PREFACE

This Memorandum describes a parsing capability embedded within the PL/I programming language. This extension allows users to specify the syntax of their parse-requests in a BNF-like language and the semantics associated with a successful parse-request in the PL/I language.

The APAREL system has been designed for a wide range of parsing applications including macro expansion, symbol manipulation, on-line command parsing, analysis of programs, and translation of programming languages.

This revised Memorandum, representing the actual implementation of the system, supersedes the authors' APAREL--A Parse-Request Language, The Rand Corporation, RM-5611-ARPA, October 1968.

APAREL has been developed as a basic tool for use in man-machine communication studies at Rand under sponsorship of the Advanced Research Projects Agency.
SUMMARY

This Memorandum describes APAREL, an extension to an algorithmic language (PL/I) that provides the pattern-matching capabilities normally found only in such special-purpose languages as SNOBOL4 and TMG. This capability is provided through parse-requests stated in a BNF-like format. These parse-requests form their own programming language with special sequencing rules. Upon successfully completing a parse-request, an associated piece of PL/I code is executed. This code has available for use, as normal PL/I strings, the various pieces (at all levels) of the parse. It also has available as normal PL/I variables, the information concerning which of the various alternatives were successful. Convenient facilities for multiple input-output streams, the initiation of sequences of parse-requests as a subroutine, and parse-time semantic checks are also included.

APAREL has proven convenient not only as a general string manipulator but also in building a powerful SYNTAX and FUNCTION macro system, an algebraic language preprocessor debugging system, an on-line command parser, and a translator for Dataless Programming.

I. INTRODUCTION

Higher-level descriptions of the problem of compiling have attracted much interest in the past few years. Along with the desire to develop higher-level specialized languages tailored to particular users, the need has arisen to develop similar specialized languages for the writing of these compilers. In general, these so-called compiler-compiler languages are characterized by their facility to define in a BNF-like manner the syntax of the target language. In addition, they possess a programming language designed to operate on and to direct the results of the parsing.

With most compiler-compilers a problem arises both in controlling the parse sequencing and in operating on the results of the parsing. In particular, flexibility is usually lacking in 1) the specification of sequences of parse attempts, 2) the determination of the success or failure of a parse attempt on other than purely syntactic grounds, and 3) the specification of when semantic routines should be invoked. Furthermore, the semantic language is usually a small special-purpose language with facilities for the production of machine code. These systems ignore such other, noncompilation applications for parsers as on-line command parsers (which produce actions instead of machine code), interpretive parsers (which produce pseudo-code), "natural-language" parsers (which produce semantic trees), macro parsers (which produce source code), reformatting programs (which produce formatted listings), and so on. In short, the nonmachine-code generation applications of parsers have generally not been well handled by the translator writing systems.

APAREL attempts to provide a single system for all these applications by providing the user with a powerful general-purpose programming language (PL/I) for performing
the wide range of semantics required, and a flexible high-level syntax language for specifying parse attempts, together with facilities for controlling the sequencing of these parse attempts, determining success and/or failure on both syntactic and semantic grounds, invoking semantics when desired, and for manipulating the parts of a successful parse. Also, the familiarity of programmers with PL/I and the simplicity of the APAREL extensions and additions make it feasible for potential users to design, implement, and modify special-purpose languages without extensive learning.
II. APAREL--A PARSE-REQUEST LANGUAGE

Our view of translation is composed of three parts:
1) A request to find sequences of syntactic constructs in the source string to be parsed;
2) Context-sensitive validity checks to be made after successful syntactic parses: (For example, has the label been defined before? Is the type of a variable arithmetic? etc.)
3) Semantic routines to be executed only if both the syntactic parse and the context-sensitive validity checks are successful.

This view of translation, while very general, is easy for nonprofessional translator writers (but experienced programmers) to use in constructing easily modifiable translators.

