ABSTRACT

One of the ways of assuring greater reliability of software is to improve testing techniques. Three of the key problems associated with software testing are: choosing adequate test cases, assuring correctness of the results, and reducing the high cost of testing. Some degree of automation is required to help solve these problems. By combining the capability of adaptive testing with the use of executable assertions, it is possible to automatically execute a program with a large number of testcases over a wide range of input values. The usual goal of adaptive testing is to maximize some performance value (objective function) for the software by automated perturbation of the input parameters in such a way as to degrade the system performance to a specified limit. This technique only indirectly leads to locating errors, because of the time-consuming task of examining the usual output from the program. In software testing, the primary goal is to locate the maximum number of errors rather than maximize the performance value. Since software errors can be detected by executable assertions, these assertions can be used to define an objective function for the adaptive tester so that a program can be tested automatically and a mapping made of its "error space." A search algorithm is used to generate new test cases based on past performance data about the number of assertion violations. Software testing can become much more efficient and effective through the use of adaptive testing with assertions, because such extensive testing increases the possibility of finding any existing errors and of improving software reliability.
INTRODUCTION

Testing is one area of the software development cycle where there is a need for vast improvement. It is frequently the most costly part of the cycle and the most time-consuming. What is needed is not to put more money and time into testing, but to devise a systematic method of exercising a program with a sufficient number of input values over the entire range of possible values in such a way that any existing errors are discovered. To accomplish this goal and to automate as much of the testing process as possible, the techniques developed for adaptive testing are being combined with the use of executable assertions for error detection.

Before software testing can be automated (and become cost effective), two primary problems must be solved: developing adequate test cases to identify errors, and verifying the results of these test cases. The problem of developing test cases has been studied in the Adaptive Verification and Validation research program.¹ The method has been to use various search techniques adapted from optimization theory and artificial intelligence research in order to maximize a performance value (objective function for the software). The original test cases (input values) are either supplied by the tester or developed stochastically. These values are then altered, through a feedback mechanism using heuristics, to maximize the performance value.

In software testing, however, we are not so much interested in maximizing performance as in locating errors. The technique of maximizing a performance function only indirectly helps to locate errors in the software. Errors are usually discovered by examining the output of a program, which is a time-consuming task. Since software errors can be detected through the use of assertions, assertions can be used as the objective function, thus allowing the adaptive testing techniques to be applied to the problem of testing software.
ADAPTIVE TESTING

Adaptive testing is a technique for identifying how well a program performs in response to changes in its input values. The Adaptive Tester was developed to test the response of simulated ballistic missile defense programs to changes in a threat scenario. The program's performance was defined by the number of re-entry vehicles which were not intercepted.

The Adaptive Tester uses the principles of feedback and adaptive search to identify scenarios which result in the maximum tolerable number of re-entry vehicles penetrating the defense. An initial scenario is described and input to the test case construction algorithm. This algorithm generates a set of input values for the program being tested. The program is executed and values are recorded which measure its performance. The performance values are then evaluated and compared with past performance values. The change in performance values is then used as input to the adaptive search algorithm which constructs a new scenario. New input data is constructed for this scenario and the program is run again. This cycle continues until scenarios are found which cause the maximum tolerable number of re-entry vehicles to penetrate the defense. The input values which characterize each such scenario, and the resulting performance values, define the "performance boundary" of the program.

METHODOLOGY FOR ADAPTIVE TESTING WITH ASSERTIONS

In much the same way as the input parameters are systematically perturbed to degrade the system performance until the performance boundary is reached, the input parameters of a program can be perturbed until areas with maximum errors (indicated by assertion violations) are located. The first step, therefore, is to add assertions to the code to be tested, if that has not already been done. Actually assertions have many uses and are extremely valuable throughout the entire software cycle. Ideally they should be written during the design phase to state
specifications about the variables before any coding takes place. Later, during dynamic tests, these same assertions can be made executable to help in program debugging. Assertions can also be left in the code as a form of documentation, because they can contain much useful information about variables (e.g., the expected range of values or, in distributed systems, path or timing constraints). These built-in specifications are a way of protecting the software during deployment or maintenance from modifications to the code which may alter the expected mode of operations.

Almost any condition or specification can be expressed using executable assertions. An executable assertion is a logical expression which, if evaluated to false, signals the violation of a specification for the program. The logical operators of the assertions have been extended to include the operators of first-order predicate calculus: implication, existence, and universal quantifiers. A preprocessor translates the assertions into executable statements. When the program is executed, the logical expression in each assertion is evaluated. If it is false, an error message is printed which states the name of the module and the line number of the assertion statement. In addition, a tabulation is made of how many times an assertion is violated.

The important role of the assertions in this type of testing cannot be emphasized enough: they should be interspersed throughout the code at appropriate places, there must be a sufficient number of assertions to monitor each variable, and they must correctly state the performance requirements of the variables. In other words, the success of this type of testing depends on the validity and comprehensiveness of the assertions.

To assure the correctness of the assertions, the second step is to perform preliminary tests of the program with varied input values. A
frequent result of this initial testing is that unsuspected errors in the code are uncovered by the assertions. Any errors in the code or the assertions should be corrected before continuing.

