ABSTRACT

A series of confined explosive tests was carried out for 12-in.-diameter steel and aluminum plates. Each plate in turn formed one end of the closed cylindrical chamber inside which the explosives were detonated. Tests were conducted with the chamber suspended in air and in water to determine pressure histories, deformation shapes, and failure modes in the inelastic range of air- and water-backed plates as well as to determine pressure decay rates resulting from venting to the atmosphere.

The final deformation shapes observed were uniform and repeatable, but the pressure records were less uniform. There was a distinct difference between the final shapes of the air- and water-backed plates; those of the former were intermediate between conical and parabolic whereas those of the latter were more parabolic and sometimes dimpled in the center. Failures occurred at the plate edge for charge standoffs greater than one plate diameter and at the plate center for closer standoffs. Measured pressure decays due to venting confirmed an analytical method established for predicting gas venting.

ADMINISTRATIVE INFORMATION

The work reported herein was accomplished under the in-house Independent Research Program of the Naval Ship Research and Development Center (NSRDC) during FY 71 and FY 72 and funded under Task Area ZR001-01-01. Preparation of the report was supported by Task Area SF 43,422,701.04, NSRDC Work Unit 1749-400.

INTRODUCTION

The explosion of a weapon inside a ship compartment can cause extensive damage both there and in adjacent compartments by rupturing bulkheads and decks. If the explosion ruptures the hull, extensive flooding of the ship can follow. The objective of this investigation was to develop an understanding of the damage mechanism associated with confined explosions and thus make possible more accurate predictions of ship damage.

Qualitatively, the explosion-response phenomena for a compartment should resemble those of a suddenly inflated rectangular balloon; with the edges offering maximum resistance to deformation and the sides undergoing membrane deformation. The complexity involved in a quantitative description of these phenomena emphasizes the desirability of devising a simple physical model to gain insight into the problems involved. Such a model might possess an
axis of symmetry and contain only one deformable surface instead of six as in a compartment. These considerations prompted the selection of a model consisting of a circular plate attached to one end of a closed cylindrical explosion chamber.

METHOD

EXPLOSION CHAMBER

A cylindrical explosion chamber, designed by the authors and fabricated in the NSRDC shops, was used to conduct a series of contained explosive tests against 12-in.-diameter circular plates of medium steel and aluminum in various thicknesses. The chamber is pictured in Figure 1, and the method of clamping a specimen plate to one end of the explosion chamber is illustrated in Figure 2.

The chamber was armed by mounting the explosive charge onto a pipe plug and threading the pipe plug into its position in the back wall of the chamber; see Figure 3.

TEST PROCEDURE

Tests were conducted against specimen plates which were either air backed or water backed. Air-backed plate tests were conducted with the explosion chamber suspended in the NSRDC test pit. Water-backed plate tests were conducted with the explosion chamber suspended in the NSRDC test pond as shown in Figure 4.

The blast loading was produced by cylindrical charges of Pentolite in weights selected to cause large plastic deformation or failure of the plates. The pressures generated in the explosion chamber by these charges were recorded for many of the tests by a single gage at one of four locations at the end of the chamber opposite to the pipe plug. Pressures were measured during explosive loading of both deformable test plates and a thick rigid plate to determine pressure distribution across the rigid plate and the effect of coupling on the measured pressure. A description of the pressure gage calibration and of the recording system is given in Appendix A, and the gage locations are detailed in Figure 5. Note that a recessed mounting was employed in an attempt to protect the gages from possible impact.

Several tests were also performed in which the side of the test plate facing the charge was covered by a 1/2-in.-thick slab of high-density styrofoam. These were included to determine the effect on pressure measurements of the pressure that was reflected back off the test plate.
All plates that had not ruptured were measured after testing to determine their deformation shape. Some plates were marked by a grid so that residual strains and thicknesses could be measured. High-elongation strain gages were mounted and strain records were obtained for a few air-backed plates.

After the series of tests had been completed, the explosion chamber was cut to one-half its original length. Tests were then repeated to determine the effect of a change in chamber volume on plate response.

Several venting tests were also conducted at both chamber volumes. A heavy steel plate with a venting hole at its center was mounted on the chamber, and pressure records were taken for various charge sizes and venting areas.

All tests and the material properties of the test plates are listed in Tables B.1 and B.2 of Appendix B.

RESULTS AND DISCUSSION

Table 1 indicates the peak pressures recorded during testing. Some typical pressure records and impulse curves derived from the pressure records are shown in Figures 6–11.

