 7 and the constrained covariance matrices for February and August are given in tables 8 and 9, respectively. It may be of interest to compare the unconstrained covariance matrix for August, given in table 1, with the constrained matrix for the same month, table 9. The elements of the matrices differ considerably only below the 10th quadrature point (around 3 km).

The calculations of $X^{-1}$ were run for both months, and for assumed rms brightness temperature measurement errors of $0.01 \degree K$, $0.1 \degree K$, and $1.0 \degree K$. The entire matrix of $X^{-1}$ for Denver, February, with $\sigma_x = 0.01 \degree K$ is shown in table 11.

The meaning of a 15x15 covariance matrix cannot be presented in simple form. A rough estimate of the standard deviation to be expected at each quadrature height is given by the square root of the corresponding diagonal element of the covariance matrix. These quantities are plotted as functions of height in figures 14 through 19. For ease of comparison, the error distributions to be expected in the constrained solution are shown in figures 20 and 21. The corresponding overall quality criterion, $\text{Tr}X^{-1}$, is tabulated in tables 12 and 13.
Table 11
Solution Covariance Matrix $X^{-1}$, in $(°K)^2$, for the 2nd to 15th Quadrature Points Using Denver, February, Radiosonde Data with Constrained Surface Temperature, $n=15$ and $\sigma_c = 0.01 °K$.

The study of $X^{-1}$ and its trace can be directed towards an important experimental consideration i.e.; namely, that of determining an optimum distribution of measurement frequencies, given that only a certain number of them (usually small) will be available. This problem has been studied by Twomey [11] from the point of view that the optimum location of measurements is determined by the integral equation itself. Further, from the analysis of a certain matrix, which depends on the kernel, he shows that the number of independent pieces of information is limited by the number of eigenvalues which are larger than the noise level of the measurements. In the absence of additional information, the above approach seems reasonable.

When additional information is available, such as the statistical information contained in $S_f$, it is clear that the optimum frequencies should be determined from a statistical compromise among $S_f$, $S_e$, and the properties of $A^T A$. This optimum set could be different for periods of different meteorological statistics. If the measuring instrument(s) is (are) not tunable, a heterogeneous ensemble averaging over yearly data might be in order. A method which properly weights all available information has the advantage of allowing the choice of frequencies such that the duplication of easily available information (that of $S_f$ and $f$) by difficult experimental measurements is made as small as possible. The concept of 'number of
independent pieces of information" is not as straightforward with this analysis as it was in Twomey's. However, an "effective number", such as the number of measurements required to reduce the a priori variance to a desired level, given that the noise level is fixed, can be defined. In a theoretical sense, such a number could always be obtained for any given level greater than zero since duplicating measurements is equivalent to lowering the noise level.

Practically speaking, if a reasonably large reduction in variance with a few well-placed measurements is not possible, the experiment is probably impractical.

An attempt was made to determine the approximate sensitivity of \( \text{Tr} X^{-1} \) to choice of and number of frequencies for one, two, and three frequencies and for \( \sigma_e = 0.01 \circ K \). The one-frequency search was carried out starting with 47.0 GHz and adding a .5 GHz increment until 56 GHz was reached. These results, for both the constrained and unconstrained data, are shown in Table 14 for the Denver, August, statistics.

The frequencies corresponding to the minimum trace are 54.5 GHz for the unconstrained (U) case \( \text{Tr} X^{-1} = 50.6 \circ K^2 \) and 4.75 GHz for the constrained (C) case \( \text{Tr} X^{-1} = 37.7 \circ K^2 \). The traces of \( S_f \) were 120.5 (C) and 68.5 (U), \( \circ K^2 \), and the traces of \( X^{-1} \) for the 15 frequencies of Table 10 were 5.7\( \circ K^2 \) (U) and 4.8\( \circ K^2 \) (C). Thus

</tbody>
</table>
the use of a single frequency, with this choice of \( \sigma_c \), reduces the variance by a factor of 2 (roughly).

The two-frequency calculations were done by fixing \( \nu_1 = 47 \) GHz and varying the second frequency, \( \nu_2 \), from 48.3 GHz to 60.0 GHz in 1.3 GHz increments. These results are shown in table 15, which indicates that the variance obtained from the one-frequency calculations is roughly halved by the addition of the second frequency.

The three-frequency calculations were done by fixing \( \nu_1 = 47 \) GHz and \( \nu_2 = 50.9 \) GHz and varying the third frequency, \( \nu_3 \), from 47.5 to 58.0 in 0.5 GHz increments. These results, again for Denver, August, and \( \sigma_c = 0.01^\circ \text{K} \), are shown in table 16. It should be observed that \( \text{Tr}X^{-1} \) is approaching that of the 15-frequency calculations, and that addition of more frequencies will yield diminishing returns. The relative minimum of \( \text{Tr}X^{-1} \) at 47.5 GHz is presumably due to the nearby resonant line at 47.4465 GHz. A rigorous search for optimum frequencies would necessarily examine the effect of each resonant line on \( \text{Tr}X^{-1} \).