The third step is to construct a set of test data by specifying the possible range of values for the input variables. The initial value of a variable is the minimum boundary value and the upper limit (and final value) is the maximum specified value. Next some interval is chosen through which the value of the variable will be stepped during the testing. In this way, a "grid" of input values is defined over the input space. Figure 1 shows the input space boundaries for a program which was used as part of an experiment to determine if it was feasible to merge the adaptive testing methods with the use of executable assertions for this type of testing. The input values of the transit times were within the range of 0 to 300 microseconds. The probability of any one pulse request in the sequence of requests being a search pulse was allowed to range between 0 and 1.

Figure 1. Input Space Boundary
Once the range of input values is specified and the interval chosen, the rest of the testing is automated. The tester is relieved not only of the chore of choosing new input data but also of the tedious task of wading through reams of output to verify the results of each test case. During the fourth step, the program is executed once for each set of input values and a mapping is made of the error space. The input variables of the program are defined as the independent variables, and the number of assertions which become false when the program is run with a particular set of input values is defined as the dependent variable. Values of the dependent variable define an objective function of errors over the input space. By maximizing this objective function, we can locate the values of the input variables which cause the program to fail.

Having defined the error function in much the same way as the performance function is defined for the Adaptive Tester, the fifth step then is to use the search algorithms of the Adaptive Tester to locate values in the program's input variables which cause the most errors to occur. The reason we search for the area of maximum assertion violations is to uncover as many errors as possible. Although some errors will cause several assertions to be violated, other errors are only indicated by a single assertion failure; therefore, it is essential that the entire input space be searched for all possible violations.

Figure 2 shows the organization of the adaptive testing programs. A test case construction algorithm takes the initial test data and constructs a set of input values with which to run the program. These input data values are also recorded in the test results file for use by the search algorithm in altering the input data. The program is run and the assertion evaluator evaluates the assertions as they are executed and records any assertions that become false. The test results file is
then read by the search algorithm, which computes new values for the input variables based upon the assertions violated and the past history of the tests. These new values are input to the test case construction algorithm, which forms a new set of input values for the program and executes it.

**EXPERIENCE WITH ADAPTIVE TESTING USING ASSERTIONS**

The process that generates a radar schedule in a missile defense simulation was chosen as the test object for a preliminary evaluation of this method of testing software. This set of modules take a sequence of requests for radar pulses and from these constructs a schedule for the radar's time. This schedule must not overlap transmitted pulses with each other or with listening times ("receive windows") and must allow sufficient time between pulses and receive windows to switch beam positions.
In order to show the error space more clearly, two of the input variables were chosen as independent variables in the experiment: the transit time for pulses (i.e., the time between the transmission of the pulse and the receive window), and the number of search pulses in the input sequence. Random input values were generated to simulate a real-time process. The number of assertion violations for each set of input values was tabulated during the testing for use in constructing a three-dimensional grid.

This purpose of this preliminary experiment was to determine what the error space of a program looked like and whether it was feasible to use adaptive search techniques to maximize an error function. The results of this experiment showed that the "error surface" from testing this set of modules was well behaved. It contained maximums, minimums, and gradients which could be used by various search techniques to locate the values in the input space which cause the most errors. Figure 3 shows the results from testing this program with the set of input values previously illustrated in Figure 1.

Figure 3. Example of an Error Space Map
A second experiment on a much larger scale is now in progress. A complex software program which computes orbital element vectors was selected as the test object. Assertions were added, and a set of errors for "seeding" the program were generated using methods developed by current research. The errors are representative of those found in large programs in both type and frequency of occurrence, and the sites chosen for the seeding were randomly selected.

The input variables to the program are considered two at a time to construct a three-dimensional error space. Two factors should be considered in deciding which variables to perturb: it is most effective to choose those variables which have the most influence on the final output values, and those which provide collateral testing by exercising other input variables that are dependent on them.

From the error functions derived from each two-variable case, a complete error map will be constructed for the program. The error space map will give a good indication of the shape and characteristics of the error function of the program. The shape of the error function will determine which search algorithms are most applicable to locating the input values of the program which lead to the most errors. The performance of the search algorithm chosen for the experiment will be evaluated.

CONCLUSION

The final results of the current experiment will provide a second evaluation of the effectiveness of using executable assertions for software testing. In addition, the performance of the adaptive search technique in locating the maximum value of the error function will indicate how much automation is possible in the testing of computer programs.
Another benefit of this project is a further merging of the testing process with the requirements of fault tolerance in software. Once an assertion indicates the presence of an error, one of two choices is possible: either uncover the error and correct the code, or leave the error in and provide a method to recover from it. Although such a suggestion at first sounds incomprehensible, there are times when an error cannot be found or, if found, is so complex that it cannot be corrected easily without the possibility of introducing more errors. Such might be the case in an algorithm that is basically correct but, within certain ranges, produces incorrect results. If these ranges are not expected to occur often, then the best solution may be to provide compensatory code in a recovery block.

A second related outcome of adaptive testing with assertions is that the tabulation of assertion violations indicates which assertions are potentially the most sensitive to errors and are, therefore, the most valuable. This information makes it possible to optimize assertion coverage in fault tolerant applications requiring minimal overhead.