The response of the plates to the explosive loading is given in Figure 12 and in Table 2 which includes the maximum permanent center deflection for all plates according to plate type. The profiles of all permanently deformed plates are included (Figure 12) together with photographs of some deformed and some failed plates (Figure 13). Failure was always at the edge (Figure 13f) unless the charge was at a standoff of less than one plate diameter, in which case center failure resulted (Figure 13d). Final thickness and strain curves for a typical deformed plate are given in Figure 14. Several determinations of plate strain-time histories obtained by using high-elongation strain gages are shown in the records of Figure 15. Results of attempts to find general scaling laws describing the magnitude of the plate response are indicated by the curves of Figure 16. Figure 17 and Table 3 summarize the results of the gas venting tests.

These tables and figures are now presented together with a discussion of their contents.

PLATE LOADINGS

Pressure records were taken for air-backed tests only. Because of the large number of pressure records taken, only those pertinent to the discussion will be shown in this report.
However, most records had the same general features, namely, an early high peak pressure which very rapidly decayed to a series of much lower oscillations. The peak pressures for all records taken during testing (except the venting test pressures given elsewhere) are listed in Table 1.

The cavity phenomena resulting from the recessed mounting (Figure 5) of pressure gages together with finite gage size and finite recording system frequency response distorted the pressure histories. Actual initial pressure rise times were probably much too small to be recorded accurately (Appendix A includes a discussion of recording system characteristics for high frequency signal components). The lack of repeatability for peak pressures (Table 1) may be due not only to recording system deficiencies but also to nonuniformity among different charges that were nominally identical. Small differences in detonation rates, for instance, could significantly affect peak pressures.

Figure 6 shows the records of repeated tests of 7-g cylindrical Pentolite charges detonated at a standoff distance (SOD) of 35 in. while the explosion chamber was closed by the rigid heavy steel plate. The shapes of these records were similar but the peak pressure differed by as much as a factor of two. Test 26 was recorded when a deformable plate closed the explosive chamber. Although the peak pressure recorded in this particular test was higher than those attained with a "rigid" plate (Tests 16, 17, and 40), its shape was similar. Other tests, especially for larger charge sizes, showed about the same peak pressures and record shapes for both deforming and "rigid" plates. Thus the presence of a deforming plate did not alter the early pressure history of the chamber in any regular way. As might be expected, larger charge sizes produced pressure records which, on the average, had larger peak pressures. The transient pressures which followed were also somewhat higher.

In the case of test plates protected by styrofoam on the side facing the charge, it had been hypothesized that as a result of being crushed, the styrofoam would attenuate a reflected shock wave and thus alter the pressure record. Actually, however, the results for such plates did not differ in any regular way from corresponding tests without styrofoam. Test 47 in Figure 7 is an example of a pressure record taken with styrofoam on the plate.

Figure 7 also shows several pressure records taken with the gage located at the center of the rigid plate in a face-on position (see also Table 1a). These and similar records taken from the other face-on positions in the rigid plate for 7-, 25-, and 50-g Pentolite charges did not appear to be very different from records of corresponding tests where the gage was mounted in the flange. Thus, the pressure history appeared to be fairly uniform across the end of the chamber. (Impulse curves derived from these pressure records, however, showed that the 7-g records did differ somewhat according to gage location. This will be discussed further later in the report.)
For most of the plate response tests, the charge was detonated while very close to the “back wall” of the chamber (at a 35-in. SOD) as shown in Figure 3. A few tests were performed at shorter SOD’s, see Figure 8 for the pressure records obtained for three of these tests. It is clear from Table 1b that on the average, the peak pressures measured at the middle ranges were much lower than those measured at the full 35-in. SOD despite the shorter distance. At a close-in (6-in.) SOD, the peak pressures recorded were again higher, about the same as those at the full 35-in. SOD. These results appear reasonable if one considers the reflecting effect of the back wall. When the charge is detonated at full range, the shock wave is reflected off the back wall almost immediately; it then follows very closely behind the direct shock wave that is moving toward the specimen plate. Since this reflected wave is traveling in the higher pressure wake of the direct wave, it moves faster, thus catching up with and becoming superimposed on the direct wave. This phenomenon would cause higher peak pressures than would the direct wave alone. As standoff distance from the back wall is increased, this “catch-up” effect no longer dominates, resulting in a lower initial peak pressure (direct wave only). Thus it makes sense for a peak pressure to be lower even though the charge is nearer, as was observed in the tests. And, of course, as the charge is brought still closer to the gage, the direct pressure wave will be stronger at the close range, and again give high values.

The total impulse delivered to the test plate in the first few milliseconds is of interest for the analysis. Most of the pressure-time histories were integrated to obtain curves of the total impulse delivered at the gage as a function of time. Figure 9 is an example of a pressure-time history and its corresponding impulse curve.