10. Summary

A method for the numerical solution of a Fredholm integral equation of the first kind has been derived and illustrated. The method requires knowledge of the covariance matrices of the constraint vector and the measurement error vector. Such knowledge is frequently available in physical problems when it is desired to derive values of physical functions from integrals involving them. If both covariance matrices $S_f$ and $S_\varepsilon$ are scalar, the equations reduce to those of Twomey [6], where the optimum smoothing parameter $\gamma$ is given by the ratio of variances between the diagonal elements of $S_\varepsilon$ and $S_f$, respectively. The present method automatically incorporates the optimum amount of smoothing in the sense of maximum-likelihood estimation.

The trace of the error covariance matrix, $\text{Tr} S_{UC-\eta}$, is used to estimate the precision of the solution. When $k = m$ (i.e., when the basis forms a nonsingular $m \times m$), $S_{UC-\eta}$ reduces to

$$X^{-1} = (S_f^{-1} + A^T S_\varepsilon^{-1} A)^{-1}.$$  

The positive number $\text{Tr} X^{-1}$ is related to the error to be expected in the solution and is used as a quality criterion. A comparison of $\text{Tr} X^{-1}$ with $\text{Tr} S_f$ indicates the amount of information contained in the integral equation with observation errors determined by $S_\varepsilon$. It is evident that $\text{Tr} X^{-1}$ can be used to study
optimization of the spacing of observations. Such a study could be valuable for planning measuring systems.

The method of estimation and the use of the quality criterion $\text{Tr} X^{-1}$ were illustrated by studying the effect of various sequences of random errors on the solution of a specific integral equation. The effect of varying the number and type of basis vectors was studied for this example. The results apparently agree with theoretical predictions, although confidence tests were not run.

Calculations of $X^{-1}$ and its trace were then performed using certain meteorological statistics of Denver, Colorado, and absorption coefficients determined from the Van Vleck absorption equations for the microwave oxygen complex with a linear temperature profile. These calculations were performed for a set of 15 frequencies selected to cover the oxygen band, and for three sets of assumed brightness-temperature rms errors of .01 °K, .1 °K, and 1.0 °K. The square roots of the diagonal elements of $X^{-1}$ were plotted as functions of height in an attempt to show the accuracy with which various parts of the tropospheric temperature profile could be
inferred from ground-based measurements of oxygen emission.

Questions of optimum choice of frequencies for this probing were discussed and illustrative calculations relevant to this choice were presented.

II. Acknowledgements

We acknowledge the contribution of Dr. M. M. Siddiqui, who read parts of the manuscript and made valuable suggestions. The encouragement of Mr. Martin Decker throughout the performance of this work is appreciated. We thank Mr. W. B. Sweezy for supplying the meteorological data which were used in constructing the covariance matrices.

[Graph showing a line graph with two curves: one labeled 'randomly-determined \( f_0 \) + UC' and another labeled 'statistically-estimated solution \( f_0 + UC \)'. The graph has a horizontal line at \( f_c = 293.997 \).]
Square Roots of Diagonal Elements of Covariance Matrices of Temperature
Statistics, $S$, and Solution, $X^{-1}$, vs. Height for Denver, August, and for
Measurement Errors, $\gamma_6$, of .01 °K.

![Graph showing temperature and solution statistics with curve labels: U: Unconstrained Lower Point, C: Constrained Lower Point.](image)

Fig. 14

80
Square Roots of Diagonal Elements of Covariance Matrices of Temperature Statistics, $S$, and Solution, $X^{-1}$, vs. Height for Denver, August, and for Measurement Errors, $c_e$, of $1^\circ K$.

Curve Labels
U: Unconstrained Lower Point
C: Constrained Lower Point

Fig. 15
Square Roots of Diagonal Elements of Covariance Matrices of Temperature Statistics, $S_i$, and Solution, $X^{-1}$ vs. Height for Denver, must, and for Measurement Errors, $\sigma_c^2$, of 1.0 °K.

**Fig. 16**

**Curve Labels**
- U: Unconstrained Lower Point
- C: Constrained Lower Point
Square Roots of Diagonal Elements of Covariance Matrices of Temperature Statistics, $S_i$, and Solution, $X^{-1}$, vs. Height for Denver, February, and for Measurement Errors, $\sigma_e$, of .01 $^\circ$K.

**Fig. 17**

83
Square Roots of Diagonal Elements of Covariance Matrices of Temperature Statistics, $S_e$, and Solution, $X^{-1}$, vs. Height for Denver, February and for Measurement Errors, $\sigma_e$, of 1°K.

Curve Labels
U: Unconstrained Lower Point
C: Constrained Lower Point

Temperature Statistics
Solution Statistics

Fig. 18
Square Roots of Diagonal Elements of Covariance Matrices of Temperature Statistics, $S_v$, and Solution, $X^{-1}$, vs. Height for Denver, February, and for Measurement Errors, $\sigma_v$, of 1.0 °K.

Curve Labels
U: Unconstrained Lower Point
C: Constrained Lower Point

Temperature Statistics
Solution Statistics

Height in km

Figure 19
Square Root of Diagonal Elements of Covariance Matrices with Constrained Lower Point of Temperature Statistics, $S_P$ and Solution $X_1$, vs. Height for Denver, August.

Standard Deviation in °K

Height in km

$\sigma_f$

$\sigma_e = 1.0^\circ K$

$\sigma_e = 0.1^\circ K$

$\sigma_e = 0.01^\circ K$