Requests for parses are specified in a language very similar to BNF (rather than Floyd-Evans production language), because nonprofessional translator writers tend to conceptualize the syntax of their language top-down (for which purposes BNF-type languages are well suited). Professional translator writers, on the other hand, have learned that the bottom-up approach (for which production-type languages are appropriate) is usually more efficient. Furthermore, the former tend to think of both the syntax and semantics at the statement level.

To keep the syntax language simple, while still allowing generality in describing conditions falling in the gray area between syntax and semantics (which one would like to verify before accepting a parse made on syntactic grounds alone), we allow the specification of "parse-time" routines that return truth values. If they return a value of TRUE, the parse will continue. However, if a value of FALSE is returned, the parse will be unsuccessful, just as if the
syntactic parse failed. (The total parse may still be successful if alternatives are available to the unsuccessful subparse.) In addition to returning truth values, these "parse-time" routines may do any semantic processing desired. They are written in the semantic language described below.

The semantic routine associated with a parse is activated upon successful completion of that parse and successful returns from all the relevant parse-time validity checks, if any, specified within the parse. The code for the semantic routine immediately follows the request for the parse in the syntax language. The semantic language, rather than being a restricted special-purpose language, is full PL/I. The wide range of desirable "semantic" actions resulting from various syntactic parses necessitates a general-purpose programming language; and a major shortcoming of most compiler-compilers has been their restrictions on the semantic language.

To facilitate the semantics, the various pieces of the successful parse are put into normal PL/I strings as specified in the syntax language; and the options chosen, where alternatives were specified in the syntax language, are made available in normal PL/I variables.

DESCRIPTION OF PARSE-REQUESTS

The syntax of the parse-request language, specified in BNF, appears in the Appendix. However, the following examples are used to describe the language informally.

All parse-requests begin and end with a parse-delimiter (a double colon). After the beginning delimiter, the name of the request (the parse-request-name) is set off by a colon. The remainder of the parse-request is a list of the alternative parses (parse-alternative-list) desired, separated by OR (|) symbols. The parse-request is successful if any one of the alternatives is parsed successfully.
These alternatives may be either parse-elements or lists of parse-elements. Letting $PE_1$ represent a set of parse-elements, we can describe the following parse requests:

:: A: $PE_1PE_2 ::$

(the parse-request named "A" will succeed if and only if the parse-string contains $PE_1$ followed by $PE_2$)

:: B: $PE_1 | PE_2 ::$

(the parse-request named "B" will succeed if and only if the parse-string contains either $PE_1$ or $PE_2$)

:: C: $PE_1 | PE_2PE_3PE_4 ::$

(the parse-request named "C" will succeed if and only if the parse-string contains either $PE_1$ or the sequence $PE_2PE_3PE_4$)

The parse-elements can either be a parse-group or a parse-atom. A parse-group is simply a named or unnamed parse-alternative list enclosed in brackets ("[" and "]"), allowing naming of parts of a parse and alternatives within a sequence of parse-elements. The parse-atoms—the basic, indivisible components of a parse-request—consist of literal strings, parse-request names, parse-request-sequence names (described below, pp. 8-10), and primitive parse-request functions; e.g., ARBNO (arbitrary but nonzero number of the first argument separated by the second argument, if there is more than one occurrence of the first argument), and BAL (balanced strings). These atoms are the components that determine whether a parse is successful or not. The literal strings require that an exact match be found between the literal and the corresponding piece of the parse-string; the parse-request and parse-request-sequence names require that the named parse-request or parse-request-sequence be
successful on the corresponding piece of the parse-string; and primitive parse-request functions require that the corresponding piece of the parse-string satisfy the conditions of that particular function. There is no syntactic distinction made between these atoms. The category determination is made in the following way: First, the list of primitive parse-request functions is checked. If the atom is not a primitive parse-request function, then the list of parse-names (both parse-request and parse-request-sequence names) is checked. Finally, if it is not one of these, it is considered to be a literal. This mechanism alleviates the need to quote most literals within the parse-request language.