Impulse curves for many of the pressure records are given in Figure 10. Impulse curves for the small 7-g charge tests showed patterns that were not apparent in the pressure records. Impulse curves obtained from pressure records taken while the gage was mounted face on to the charge (in the “rigid” plate) were usually lower than those derived from measurements taken at the flange position. The two face-on curves (broken lines in Figure 10a) diverged from the other curves as time increased. Other curves not shown there followed the same pattern. The curve for Test 16 was the only exception in a total of 11 curves. Thus, it appears that the gage location is important and that the impulse delivered to the center of the test plates is somewhat less than that delivered to the flange area. This pattern, however, was not as clear for larger charge tests (see Figures 10c and 10d). Only a few face-on curves are available for larger charges, and it is not yet clear whether the pattern would have reemerged had more records been taken with larger charges.

A coupling effect was a second trend noted for the 7-g charges. The presence of a rapidly deforming plate gave impulse curves which rose very steeply at first and then leveled off (see the curve for Test 26 in Figure 10a; the curve for Test 53, not shown, was very similar). Apparently the pressure record was altered in its very early phase by the plate
response. Again, the pattern was not apparent for larger charges. It appears likely that coupling effect and gage orientation are less significant at higher overpressures.

In order to compare the general features of the impulse curves for charges of different weights, those corresponding to the full SOD (the pressure gage recording from the flange position) were averaged for each charge size. As indicated in Figure 11, the results were quite similar up to about 0.1 msec.

**PLATE RESPONSE**

**Experimental Data**

The maximum permanent deflections of all plates tested are listed in Table 2 and the final deformed shapes are shown in Figure 12. Except for dimpled plates (which will be mentioned later), the maximum plate deflection was always at or near the center of the plate and the deformation shape was always nearly symmetrical about that center. The plots of Figure 12 show the average deflection (based on measurements along two mutually perpendicular diameters) from the original plane of the plate. Plate deformations were reasonably repeatable and uniform.

There was very little evidence of edge movement or “pull in”; most tests showed no detectable edge movement at all. Photographs of typical deformed or failed plates are presented in Figure 13.

The deformation shapes observed led to several generalizations:

1. When the charge was detonated near the back wall of the longer chamber, air-backed plates tended to deform to a conical shape, particularly for large deformations. Corresponding water-backed plates had a more parabolic shape. Moreover, some water-backed plates formed a pronounced dimple (see Figures 12f and 13e). This dimpling effect is the result of water cavitation collapse or other hydrodynamic reactions and so was not observed in the air-back tests.

2. When the charge was detonated near the center of the longer chamber or in the shortened chamber, the shape of air-backed plates was more parabolic than when the charge was detonated at the far end of the long chamber. Probably this is because the shock loading across the face of the test plate is less uniform when the charge is near to the test plate than when farther away. Most likely there is a fully developed plane shock front at maximum SOD.

3. The maximum center displacement of air-backed plates was approximately 2 1/2 times that of corresponding water-backed plates.
4. For tests conducted with the charge at the far end of the chamber, air-backed plates had about the same maximum center displacements, in both the long and short chambers. Plates tested on the short chamber failed at lower center displacements, however, and, as already noted, unfailed plates had a more parabolic shape.

5. Plate deformation was greater when the charge was detonated near the back wall of the chamber than at its center. This corresponds to the fact that peak recorded pressures were greater when the charge was at the back than at the center.

6. In all tests, plate failure always occurred at the edge of the plate except when the charge was less than two plate radii from the target plate. Failed plates showed evidence of “necking down” at the edge before failure and then shearing away in one piece, leaving a sharp, thin edge around the circumference (see Figure 13f). Unfailed plates with large deformations also exhibited considerable “necking down” at the circumference. If plate failure was caused by a near charge (one plate radius or less), failure was by rupture at the plate center and large petals tore away from the center (see Figure 13d); however, a large amount of necking down can also occur at the circumference. One air-backed plate failed at both the edge and center when the charge was at 1 1/2 plate radii.

In addition to data on permanent deformation shapes of all unfailed plates, the results include measurements of final thickness and principal strains across a few typical deformed plates. Representative values from a nearly failed plate are shown in Figure 14. It can be seen that strains were greatest in the meridional direction and near the center. As might be expected, the plate center was also the thinnest part of the plate (if the necking down at the edge is ignored).

