FFT AS NESTED MULTIPLICATION, WITH A TWIST

Carl de Boor

Technical Summary Report #1968
June 1979

ABSTRACT

A simple, yet complete and detailed description of the Fast Fourier Transform for general $N$ is given, with the aim of making the underlying idea quite apparent. To help with this didactic goal, a simple twist, i.e., a shifting of information from rows to columns during the calculations, is introduced which allows to give a simple meaning to intermediate results and assures that the final results need no further reordering.

AMS(MOS) Subject Classification: 65T05

Key Words: FFT = Fast Fourier Transform
nested multiplication

Work Unit No. 8 - Computer Science

Sponsored by the United States Army under Contract No. DAAG29-75-C-0024.
Significance and Explanation

In the last twenty years, various forms of a fast Fourier transform (FFT) have become popular. The various algorithms have in common that they produce the discrete Fourier transform on \( N \) points in about \( N \ln(N) \) rather than \( N^2 \) operations. But, while these ideas, notably through Cooley & Tukey, have found wide application in computations, their didactic treatment has left something to be desired.

This report is an attempt to remedy this situation.
FFT AS NESTED MULTIPLICATION, WITH A TWIST

Carl de Boor

1. Introduction. The discrete Fourier transform (DFT) \( \hat{z} = F_N z \) of an N-vector \( z \) is given by the rule

\[
\hat{z}_v = \sum_{n=1}^{N} z_n \omega_N^{(v-1)(n-1)}, \quad v = 1, \ldots, N,
\]

with

\[
\omega_N = \exp(-\sqrt{-1} \frac{2\pi}{N})
\]

a principal N-th root of unity. Thus, \( \hat{z}_v \) is given as the value of a polynomial of degree \( < N \) at the point \( \omega_N^{v-1} \) and can therefore be calculated, by nested multiplication, in \( N \) operations. Here, I follow Cooley & Tukey [1] in counting a complex multiplication followed by a complex addition as one operation.

In the last twenty years, various forms of a fast Fourier transform (FFT) have become popular. The various algorithms have in common that they produce the DFT on \( N \) points in about \( N \ln(N) \) rather than \( N^2 \) operations. See Winograd [10] for the latest developments. But, while these ideas, notably through Cooley & Tukey [1], have found wide application in computations, their didactic treatment has left something to be desired.

In a recent article [7], H. R. Schwarz attempts, as he says, to remove the mystical aspect which the FFT has for many people. He does this by describing the FFT in terms of a factorization of the transformation matrix, an idea which he ascribes to Theilheimer [9] but which occurs already in Good [5] where a FFT different from that of Cooley & Tukey is given. A factorization of the transformation matrix is also the basic idea on which Glassman [4] builds his FFT, and Drubin [2] has refined this further; see Ferguson [3] for a lucid description and a simple Fortran program.

By contrast, I want to give here what I believe to be a simple description of the FFT for a general \( N \) in terms of **nested multiplication**. Certainly, Cooley & Tukey [1] thought of the FFT in these terms.

Sponsored by the United States Army under Contract No. DAAG29-75-C-0024.
2. The case of two factors. Suppose that $N = PQ$ for two integers $P$ and $Q$ greater than 1. Think of the $N$-vector $\mathbf{z}$ as stored Fortran fashion in a one-dimensional array. Then we can interpret that array also Fortran fashion as a two-dimensional array $Z$, of dimension $(P,Q)$. This means that

$$Z(p,q) = z_{P+P(q-1)}, \quad p = 1,\ldots,P, \quad q = 1,\ldots,Q.$$  

Correspondingly, factor the sum (1) for $\hat{z}_v$ into a double sum,

$$\hat{z}_v = \frac{P}{p=1} \frac{Q}{q=1} Z(p,q) \omega_N^{(v-1)(P-1)+P(q-1)}.$$

Here, we have made use of the fact that $\omega_N^Q = 1$. This makes apparent the crucial fact that the inner sum in the last right hand side is $Q$-periodic in $v$, i.e., replacing $v$ by $v+Q$ does not change its value, due to the fact that $\omega_N^Q = 1$. This means that we need only calculate this sum for $v = 1,\ldots,Q$ (and for each $p$). Thus, for each $p = 1,\ldots,P$, we calculate from the $Q$-vector $Z(p,\cdot)$ the $Q$-vector whose entries are the numbers

$$\omega_N^{(v-1)(q-1)}, \quad v = 1,\ldots,Q,$$

i.e., we calculate the DFT $F_QZ(p,\cdot)$, $p = 1,\ldots,P$, at a total cost of $P \cdot Q^2 = N \cdot Q$ operations.