Consider the following set of parse-requests to parse PL/I DO statements:

```plaintext
:: do_statement:  do iterative-specification
   while_clause ';'::
:: iterative_specification:  variable = expression
   (to_clause by_clause|by_clause to_clause) |:::
:: to_clause:  to expression|:::
:: by_clause:  by expression|:::
:: while_clause: while '('expression')'|:::
```

The do_statement request requires the sequence of atoms

do  iterative_specification  while_clause  ;
in the parse-string to be successful. Of these, the middle two are parse-names and invoke parse-requests as they are encountered in a left to right scan. The first and last atoms are literals (because they are not defined as parse-names or primitive functions), and require exact matches with a piece of the parse-string. The final atom is quoted because semicolons are part of the parse-request language (explained below), and the semicolon here is used as a literal.

The iterative_specification request requires either the sequence:
1) Variable=expression
2) either 2a. to_clause
   2b. by_clause
   or 2a. by_clause
   2b. t: clause
or NULL.

Variable and expression are primitives and are defined as specified in the PL/I language specification [1]. Similarly, a to_clause is the literal "to" followed by an expression, or is null, and a while clause is the literal "while" followed by an expression enclosed in parentheses (quoted because they are part of the syntax language and are used here as literals), or is null.

Thus, the do statement parse-request invokes parse-requests for iterative specification and while_clause, and iterative specification invokes parse-requests for to_clause and by_clause and functions calls for variable and expression.

Unless otherwise specified, the parses allow an arbitrary number of blanks (including none) between pieces of the parse-string and require that the parse start at the beginning of the parse-string although it may be satisfied before the end of the parse-string. Thus, with the above set of parse-requests, successful parses will occur on the following parse-strings;

```
do I = 1;
doi = 1 by 5 to (n-3/2);
do;
do while (A=B);
```

and will fail on the following parse-strings:

```
I = 1 to 10: (no initial do)
Now do I = 1; (no initial do)
do I = 1 to 5 (no semicolon)
do I = 1 to 5 to 6; (to_clause followed by to_clause)
```
The portion of the parse-request language described so far allows fairly sophisticated parse-requests to be specified easily and naturally in a language similar to the normally used syntax description languages (BNF or IBM's syntax notation). However, this is not yet a useful facility, because neither the sequencing rules for initiating parse-requests and for making sequencing decisions based upon the success or failure of a parse-request, nor the method of accessing the various parts of a successful parse have been defined.

PARSE-REQUEST SEQUENCING RULES

A parse-request-sequence is composed of all parse-requests occurring in a common do-group or block. This does not include any parse-requests contained in blocks or do-groups within the common do-group or block forming parse-request-sequences of their own. The order of parse-requests within a parse-request-sequence is the same as their lexicographical ordering in the block or do-group. The semantic portion of a parse-request is the code between the end of the syntax portion of the parse-request and the beginning of the next parse-request in the parse-requesting-sequence, or the end of the do-group or block if there are no more parse-requests in the sequence.

A parse-request sequence begins with the first parse-request. If the initial parse-request fails, its semantic code portion is skipped, and the next parse-request in that sequence is tried, and so on, until either a successful parse-request is found or all parse-requests fail. If a successful parse-request is found, the associated semantic code portion is executed; then, normally, the parse-request-sequence is terminated with a successful indication (see Sec. V, Additional Features). Otherwise, the parse-request-sequence is terminated with an unsuccessful indication.
There are three ways in which a parse-request-sequence can be initiated. The first is as a parse-atom in a parse-request. Upon termination, its success-failure indicator is used in determining which alternatives, if any, are successfully parsed. The second is through use of an explicit command, INITIATE PARSE, which specifies which parse-request-sequence to initiate and can be issued in any code portion. Upon termination of the parse-request-sequence, its success or failure is available (see Sec. III, Parse Results), and control continues with the statement following the INITIATE PARSE command. The third method is by program control flowing into the first parse-request in a parse-request-sequence. Upon completion of the parse-request-sequence, its success or failure is available, and control passes to the end statement at the end of the do-group or block in which the parse-request-sequence occurs. Thus, if it is contained in an iterative do-group, control will continue around in the loop until iteration is complete. Otherwise, in blocks or non-iterative do-groups, control will flow out the bottom of the block or do-group upon termination of the parse-request-sequence.