Several successful attempts were made to obtain strain histories of test plates. Special adhesives and high-elongation strain gages enabled good records for steel test plates which were deformed only moderately. As indicated in Figure 15, most of the strain occurred within the first 1/2 msec after the arrival of the shock wave. Attempts to obtain strain histories for plates deformed nearly to failure were unsuccessful because the gages or the lead wires, especially those at the plate center, came off during the explosion.

**Analytical Determination**

The experimental data were utilized to develop a tentative empirical law governing the maximum deflection that an unfailed plate would assume. The normalized deflection \( d/a \), which is the ratio of maximum plate deflection to plate radius, was plotted as a function of different combinations of parameters for all test plates that did not fail. Two empirical laws resulted, one for air-backed and one for water-backed plates;
Air-backed plates:

\[
\frac{d}{a} = 0.156 \left[ \frac{W_c}{W_p} \cdot \frac{a}{h} \cdot \frac{\sigma_R}{\sigma_p} \right]^{0.641}
\]

Water-backed plates:

\[
\frac{d}{a} = 0.0729 \left[ \frac{W_c}{W_p} \cdot \frac{a}{h} \cdot \frac{\sigma_R}{\sigma_p} \right]^{0.506}
\]

In both instances, \(d\) is the maximum deflection, \(a\) is the radius, \(W_c\) is the charge weight, \(W_p\) is the plate weight, \(h\) is the plate thickness, \(\sigma_p\) is the average of 0.2 percent offset and ultimate stress of test plate (in pounds per square inch), and \(\sigma_R\) is a reference stress taken as 40,000 psi.

The curves for these two equations are shown in Figure 16a along with all data points from the tests. These equations were determined from tests for which the charge was detonated at the back wall of the long chamber. Similar curves for unfailed plates tested on the short chamber are given in Figure 16b.

Chamber length and charge location were held constant in determining the empirical laws. Actually, however, when the chamber length was halved, the effect on the center deflection was quite slight as can be seen in Figure 16b; data for air-backed plates that deformed on the shortened chamber fall fairly well along the curve determined from the long chamber data. A change in charge location, however, had a very strong effect on the center deflection. Data are available for only a few air-backed plates for cases where the charge was not at the back wall, but the deformation for these cases was substantially less than predicted by the empirical law. However, it is worth noting that the few available points did fall on a line roughly parallel to that shown for air-backed plates in Figure 16a.

The method of Sewell and Kinney\(^1\) was applied in the first attempt at establishing a criterion to predict the onset of failure. A critical impulse to be delivered in a critical time was established for each of the NSRDC test plates. The calculated critical impulses were then compared with the measured impulses delivered to the test plates in the critical time to see

---

how well failure was predicted. As can be seen in the tables of Appendix C, however, all plate types survived impulses much greater than those predicted. Further, the ratio of delivered impulse to critical impulse at which failure did begin to occur was not the same for different plate types and standoff distances. The general concept of a critical impulse in a critical time is attractive because of its simplicity. However, the critical impulse apparently depends on other parameters in addition to those material properties used by Sewell and Kinney. A more thorough analysis seems necessary for developing an accurate criterion for failure.

VENTING TO THE ATMOSPHERE

A detonation inside a ship compartment is followed by venting of the explosion products through openings into adjacent compartments and perhaps into the atmosphere. The pressure loading, the subsequent response, and possibly the manner of failure of structural elements will be sensitive to the rate of venting.

Proctor\(^2\) has derived an equation for determining the rate of pressure decay during venting to the atmosphere. His analysis assumes an isentropic nozzle flow process, and his results are in good agreement with pressure decays measured during venting tests of an explosion testing facility at the Naval Ordnance Laboratory. But the charge weight/chamber volume ratios of those tests were small.

To check the Proctor analysis at higher pressures, Pentolite charges were detonated in the center of the NSRDC explosion chamber described in this report. Venting was permitted through a hole in a heavy steel plate clamped on the end of the chamber, and the pressure history was recorded in the same manner as for the plate response tests. Seven venting tests were performed in the long chamber for various charge weights and hole areas, and a single test was performed in the shortened chamber.

Figure 17 shows a few typical pressure records taken during the tests. Superimposed over each record is the pressure history predicted by the Proctor analysis. The initial over-pressure \(P_0\) used in the predicted pressure history is derived from the Weibull empirical relationship\(^3\) for TNT explosions in partially confined spaces.

Converted for Pentolite, the Weibull equation is:

\[ P_0 = 2410 \left( \frac{0.773 \ W}{V} \right)^{0.72} \]

where \( P_0 \) is the overpressure in pounds per square inch,

\( W \) is the weight of Pentolite in pounds, and

\( V \) is the volume of the chamber in cubic feet.

