<td>In this work the electron cyclotron maser oscillator interaction is analyzed in an open resonator configuration. One of the salient features of this configuration for generating high power short wavelength radiation is its ability to mode select. Both the linear and nonlinear analysis are developed for an arbitrary value of the refractive index ( n = k c/\omega ). Specializing to luminous waves, ( n = 1 ), it is shown that the linear gain curve is symmetric.</td>

about synchronism and that instability can occur even at exact synchronism, for appropriate initial beam distributions. The nonlinear integrals of the motion are obtained, indicating that the total energy is available, the nonlinear evolution is described by a single differential equation, and the nonlinear efficiency is shown to depend on only four combinations of the beam, field, and resonator parameters. Nonlinear efficiencies up to 15% can be achieved. For a relativistic beam, a substantial frequency upshift is possible, with efficiencies up to 10%. Efficiency enhancement is possible, e.g., by the introduction of a two-stage resonator. In such a configuration, efficiencies exceeding 30% are calculated. Finally, the requirements for beam temperature and mode selectivity are found not to be particularly restrictive.

LINEAR AND NONLINEAR ELECTRON CYCLOTRON INTERACTION
IN OPEN RESONATORS

I. INTRODUCTION

One of the most recently developed devices for the generation of
coherent radiation in the millimeter and centimeter range is the gyrotron
(or, electron cyclotron maser). In this device, radiation power is pro-
duced by the interaction of the TE fields of the cavity with an electron beam
which propagates and gyrates along an external static magnetic field. This
interaction has been studied extensively,¹⁻¹⁸ both theoretically and experi-
mentally, with impressive results, such as a 22% efficiency of conversion of
beam kinetic power to radiation at a 2 mm wavelength with 22 kW CW output
power. Substantial improvements are possible if axial nonuniformities are
introduced in the form of gradients either in the oscillator cross-section,¹⁹,²⁰
or in the external magnetic field.²¹⁻²³

The frequency of the gyrotron is determined by the relativistic gyro-
frequency of the electrons in the external magnetic field. For efficient
operation, this gyrofrequency, Doppler-shifted in the electron beam rest
frame, must be in close synchronism with the eigenfrequency of the cavity.
However, since the size of the cavity cannot be made arbitrarily small, a
large value of the gyrofrequency may result in synchronism with more than
one of the cavity eigenfrequencies. Although preliminary investigations²⁴⁻²⁸
have not been conclusive, it is expected that multi-mode effects may prove a
problem for wavelengths less than ≈1 mm.

To avoid such potential limitations, it is proposed that the gyrotron
cavity be replaced by an open quasi-optical resonator, Fig. 1, formed by two
mirrors of appropriate shape. Taking the z-axis as the axis of the radiation,
the fields can be shown to be derivable from the usual vector potential

Manuscript submitted March 10, 1981.
Fig. 1 — Schematic representation of the quasi-optical resonator and electron beam configuration. The diffracted fields are contained by the two mirrors, one or both of which may be partially transmitting. The individual electrons of the beam execute, to zero order, a helical motion in the external magnetic field $B_0$. 
\[
A = 2A(r,z) \sin \left[ k z + \alpha(r,z) \right] \left[ \hat{\mathbf{e}}_x \cos(\omega t) + \varepsilon \hat{\mathbf{e}}_y \sin(\omega t) \right]
\]

\[
+ \frac{2}{kr} \frac{\partial}{\partial r} \left[ A \cos(kz + \alpha) \right] \left[ x \cos(\omega t) + \varepsilon y \sin(\omega t) \right] \hat{\mathbf{e}}_z
\]

where \( \omega \) is the radiation frequency, \( k = \omega/c \) is the dominant term of the wavenumber, \( \alpha(r,z) = kr^2/2R + \tan^{-1}(z/z_o) \) is the spatially dependent phase, \( A(r,z) = A_0 (r_0/r_s) \exp(-r^2/r_o^2) \) is the position dependent amplitude for the fundamental mode, \( \varepsilon \) is the ellipticity of the radiation, \( r = (x^2 + y^2)^{1/2} \) is the transverse coordinate, \( r_s(z) = r_o(1 + z^2/z_o^2) \) is the spot size at \( z \) with \( r_o \) its minimum value at \( z=0 \), \( R(z) = z(1 + z_o^2/z^2) \) is the radius of curvature of the wave front at \( z \), \( z_o = \pi r_o^2/\lambda \) is the Rayleigh length, and \( \lambda = 2\pi/k \) is the wavelength. The diffraction angle of the fundamental mode is \( \Theta_d = \lambda/\pi r_o \). The diffraction angle of the higher order modes is larger. Therefore, if the radius of the mirrors is somewhat larger than \( r_s \), most of the energy of the fundamental mode will be intercepted, resulting in a high value of \( Q \). The higher order modes on the other hand will suffer from diffraction losses, their \( Q \)'s will be small, and therefore these modes will not be excited. Thus the introduction of open resonators provides an effective natural means for transverse mode selection.