In the first two cases, in which a parse-request-sequence is explicitly named, it is specified by referring to the label (which must be in the same block as the invoking statement) of the do-group or block in which the parse-request-sequence occurs. If the name of a parse-request is specified instead, only that parse-request will be initiated, and no others in its parse-request-sequence.

These sequencing rules allow the creation of sequences of parse-requests to be attempted, and the control of the execution order of these requests based on the results of the parses and/or explicit program control.

As stated previously, the semantic routine associated with a parse-request is activated upon successful completion of that parse-request and upon successful return from all the
relevant parse-time validity checks, if any, specified within the parse-request. This is true whichever way the parse-request is initiated. Thus, if a parse-request, P1, is initiated as a parse-atom or a parse-request, P2, and if it is successful, then its semantic routine will be initiated at that point, in the midst of the parse of P2. Semantics thus can be initiated at any point during a parse, giving the user considerable flexibility. However, care must be exercised when specifying "intermediate" semantics because the parse may fail later in the parse element list, which contained the parse-request that invoked the semantics, and either move on to the next alternative or fail completely.
III. PARSE RESULTS

APAREL also contains capabilities to make the results of a successful (or unsuccessful) parse available to the code portions of the language. This information is of two kinds: 1) pieces of the string parsed, and 2) information about which alternatives were successful in the parse.

Various parse-elements, such as parse-request-sequences, parse-requests, parse-alternatives, and parse-groups, can have names specified in APAREL. These names are the means by which the semantic code portions can utilize information about a parse. If "NAME" is the name of one of these parse-elements, then after a parse, a PL/I varying length string variable with the same name will contain that portion of the parse-string corresponding to the named parse-element. (In the case of a parse-request-sequence, the name is both the name of the result string and the label of the DO-block. APAREL contextually resolves all uses of this name to remove any ambiguity.) Also, a PL/I variable, whose name is "NAME_OPTION" (i.e., "_OPTION" is appended to the end of the name of the parse-element), will contain the index of the alternative selected within the parse-element. Thus the semantic portions can manipulate desired portions of the parse-string through PL/I's normal string-handling capabilities, and can interrogate any portion of the parse-tree to determine which alternatives were selected.

In applications with large syntax specifications, changing the syntax--either by addition or deletion of an alternative from the syntax--can affect the semantics, because alternative determination is made on an indexed basis; and altering the syntax alternative alters the indexing. To alleviate the problem, APAREL allows the user to label any or all of the alternatives. If a labeled alternative is selected, then the OPTION variable for that group will contain the name of the alternative selected.
rather than its index (APAREL contextually resolves all uses of this variable so that it can, in effect, take on either string or numeric values). This naming correspondence is invariant under additions or deletions to the set of alternatives.
IV. PARSE-TIME ROUTINES

Sometimes success or failure of a parse cannot be made on purely syntactic grounds alone; or, it is desired to perform some semantic operations during a parse. For these reasons, the parse-time facility has been included in APAREL. Parse-time routines are indicated in a parse-element by placing the parse-time routine name followed by its arguments, if any, enclosed in parentheses after a semicolon at the end of the parse element. The parse-time routine will be initiated if and only if the parse-element in which it occurs was successfully parsed. The initiation results in a function call of the parse-time routine, passing its arguments, if any. The parse-time routine, like the semantic portions of APAREL, is coded in full PL/I and can make use of all the facilities of APAREL, such as initiating parse-requests, manipulating parse-strings, and interrogating the parse-trees. In addition, the parse-time routine can perform any semantics desired and return a true or false value indicating whether the parse-element to which it is attached should be considered successfully parsed.