The charge weight was adjusted in the above equation by multiplying by 0.773, the ratio of the heat of combustion of Pentolite and TNT. To a first approximation, the Proctor analysis predicted the pressure histories reasonably well for peak overpressures as high as 230 psi, as can be seen in Figure 17.

Table 3 is another comparison of predicted and observed pressure decay. In the Proctor analysis, venting through the nozzle is sonic until the initial peak pressure decays to a critical pressure. The nozzle flow then becomes subsonic and venting continues at a decreased rate until the pressure has decayed to the ambient pressure level. If the ambient pressure is atmospheric, or 14.7 psi, the critical pressure is about 27.8 psia. Table 3 shows the calculated and measured times to reach this critical pressure for all the venting tests performed. In all cases the agreement was reasonably good.

In summary, the Proctor analysis of gas venting to the atmosphere appears useful for predicting venting at the higher pressures of interest in ship damage studies. Proctor has prepared a newer (and soon to be published) version of the analysis which promises to give a still better description of both the maximum pressure and the pressure decay. It remains to be seen whether the Proctor analysis can be successfully applied to venting through very large openings and whether it can be used in modified form to describe venting into adjacent chambers. Additional tests are needed to answer these two questions.

**EXISTING METHODS FOR PREDICTING EXPLOSION CHAMBER IMPULSE AND PRESSURE**

The pressure field resulting from the confined explosion is exceedingly complex because of multiple reflections from chamber surfaces. The authors have found no truly satisfactory method for predicting pressure histories strictly from charge weight and geometry. A comprehensive collection of explosion data\(^4\) did not contain information directly applicable to

impulse or pressure calculations for the tests reported herein. However, impulse values for NSRDC cylindrical chamber geometry were approximated from data available on rectangular compartments by "rectangularizing" the explosion chamber (i.e., determining the impulse values for a square shock tube of the same length and volume as the explosion chamber but made of four equal flat sides). The NAVFAC impulse charts included the effects of "adjacent" surface reflections but not those due to the back wall behind the charge with respect to the surface at which impulse is sought. This led to difficulties for cases in which the charge was located near the back wall. In such cases, the impulse at the back wall was crudely assumed to translate intact to the opposite end of the chamber and become superimposed on the impulse delivered by the direct wave at that end. For tests in which the charge was not near the back wall, it can be shown that the reflected impulse off the back wall does not arrive at the opposite end of the chamber within a millisecond or so of the arrival of the direct impulse and thus that the back wall does not have to be taken into account in determining the initial impulse. Impulse values so calculated are compared in Table 4 along with measured values.

The best description of pressure found by the authors was that by Weibull, but his empirical formula gives only the maximum value of the mean pressure. Actually, because of the presence of high initial peaks in any pressure record, this value represents only a small fraction of the true peak pressure (Figure 18).

The long-term decay characteristics were sought by using the pressure history obtained from Proctor. In these calculations, the maximum pressure was assumed to be that of Weibull

\[ P_w = P_m(0) \]

(see Figure 18). The vent area of the chamber during specimen plate tests was that of the small 3/16-in. opening in the chamber used for inserting the detonator (Figure 3). The resulting decrease in pressure was found to be entirely negligible over the plate response time (\( \sim 1 \) msec). It was therefore assumed that "long-term" decay could be neglected, i.e., that the "long-term" pressure could be considered constant.

A tentative approach to synthesizing pressure histories was formulated as follows:
1. The initial spiked "impulsive part" of the pressure record was assumed to be:

\[ P = P_m \]

where \( P_m \) is the measured peak pressure.
2. The pressure at time \( t_1 \) (and thereafter) was assumed to be that of Weibull:

\[ P_w = 2410 \left( \frac{0.773 W}{V} \right)^{0.72} \]
where $W$ is the weight of the Pentolite charge in pounds, 
$V$ is the volume of the chamber in cubic feet, and 
$P_w$ is the overpressure in pounds per square inch.

3. The pressure at $t = t_1$ was assumed to be continuous, giving

$$P_m e^{-\alpha t_1} = P_w$$

4. The impulse $i$ at $t = t_1$ was assumed to be:

$$i = i(t_1)$$

From the above,

$$i = \frac{P_m}{a} (1 - e^{-\alpha t_1}) = \frac{P_m}{a} \left(1 - \frac{P_w}{P_m}\right) = \frac{P_m - P_w}{a}$$

$$a = \frac{P_m - P_w}{i}$$

$$t_1 = -\frac{\ln \frac{P_w}{P_m}}{a} = -\frac{i \ln \frac{P_w}{P_m}}{P_m - P_w}$$

The pressure histories so synthesized have been superimposed on measured histories in Figure 19.