This paper is intended as a preliminary but comprehensive analysis of the electron cyclotron interaction with the diffracted fields of Eq. (1). The limit we have considered throughout the paper is that of an electron beam propagating along the radiation axis.\(^{29} \) We have assumed that the transverse extent of the beam is small compared to the radiation spot size \( r_s \), therefore the action of the field on the beam electrons is that of a plane wave. In this limit we have developed the linear theory
(Sec. II) and the nonlinear theory (Sec. III) of the interaction in a bounded system (oscillator). Various issues pertaining to the basic theory are discussed in Sec. IV, along with the presentation of numerical examples.

In Section II the linear dispersion relation is obtained for an oscillator. For the sake of generality, an arbitrary electron beam distribution is assumed. All forward and backward components of the field perturbation are kept and the value of the refractive index $n = kc/\omega$ is left unspecified in the bulk of the analysis in this Section. Specializing to the case of a monoenergetic beam, affected only by the forward wave, yields a compact result and reproduces the expressions for the gyrotron in the cut-off frame, when $n \to 0$. For luminous waves, $n > 1$, the gain curve has two interesting features, viz. it possesses even symmetry about the frequency of synchronism and can lead to instability even at exact synchronism, provided that the transverse beam velocity satisfies a certain inequality.

The nonlinear theory is developed in Section III for a constant amplitude wave. The equations of motion for the electrons are expressed using the axial coordinate $z$ as the independent Lagrangian variable. These equations are interrelated by four invariants. Two of these invariants relate the transverse displacement to the velocity, while the other two relate the velocity components. These invariants reproduce earlier results when $n \to 0$ or $n > 1$. A transformation to slowly varying variables eliminates an additional variable and results in a single integrable equation. The phase space plots are studied and distinction between closed and open orbits is made. A condition for complete electron
kinetic energy depletion is identified. The nonlinear efficiency is found to depend on only four combinations of the field and electron beam parameters and is conveniently presented in contour plots.

Finally, certain aspects related to the applicability of our analysis are discussed in Section IV. It is shown that the symmetry of the gain spectrum can be used to relax the temperature requirements. The interaction is also shown to have inherent abilities for axial mode selection. In our example of a gyrotron type operation we obtained a 13.7% efficiency at $\lambda = 2$ mm with a 61 kW output power. The potential application of this interaction as a free-electron laser is discussed and a scheme for efficiency enhancement is proposed. By utilizing a two-oscillator configuration, an efficiency $n = 35\%$ is obtained, while estimates predict efficiencies can reach 60%.

The cyclotron interaction of electrons with luminous waves has been the subject of two recent investigations.\textsuperscript{31,32} In the first paper the dispersion relation was obtained and analyzed for waves with arbitrary values of $n = kc/\omega$ in the limit of vanishing axial beam velocity. In the second paper the stability was investigated in terms of particle energy loss, obtained from an expansion of the equations of motion in the radiation field amplitude. Both these analyses assume a uniform medium of infinite extend in $z$ and use the time as the independent coordinate. Accordingly, their results differ from ours, since in the present work the axial position $z$ is used as the independent variable and the presence of the oscillator boundaries is important.
II. LINEAR THEORY