Since parse-request-sequences initiated in the syntactic portion of a parse can be a block or a do-group that may begin with a code section or may not contain any parse-requests at all, these parse-request-sequences can be considered parse-time routines that return a success or failure indication (and are formally the same as the parse-time routines discussed above). Both ways of specifying these parse-time routines have been allowed in APAREL, enabling users to choose the one corresponding to their way of conceptualizing its function in their particular application.
V. ADDITIONAL FEATURES

In the semantic portions of APAREL, very often one would like to output a modified or "translated" version of the parse-string. To make this operation simpler, a special variable, TRANSLATION, has been defined; and whenever an assignment is made to this variable, the value assigned is output to the SYSPRINT data set. For more flexibility, the user may define additional variables as being output variable of specified size and associated with a specified file. When an assignment is made to one of these variables, if the value can be added to the end of the present string value without exceeding the maximum size of the variable, then the new value is concatenated onto the existing value. If not, then the existing value is output on the file specified, and the new value becomes the value of the variable. If the size is not specified, then outputting occurs with every assignment. If neither a file nor a size is specified, then a user-defined procedure of the same name as the output variable is called with the new value as the argument. This allows the user to define arbitrarily complex procedures for outputting, and corresponds to the updating routine (left-hand size function) definitional capability of Dataless Programming [2] and CFL [3].

Similarly, for input, a variable, PARSE_STRING, will be automatically defined to hold the input to be parsed. When the amount of input in this variable falls below a system-defined limit, new input will be concatenated to the variable to fill it out to its maximum size. The user may define additional input variables together with their minimum sizes, maximum sizes, and file from which input is to come. If the minimum and maximum sizes are not specified, references to the input variable will invoke a user-defined accessing function of arbitrary complexity, a la Dataless Programming. These minimum and maximum sizes limit the amount of backtracking that can occur.
The user also can control which of several input sources is used via the CONSIDER command. He may later re-establish an input source via the RECONSIDER command. These commands stack and unstack respectively which input source is being parsed. CONSIDER_LEVEL contains the number of input sources so stacked, and CONSIDER_STRING is an array containing, in ascending order, the names of those stacked input sources.

In parsing there are normally three requirements for blank separation between the individual segments of the parse-string matched by parse-atoms. The first is that no blank may occur between the segments. This is indicated in a parse-request by placing a minus sign between the parse-elements. The other two normal blank-separation requirements are that either any number of blanks (perhaps none), or at least one blank (perhaps more), separate the segments. Since the need for each of these requirements is highly application dependent, APAREL allows the user to define the normal mode (used between parse-elements unless otherwise specified) and to request the other requirement by placing a period between the parse-elements. The normal mode is set by either NORMAL SEPARATION IS 0 or NORMAL SEPARATION IS 1 command. The default setting is NORMAL SEPARATION IS 1.

Similarly, the two normal ways to view the semantic code portion are either as open or closed subroutines. In an open subroutine, flowing out of the bottom of a semantic code portion into a parse-request initiates that parse-request. Whereas in a closed subroutine, flowing out the bottom of a semantic code portion into a parse-request effects a return to the caller of the parse-request whose semantics have just completed. APAREL allows a user to define which of these two modes he is using via the SEMANTICS OPEN and SEMANTICS CLOSED. The default setting is SEMANTICS CLOSED.

Both the SEPARATION and SEMANTICS commands are compile-time commands and affect the interpretation of all lexico-graphically following parse-requests in the current or contained blocks or do-groups, until either the end of the block
or do-group, or another mode command, overrides the present normal mode.

Within a semantic code portion, the user may desire to initiate a remote parse-request, or to terminate the semantics for the present parse. These capabilities are available, respectively, through the INITIATE PARSE and TERMINATE PARSE commands.

The TERMINATE PARSE command is also used to specify the success or failure of a parse-request. TERMINATE PARSE SUCCESSFULLY indicates a successful termination, while TERMINATE PARSE UNSUCCESSFULLY indicates an unsuccessful parse. TERMINATE PARSE with neither operand specified defaults to TERMINATE PARSE SUCCESSFULLY. Thus, a parse-request can be declared unsuccessful in three ways: 1) in the syntactic specification of the parse-request when a syntactic parse is unsuccessful; 2) in a parse-time routine; or 3) in the semantics of a parse-request. The parse is successful only if none of these indicates an unsuccessful parse.