**SUMMARY AND CONCLUSIONS**

The loading and response phenomena of circular plates under confined explosive pressure loading were investigated experimentally and analytically. The results were as follows:

1. Pressure loading is characterized by a steep, high-amplitude pulse followed by a slowly decaying oscillatory signal of much lower amplitude.
2. An approximate loading history can be predicted from charge weight chamber geometry, and one experimental parameter (maximum pressure).
3. Reflection from a surface near the charge significantly increases the impulse delivered to the opposite surface. Thus reflection from a chamber surface may have a significant early time influence on the pressure loading even though that surface is blown out immediately thereafter.
4. The final plate deformation shape was fairly repeatable and was more conical than the parabolic shape typical of static tests.

5. The response of air-backed and water-backed plates differed substantially in shape and amplitude. Air-backed plates sustained two to three times the deformation of corresponding water-backed plates. Air-backed plates deformed into a conical shape whereas water-backed plates tended to deform more spherically and some had a center “dimple” caused by hydrodynamic effects.

6. Preliminary scaling relationships for the center deflection of both air- and water-backed plates have been deduced from the data.

7. Plate failures were at the edge for all cases except those in which the charge was near the plate at a stand-off of 1 1/2 plate radii or less. At those near ranges, center failure occurred.

8. Plate failure cannot be predicted accurately by the analytical method of Sewell and Kinney\(^1\) for the load and support conditions investigated here. A more complex analysis appears necessary for the development of a reliable criterion for failure.

9. Rate of pressure decay during venting to the atmosphere through small openings can be estimated well by the analysis method of Proctor\(^2\) for initial pressures in excess of 200 psi.

ACKNOWLEDGMENTS

Space precludes individual acknowledgment of the numerous NSRDC personnel without whose assistance this work would not have been possible.

Explosives handling was performed by Mr. N. Pickford, assisted by Mr. M. Gibbons. Mr. Pickford also devised the rigging scheme. The NSRDC metalworking shop fabricated the test chamber and plates. Many helpful suggestions and comments were made by their personnel.

Note: The integration was performed on all records obtained with the gage in the flange position for all tests except venting tests and tests where plate failure occurred. The integration was from \( t = 0 \) to \( t = t_1 \), where \( t_1 \) was as derived in this section as:

\[
 t_1 = \frac{i \ln \frac{P_w}{P_m}}{\frac{P_m - P_w}{P_m} - \frac{P_w}{P_m}} 
\]

A 2-in. standoff from the back wall was used to determine the impulse delivered to the back wall. This impulse was then assumed to reflect intact to the target plate; it was added to the direct impulse in order to arrive at the value given here.
INTRODUCTION

In order to determine the pressure resulting from the detonation of the explosive charge and to measure the strain response of selected diaphragms, a recording system was installed in an instrumentation van located near the test area.

COMPONENTS OF THE RECORDING SYSTEM

1. A bonded strain gage sensing element-type pressure transducer (Micro Systems Type PT 38-C1) with its associated driver was used to measure pressures. Both static and dynamic calibrations were conducted to verify linearity and proper operation. The system gave linear readings over the entire 0- to 4000-psi static pressure range tested. The dynamic test was performed by mounting the gage onto a small water-filled chamber which was fitted with a piston at its top. A weight was dropped onto the piston, and the resulting pressure pulse in the chamber was measured by the gage. Since the drop height and mass of the weight were known, it was possible to calculate the theoretical peak pressure and time duration of the pressure pulse as described by Gesswein and Chertock.\(^5\) They have shown that a sine pulse would result; use of their equations gave a value of 2820 psi for the peak pressure and one of 0.708 msec for the half-period of the sine pulse. As shown in Figure A.1 of this appendix, comparable experimental values were 2280 psi and 1.06 msec, respectively. Although the measured peak pressure was lower than the calculated value, the pressure record did show the correct total impulse; this can be seen in Figure A.1 by comparing the pressure record with the sine curve which contains the correct calculated total impulse.

Since the transducer would be exposed to temperatures exceeding its compensated range (30 to 130 F), a series of tests was conducted to determine the response of the transducer to rapid temperature changes; a photographic flashbulb was used as the heat source. The results of these tests indicated that the first 2 msec of a pressure record would not be appreciably affected by a rapid change in temperature.

2. Micro-Measurements Type EP-08-125AD-120 gages were used in most of the strain
gage tests. These gages are a high elongation, post-yield type and were installed with
Eastman 910 cement or AE-10 epoxy.