Now, we could store the transform of $Z(p,\cdot)$ over $Z(p,\cdot)$. But in anticipation of further developments, we choose to store the transform $F_QZ(p,\cdot)$ in $Z_1(\cdot,p)$, where $Z_1$ is a two-dimensional array of size $(Q,P)$, rather than $(P,Q)$.

With this, the calculation of $\hat{z}_v$ is reduced to the evaluation of the sum

$$\hat{z}_v = \frac{P}{p=1} \sum_{\nu=1}^{Q} Z_1(\nu,p) \omega_N^{(v-1)(p-1)}, \quad v = 1,\ldots,N.$$

Here, we have used the notation $\nu_Q$ to indicate the integer between 1 and $Q$ for which $v - \nu_Q$ is divisible by $Q$. At this point, it becomes convenient to think of the one-dimensional array which is to contain the $N$-vector $\hat{z}$ equivalently
as a two-dimensional array $Z_0$, of size $(Q, P)$. This means that

$$Z_v + Q(v-1) = Z_0(v, u), \text{ for } v = 1, \ldots, Q, \ u = 1, \ldots, P.$$  

With this, (5) can be written equivalently as

$$Z_0(v, u) = \sum_{p=1}^{P} Z_1(v, p) u_N^{[(v-1 + Q(u-1))(p-1)]} \quad v = 1, \ldots, Q, \ u = 1, \ldots, P.$$  

Here, the right hand side is a polynomial of degree $< P$ in the quantity $u_N^{[(v-1 + Q(u-1))]}. This quantity can be generated as one goes along, as in the following convenient arrangement of the calculations:

$$x := 1$$

for $\mu = 1, \ldots, P$, do:

$$x := \prod_{p=1}^{P-1} x$$

for $\nu = 1, \ldots, Q$, do:

$$Z_0(v, u) := \sum_{p=1}^{P} Z_1(v, p) x^{p-1}$$

The sum in the innermost loop is, of course, to be evaluated by nested multiplication. The total cost of this step is then $Q \cdot P^2 = N \cdot P$ operations (if we neglect the $N$ multiplications needed to generate the various $x$'s). In this way, we have obtained in $Z_0$ the discrete Fourier transform $\hat{\hat{Z}}$ of $\hat{Z}$ at a cost of only $N(P+Q)$ rather than $N^2$ operations.
The general case. It is easy to see how successive applications of the above procedure, starting with its application to (4), give an m-step algorithm requiring

\[ T = N(P_1 + P_2 + \ldots + P_m) \]

operations, where

\[ N = P_1 \cdot P_2 \cdot \ldots \cdot P_m. \]

So say Cooley & Tukey [1] (except for a change in symbols and equation numbers).

In effect, they point out that the first step of the calculations above consists in forming the DFT of various \( Q \)-vectors. Hence if \( Q \) itself is the product of two integers greater than 1, this calculation can be carried out in fewer than \( Q^2 \) operations by applying the same procedure to it, etc. The actual implementation of this idea may not be immediately obvious, though. For this reason, I now discuss a slightly different (and novel) view, according to which the entire transform can be effected by \( m \) applications of a slightly enlarged version of (7).

The basic idea is to interpret the storage arrays for the various \( N \)-vectors involved in various ways as multidimensional arrays and to shift information appropriately from "rows to columns" as we did earlier when storing the DFT of the row \( Z(p,\cdot) \) of \( Z \) in the column \( Z_1(\cdot,p) \) of \( Z_1 \). For this, I need some notation to indicate that a given one-dimensional array is being considered equivalently as a two- or three-dimensional array.