When initiating a parse-request-sequence, a user often wishes to be able to inspect and manipulate the results of the parse-requests before accepting any translation produced. Since these parse-requests should not (and need not) know that they have been initiated from above, they must be able to create translations just like any other parse-request. Therefore, the user needs a way of telling APAREL to redirect the translation (or output variables) of any parse-request. This redirection causes the translation produced for the specified output variables to be collected into the specified strings for review and/or manipulation by the initiating routine. This redirection is specified as additional operands (of the form \( x \text{ IN } y \), and separated by 'AND') to the initiate parse-command. For example:

\[
\text{INITIATE PARSE } k \text{ COLLECTING translation IN } s \text{ AND output IN def;}
\]
The parse-request-sequence named k will be initiated. All translation it, or any parse-request it initiates, produces in the output variable named "translation" will be collected instead in the string named "s". and all translation produced in the output variable named "output" will be collected instead in the string named "def".

Finally, by placing a dollar sign ($) in front of parse-names, parse-time routine names, or parse-atoms, the user can indicate indirection; i.e., the parse-name, parse-routine name, or parse-atom specified is the contents of the named string. This facility, accomplished via a run-time symbol table of all parse-related names (which must all be unique), provides considerable flexibility for users desiring to alter the parse-requests dynamically. It also facilitates context-sensitive parses requiring repetition of a parse-element within the input string.
VI. EXAMPLES

One use of APAREL is as a macro processor, handling macros of the type commonly referred to as SYNTAX and/or FUNCTION macros [4]. In such an application, a user passes the macros over the source text, translating those portions that satisfy the macro syntax while leaving the rest of the text undisturbed. APAREL is easily restricted to this mode by defining a parse-request that picks off source-language statements, one at a time, from the input stream. The result of this parse, a single source-language statement, is then passed through the various macros that produce the desired translation when a parse request for a macro is satisfied. If the source statement passes all the way through the macros without matching, it is output unmodified. Assuming the parse-request, PLI_statement, has been predefined and will pick off one PL/I statement at a time, the following is an APAREL program that acts as a SYNTAX and FUNCTION macro processor for any parse-requests defined in its body.

/* Method: PL/I statements are picked off the input stream one at a time and used as the parse-string input for the user-defined syntax and function macros contained in the parse-request-sequence USER_MACROS. If no parse-request in this parse-request-sequence is successful, then the PL/I statement is output. Otherwise, the translation produced is added to the front of the string RESCAN. If this string is not already being CONSIDERed as the input string from which PL/I statements are picked off, it is so CONSIDERed. Thus all PL/I statements in the translation produced by the USER MACROS are processed before any more is taken from the original input source. After RESCAN has been exhausted, the original input source is RECONSIDERed */
next_PL1_statement:

INITIATE PL1_statement; /* get next PL/I statement*/
IF PL1_statement_option = 0 /* was the parse successful*/
  THEN DO; /* no, end of input must have been reached*/
    IF CONSIDERED_STRING (CONSIDER_LEVEL)='rescan'
      THEN DO; /*reconsider the original input string*/
        RECONSIDER;
        GO TO next_PL1_statement;
      END;
  ELSE /* we have exhausted the original input string*/
    TERMINATE PARSE; /* terminate the parse in this manner in case we were initiated by someone, and are not the top-level routine*/
  END;
ELSE /* parse was successful, we now have a single PL/I statement*/
  CONSIDER PL1_statement; /* use result of PL/I statement as parse-string for user_macros*/
  INITIATE user_macros COLLECTING translation IN partial_translation; /* initiate users syntax and function macro parse-request-sequence contained in the block or dc_group labeled "user-macros". The translation output of these macros is collected in the PL/I string "partial_translation"*/
  RECONSIDER; /* stop considering PL1_statement and reconsider the parse-string in effect before it*/
If user_macros_option = 0 THEN DO; /* one of the parse-
requests in the user_macros parse-
request-sequence was successful*/
    rescan = partial_translational||rescan; /* add
    partial translation to front of
    rescan string so that it will be
    retranslated first. Notice that
    this defines a depth first
    translation*/
    IF CONSIDERED_STRING (CONSIDER_LEVEL)¬ = 'rescan'
        /* is rescan the currently considered
        parse-string*/
        THEN/* no it is not the currently considered
        string*/
        CONSIDER rescan; /* make it the current
        parse-string*/
    GO TO next_PLL_statement;
END;
ELSE DO; /* none of the parse-requests in the user-macros
parse-request-sequence were successful*/
    TRANSLATION = PLL_statement; /* output the
    PLL_statement that did not match*/
    GO TO next_PLL_statement;
END;