3. A pressure transducer conditioner and amplifier (NSRDC Type 470-1A) was used to
supply power to the transducer driver, to provide balancing and shunt calibration networks,
and to amplify the transducer output signal.

4. A strain gage conditioner and amplifier (NSRDC Type 450-2A) was used to supply
bridge voltage to the gage, to provide balancing and shunt calibration networks, and to
amplify the output from the strain gage.

5. An FM tape recorder (Ampex CP-100) was used to record and reproduce the
amplified signals; a 5-kHz sine wave was also recorded for timing purposes.

6. A string oscillograph (Consolidated Electrodynamics Corporation Type 5-124) with
Type 7-323 galvonometers was used for visual reproduction of the recorded signals.

The components used are shown schematically in Figure A.2.

RECORDING TECHNIQUE

The signals were recorded at a tape speed of 60 ips using FM electronics with a fre-
quency response of 0 to 20 kHz. Prior to each test, several calibration steps were recorded;
these were produced by shunting a known resistance across one arm of the bridge. A tape
speed of 1.875 ips was used for the playback of the signals onto the string oscillograph. At
this playback speed, the effective frequency response of the string galvonometers was 0 to
19 kHz.

SIGNAL GAIN AND DISTORTION CAUSED
TAPE RECORDER CHARACTERISTICS

To test the ability of the recording system to record and reproduce signals rich in high
frequency components, square wave signals were fed into the recorder through the amplifier
and played back through the oscillograph. The playback records were characterized by rise
times of approximately 0.035 msec and short-duration “overshoots” of approximately
16 percent of the square wave amplitude (see Figure A.3). The rise times and overshoots
were constant throughout the 0- to 10-kHz frequency range tested and throughout a ten-
fold increase in amplitude. This rise time is long in comparison with the very short rise
times associated with the incident airblast shock waves. Thus considerable distortion in the
shape and magnitude of the initial pulse is to be expected.

50
The lowest frequency of the pressure gage plate sensing element is 140 kHz, corresponding to a maximum quarter period of 0.00176 msec or less. Thus the rise time of the tape recorder was at least 20 times the maximum possible quarter period of the gage, and the tape recorder limited the recorded signal rise time.

**SIGNAL ATTENUATION CAUSED BY PRESSURE GAGE GEOMETRY**

The ratio of average pressure $\bar{p}$ to maximum pressure $p_m$ is obtained by averaging the pressure wave $p$ as it sweeps across the circular face of the gage (Figure A.4).

$$\bar{p} = \frac{1}{A} \int_A \left[ \frac{1}{T} \int_0^T p \, dt \right] \, dA$$

$$= \frac{1}{\pi a^2} \int_{-a}^{+a} \left[ \frac{c}{2a} \int_0^{2a} p_m H \left( t - \frac{x}{c} \right) e^{-\alpha \left( \frac{t}{c} - \frac{x}{c} \right)} \, dt \right] (2\sqrt{a^2 - x^2} \, dx)$$

$$\frac{\bar{p}}{p_m} = \frac{1}{\left( \frac{a}{c} \right)^2 \pi a^2} \int_{-a}^{+a} \left( 1 - 2e^{-2\beta} \right) \left( 1 - e^{-\frac{2a}{c}} \frac{a}{c} e^{\frac{x}{c}} \right) \sqrt{a^2 - x^2} \, dx$$

$$= \frac{1}{2\beta} \left[ 1 - e^{-2\beta} \left( 1 + \frac{\beta^2}{8} \right) \right], \beta \gtrsim 0.075$$

where $H \left( t - \frac{x}{c} \right) = \begin{cases} 0 & t < \frac{x}{c} \\ \frac{1}{2} & t = \frac{x}{c} \\ 1 & t > \frac{x}{c} \end{cases}$
\( \alpha \) is a positive decay constant,

\[
\beta = \alpha \frac{a}{c}
\]

\( \chi = \frac{x}{a} \), and

\[
e^{\beta \chi} = 1 + \beta \chi + \frac{\beta^2}{2} \chi^2 \quad \text{for} \quad \beta \lesssim 0.075.
\]

A plot of \( \frac{p}{p_m} \) is given in Figure A.5.

It should be noted that the above analysis is based on the assumption that the wave has a steep front and decays exponentially. This assumption has been observed to be valid for shock waves in tubes. It is also hypothesized that the gage is flush mounted rather than slightly recessed as for the tests reported herein. The diffraction phenomena associated with the recess have not been taken into account because of their complexity.