If \( Z \) is a one-dimensional array of length \( N \), then \( Z^A \) denotes the equivalent two-dimensional array of dimension \((A,N/A)\), and \( Z^{A,B} \) denotes the equivalent three-dimensional array of dimension \((A,B,N/(AB))\). Thus

\[ Z^{A,B}(a,b,c) = Z^A(a,b+B(c-1)) = Z^{AB}(a+A(b-1),c) = Z(a+A(b-1+B(c-1))). \]

Let now \( Z \) be a one-dimensional array containing \( z \), as before, and, for \( k = 0,\ldots,m \), let \( z^k \) be a one-dimensional array satisfying

\[ z^k(\cdot,c) = z^{AB}(\cdot,A(c-1)) = z^{A,B}(\cdot,A+B(c-1)), \quad c = 1,\ldots,B^P, \]

with
Then \( Z_m = Z \), and \( Z_0 \) contains \( \mathbb{Z} / n \mathbb{Z} \). Further, with \( A, P, B \) as given by (11), one obtains \( Z_{k-1} \) from \( Z_k \) by the following slightly extended version of (7):

\[
x := 1
\]

\[
\text{for } p = 1, \ldots, P , \text{ do:}
\]

\[
\text{for } a = 1, \ldots, A , \text{ do:}
\]

\[
\text{for } b = 1, \ldots, B , \text{ do:}
\]

\[
Z_{k-1}^{A,P}(a,p,b) := \sum_{\pi=1}^{P} \sum_{a=1}^{A} \sum_{b=1}^{B} Z_k^{A,B}(a,b,\pi) \cdot x^{n-1}
\]

Indeed, the algorithm produces

\[
Z_{k-1}^{A,P}(a,p,b) = \prod_{\pi=1}^{P} Z_k^{A,B}(a,b,\pi) \cdot [a-1 + A(p-1)](\pi-1).
\]

On the other hand, (10) implies that

\[
Z_{k-1}^{A,B}(a,b,\pi) = \prod_{\pi=1}^{P} Z_{k-1}^{A,B}(b,\pi,\alpha) \cdot [\gamma-1](\alpha-1).
\]

Therefore,

\[
Z_{k-1}^{A,P}(a,p,b) = \prod_{\pi=1}^{P} \prod_{a=1}^{A} Z_{k-1}^{B,B}(b,\pi,\alpha) \cdot P(a-1)(\alpha-1) + [a-1 + A(p-1)](\pi-1).
\]

But now, since \( \omega_{AP}^m = 1 \), we may add to the exponent on the right hand side any integer multiple of \( AP \), and this allows the conclusion that

\[
Z_{k-1}^{A,P}(a,p,b) = \prod_{\pi=1}^{P} \prod_{a=1}^{A} Z_{k-1}^{B,B}(b,\pi,\alpha) \cdot [a-1 + A(p-1)](\pi-1+P(a-1))
\]

and so proves that \( Z_{k-1} \), as produced by (12), satisfies (10) (with \( k \) replaced by \( k-1 \)).

This shows that the DFT \( \mathbb{Z} / n \mathbb{Z} \) is obtainable, in \( Z_0 \), by \( m \) applications of algorithm (8), starting from \( Z_m \) containing \( \mathbb{Z} / n \mathbb{Z} \). Since the \( k \)-th such application costs \( P_k A_k B_k P_k \) operations, the total number of required operations is indeed given by (8).

In a Fortran implementation of the algorithm, one would, of course, need only two arrays to play the role, in alternation, of the \( m+1 \) arrays \( Z_m, \ldots, Z_0 \).
SUBROUTINE FFT (Z1, Z2, N, INZEE)

CONSTRUCTS THE DISCRETE FOURIER TRANSFORM OF Z1 (OR Z2) IN THE COOLEY-
TUKEY WAY, BUT WITH A TWIST.

RETURN

There is no claim that the above program is competitive with the carefully
constructed codes such as that of Singleton [8]. Its virtue lies chiefly in its
simplicity and transparency. On the other hand, Eric Grosse [6] found that the
above code, modified to give special treatment in FFTSTP for the case NOW = 2,
and to avoid subroutine calls for the complex arithmetic operations, and compiled
by an optimizing compiler, needed only 1.5 to 2 times as much computing time as
did Singleton’s program for a variety of choices of N.

Finally, the above discussion is based on the Fortran convention whereby
multidimensional arrays are stored “column by column”, i.e., with the first index
running fastest. It is easy to base the discussion instead on the Algol convention
whereby arrays are stored “row by row”, i.e., with the last index running fastest.

Acknowledgement. I am grateful to Warren Ferguson for several discussions
concerning fast Fourier transforms and for comments on an earlier draft. I am in-
depted to Eric Grosse for carrying out the comparisons mentioned above and for sug-
gesting that the more leisurely discussion in an earlier draft be replaced by
showing directly that the $Z_k$ as generated by (12) satisfy (10).