Continuing the above example, two parse-requests are
shown below, both of which provide translations into PL/I.
They are placed in the do_group labeled "user_macros" to
conform to the preceding example's initiation command. The
first is a syntax macro that translates increment or decre-
ment commands, and the second is a functional macro that
translates various notations for asking if a value is equal
to one of a number of items. Notice that the only differ-
ence between syntax and function macros is that syntax
macros require successful parses to be anchored to the
beginning of the parse-string, while functional macros allow successful parses anywhere within the parse-string.

The annotated parse-requests are given below, followed by a set of example input parse-strings with their translations:

user_macros:  DO; /* begin labeled do group that defines a parse-sequence*/
NORMAL SEPARATION IS 1; /* unless otherwise specified parse-elements must be separated by one or more blanks*/
SEMANTICS CLOSED; /* upon reaching the end of the semantics of a parse-request, automatically generate a terminate-parse command*/
:: Increment_command: command_type (updated_variable: subscripted variable) by 'increment amount: ARB^ . ';' :: /* ar. increment command is a command type followed by a possibly subscripted variable, called "updated_variable", followed by the literal "BY" (literal since it is not defined), followed by an arbitrary string called "increment amount", followed by a semicolon. (The semicolon has to be quoted since it is part of the parse-request language.) The period indicates that a space is not required in front of the semicolon.*/
IF command_type_option = "increment command" /* was the option in command_type labeled "increment_command" chosen*/
THEN /* yes this is an increment command*/
translation = updated_variable||'='||updated_variable||'+'||increment-amount
ELSE /* no, must be decrement command*/
    translation = updated_variable || '=' || updated_variable || '-' || increment_amount || ');
 /* output PL/I assignment for decrementing variable enclosing increment_amount in parentheses*/

/* the next statement is a parse-request in the same block or do group as the present parse-request; therefore, it indicates the end of this semantic code; and since semantics have to be set closed, it automatically generates a terminate-parse command.*/

/* this parse-request will be activated if the preceding parse-request failed*/
:: one_of:(front:ARB)\x: subscripted_variable\is\is among\.=.\ alternative_list(back:ARB)::
/* a one_of function macro is an arbitrary string (the ARB primitive parse-request function matches the smallest string that allows the rest of the parse-request to be successful; this may require backup and repeated attempts, each time increasing the length of the string matched by .ne ARB parse-request function) named "front" followed by a subscripted variable named "x" followed by either "is", "is" followed by "among", or by ".=". This is followed by an alternative_list followed by an arbitrary string named "back". The separation between
these elements is one or more blanks—
except for the equal sign, which may
have zero or more blanks on either
side of it as indicated by the normal
separation override notation (the
periods). */

VII. TRANSLATION RESULTS

Using the APAREL program defined in Sec. VI, we indicate below the translations that would result for various input examples. If the input passes through unchanged, the translation entry is left blank to facilitate recognition.