For the fairly representative value \( \alpha = 17.5(\text{msec})^{-1} \), Figure A.5 gives a ratio \( \frac{p}{p_m} = 88 \) percent. The value of \( \alpha \) was determined by measuring values of \( p_m \), \( p_f \), and \( t_f \) (as defined in Figure A.6) for typical pressure records by applying the relationship:

\[
\alpha = - \left[ \log_e \left( \frac{p_f}{p_m} \right) \right] / t_f
\]

to find the corresponding value of \( \alpha \), and taking a mean of values so obtained.

The signal amplitude entering the electronics of the system is \( p \). As indicated earlier in discussing signal gain and distortion caused by tape recorder characteristics, the recorded pressure amplitude \( p_R \) is

\[
p_R = 1.16 \ p
\]

But as noted in the preceding paragraph, \( p \) itself represents a reduction

\[
\bar{p} = 0.88 \ p_m
\]

Thus the overall relationship is

\[
p_R = 1.16 * 0.88 * p_m = 0.98 \ p_m
\]

It is not the intent of the authors to imply that this close correspondence of \( p_R \) and \( p_m \) is generally true. They wish only to convey the idea that the recorded pressure amplitudes ought at least to resemble the actual ones due to compensating errors in the recording process.

APPENDIX B
SUMMARY OF TEST DATA

In Table B.1, water-backed plate tests are indicated by a W after the plate type; all other tests were air backed. Permanent deflections were measured at the plate center except for water-backed plates which formed dimples. Those deflections were measured at the side of the dimple where the deflection was greatest; deflections so measured are indicated by a D following that deflection value in the table. Superscript numbers following peak pressure values indicate pressure gage location:

1. Mounted in the flange and side on to the charge
2. Mounted at \( r = 0 \) in the rigid plate, face on to the charge
3. Mounted at \( r = 3 \) in. in the rigid plate, face on to the charge
4. Mounted at \( r = 5 \frac{3}{8} \) in. in the rigid plate, face on to the charge

Amplifying remarks for test numbers marked by an asterisk in Table B.1 are as follows:

APPENDIX C

CENTER DEFLECTION AND FAILURE AS A FUNCTION OF CRITICAL IMPULSE DELIVERED IN A CRITICAL TIME

The critical time $t_c$ is one-fourth of the natural period. The natural period is calculated as (see page 450 in Timoshenko\textsuperscript{6})

$$p = \frac{a}{a^2} \sqrt{\frac{gD}{\gamma h}}$$

where $D = \frac{Eh^3}{12 (1-\nu^2)}$,

- $h$ is thickness in inches,
- $\gamma h/g$ is the mass per unit area of plate (slugs per inch$^2$),
- $a$ is plate radius in inches, and
- $a = 10.21$.

The critical impulse is calculated from $I_c = \rho \delta V_c$ as in Sewell and Kinney.\textsuperscript{1} Here $V_c$ is taken as 200 ft/sec for steel and 240 ft/sec for aluminum. The minimum Heaviside pressure to failure is $I_c/t_c$.

Values for $t_c$ are given in Table C.1 for each plate type. This table also gives ratios of minimum pressures. The minimum mean pressure achieved in the chamber was taken as simply the Weibull\textsuperscript{3} pressure. Comparisons with pressure records showed that the Weibull pressure was a lower bound to the actual mean pressure at early time. The ratio of this Weibull pressure to the calculated minimum mean pressure to failure is listed in Table C.2 as a check on the failure criterion, one which is independent of the pressure records. As can be seen, plates survived at actual mean pressures well above the minimum mean pressures calculated by the method of Sewell and Kinney.\textsuperscript{1}

TABLE C.2 - COMPARISON OF CALCULATED AND MEASURED CRITICAL IMPULSES

(The measured impulses for all tests at the 35-in. SOD were interpolated from the average impulse curves of Figure 11 of this report. Impulses at closer SOD were read from individual impulse curves. In all cases the impulse was read at the critical time \( t_d \).)

A series of confined explosive tests was carried out for 12-in.-diameter steel and aluminum plates. Each plate in turn formed one end of the closed cylindrical chamber inside which the explosives were detonated. Tests were conducted with the chamber suspended in air and in water to determine pressure histories, deformation shapes, and failure modes in the inelastic range of air- and water-backed plates as well as to determine pressure decay rates resulting from venting to the atmosphere.

The final deformation shapes observed were uniform and repeatable, but the pressure records were less uniform. There was a distinct difference between the final shapes of the air- and water-backed plates; those of the former were intermediate between conical and parabolic whereas those of the latter were more parabolic and sometimes dimpled in the center. Failures occurred at the plate edge for charge standoffs greater than one plate diameter and at the plate center for closer standoffs. Measured pressure decays due to venting confirmed an analytical method established for predicting gas venting.