<table>
<thead>
<tr>
<th>input</th>
<th>translation</th>
<th>comments</th>
</tr>
</thead>
<tbody>
<tr>
<td>increment x by 5;</td>
<td>x = x+5;</td>
<td>the decrement translation supplies parentheses around the decrement amount.</td>
</tr>
</tbody>
</table>
| d abc by x-4;             | abc = abc - (x-4);                 | no separating blank after 'by'
<p>|                           |                                    | 'by' is picked up as the subscripted variable, but the parse then fails because 'by' cannot be found. |
| i def by7;                |                                    | comma after 5 causes parser to pick up &quot;or&quot; as an expression rather than as the separator between |
| decrement by 3;           |                                    |                                                                         |
| if abc is x-3 or 0 then do; | if abc = x-3 |                                                                         |
| R = (def is among 1,2,z-4 or 9); | abc = 0 then do;                 |                                                                         |
| when h = 5, or 7 then do; | R = (def = 1 | def = 2 |                                                                         |
|                           | def = z-4 | def = 9);                                                 |                                                                         |
|                           | when h = 5 | h or 7 then do;                                           |                                                                         |</p>

VIII. IMPLEMENTATION

The initial implementation of APAREL, which has been completed on an IBM-360 computer, consists of two parts: 1) a preprocessor that converts APAREL programs into equivalent legal PL/I programs with external calls for parse-requests, and 2) the run-time parser, which provides APAREL's parsing capabilities. The preprocessor is an APAREL program that was bootstrapped into operation, and the run-time parser is an assembly-language program. The current implementation of each of these parts imposes the following restrictions on the full APAREL language.

1) The BAL primitive parse-request function is not implemented.

2) The scan of parse-requests is strictly left to right. Thus, in the parse-request

\[ \langle A|B\rangle C \]

if A is matched, B will be skipped; if C then fails, the sequence B followed by C will not be tried. This can be remedied by

\[ \langle AC|BC \rangle \]

3) The parser matches the maximum string possible. This applies only to the nonliteral matches; e.g., ARBNO and the blank scan, which match as much as possible. Note that this will prevent the parse-request

\[ \text{ARBNO}(A,"\)A} \]

from being parsed successfully because the arbitrary number of A's separated by NULLs will include all such A's in the input, forcing the final A after the ARBNO to fail.

4) Left-recursion is handled in a rather unique way. The state of the parser is determined by two variables: 1) the position in the input string, and
2) the position in the parse-request. Before attempting a match for any alternative, the parser checks to see if the present state has occurred before (during the current initiation of the original parse-request). If it has, a left recursive loop has occurred, and the parser simply moves on to the next alternative to break this left recursive loop. This, therefore, would cause the rule

\[ \text{number: number digit|digit} \]

A number is an arbitrary nonzero number of digits separated by NULLs. Or even more elegantly:

\[ \text{expression: ARBNO(expression,operator)|(expression) } \]
\[ \text{|variable|number } \]
\[ \text{|unary_operator expression} \]

An expression is an arbitrary nonzero number of expressions separated by operators, a parenthesized expression, a variable, a number, or a unary operation followed by an expression.
Appendix

BNF DEFINITION OF APAREL'S SYNTAX LANGUAGE

```
'PARSE_REQUEST' ::= 'PARSE_DELIMINATOR' 'PARSE_NAME':
   'PARSE_ALTERNATIVE_LIST' 'PARSE_DELIMINATOR'

'PARSE_ALTERNATIVE_LIST' ::= 'PARSE_ALTERNATIVE_NAME':
   'PARSE_ELEMENT_LIST': ('PARSE_TIME_ROUTINE_NAME':
   'PARSE_ELEMENT': 'PARSE_ELEMENT_LIST':)

'PARSE_ELEMENT_LIST' ::= 'PARSE_ELEMENT':
   'PARSE_ELEMENT': 'PARSE_ELEMENT_LIST':

'PARSE_ELEMENT' ::= 'PARSE_ATOM':
   '(' 'PARSE_NAME': 'PARSE_ALTERNATIVE_LIST':)

'PARSE_ATOM' ::= 'PARSE_NAME':
   'TEXT_LITERAL':

'PARSE_NAME' ::= '.PL/1 IDENTIFIER'

'PARSE_DELIMINATOR' ::= ':':

'PARSE_TIME_ROUTINE_NAME' ::= 'NAME OF A PL/1 BIT VALUED FUNCTION'