The fields of the oscillator are given in terms of the vector potential $\mathbf{A}$ by the simplification of Eq. (1),

$$\mathbf{A} = A_0 \sin(kz) \left( \hat{\mathbf{e}}_x + i \epsilon \hat{\mathbf{e}}_y \right) e^{-i\omega t} + c.c.$$  \hspace{1cm} (2)

$$= 2A_0 \sin(kz) \left[ \hat{\mathbf{e}}_x \cos(\omega_R t) + \epsilon \hat{\mathbf{e}}_y \sin(\omega_R t) \right] e^{i\gamma t},$$

where $A_0$ is the amplitude, $k$ is the axial wavenumber (along the $z$ axis), $\omega_R$ is the complex frequency consisting of the real frequency and the growth rate, $\omega_R = \omega - i\gamma$, $\epsilon$ characterizes the ellipticity of the polarization, and $\hat{\mathbf{e}}_x$ and $\hat{\mathbf{e}}_y$ are unit transverse vectors. The oscillator fields $\delta \mathbf{E}$ and $\delta \mathbf{B}$ are given by

$$\delta \mathbf{E} = -\frac{1}{c} \frac{\partial \mathbf{A}}{\partial t} = i \frac{\omega}{c} A_0 \sin(kz) \left( \hat{\mathbf{e}}_x + i \epsilon \hat{\mathbf{e}}_y \right) e^{-i\omega t} + c.c.,$$  \hspace{1cm} (3)

$$\delta \mathbf{B} = \nabla \times \mathbf{A} = -i k A_0 \cos(kz) \left( \epsilon \hat{\mathbf{e}}_x + i \hat{\mathbf{e}}_y \right) e^{-i\omega t} + c.c.$$

In addition, a static uniform axial magnetic field is present, $\mathbf{B}_0 = B_0 \hat{\mathbf{e}}_z$.

The fields given by Eq. (3) are appropriate for those in an oscillator formed by two parallel plates of infinite extent in the transverse direction. They are also applicable to a general case of an oscillator consisting of two concave boundaries, provided that $A_0$ and $k$ are appropriate functions of $x$, $y$, and $z$ and the small axial field components are included. These modifications depend on the waist of the radiation field, $r_0$, and the Rayleigh length $z_0 = \omega r_0^2/2c$ and are negligible if the beam width and
the electron Larmor radius are small compared to \( r_0 \), and if the axial interaction length is small compared to \( z_0 \). Accordingly, under such conditions the fields in Eq. (3) can be used with \( A_0 \) and \( k \) constant.

The behavior of the field is governed by the wave equation,

\[
- \nabla^2 A + \frac{1}{c^2} \left( \frac{\partial^2}{\partial t^2} + \nu \frac{\partial}{\partial t} \right) A = \frac{4\pi}{c} j,
\]

where \( \nu \) is a real quantity representing losses. It will be shown later that \( \nu = \omega R/Q \), where \( Q \) is the quality factor of the resonator. Expressing the current density as

\[
j = \sqrt{2} e^{-i\omega t} + \text{c.c.},
\]

it is found that Eq. (4) together with Eq. (2) can be put in the form

\[
\frac{L}{2} \left[ (k^2 c^2 - \omega_R^2) - i(2\Gamma + \nu)w_R \right] A_0 (\hat{\mathbf{E}}_x + i\epsilon \hat{\mathbf{E}}_y)
= \int_{0}^{L} 4\pi c \sqrt{2} \sin(kz) dz,
\]

where \( L \) is the interaction length.

Before continuing, it is necessary to evaluate \( \nu \) in Eq. (6). This is accomplished by integrating Poynting's theorem along the interaction region,

\[
\frac{\partial}{\partial t} \int_{0}^{L} udz + S_z(z=L) - S_z(z=0) = - \int_{0}^{L} \delta E \cdot j \ dz,
\]

7
where $u$ is the radiation energy density and the $z$ component of Poynting's vector $S_z$ vanishes at $z=0$ and has the value $S_z = \left(\frac{\omega_R}{Q}\right) \int_0^L u dz$ at $z=L$, by the definition of $Q$. The definition of $\Gamma$ implies an exponential variation, $\exp(2\Gamma t)$, for the energy, thus

$$
(2\Gamma + \frac{\omega_R}{Q}) \int_0^L u dz = - \int_0^L \delta E \cdot J dz ,
$$

(8)

and from a comparison with Eq. (6) it is seen that

$$
u = \frac{\omega_R}{Q} .
$$

(9)

The current density in Eq. (6) will be evaluated from the appropriate moment of the distribution function, the latter obtained from the solution of the Vlasov equation. Employing the expansion $f = f^{(0)} + f^{(1)}$ of the distribution function, $f^{(0)}$ describes the zero-order trajectories in the external magnetic field and is therefore a function of the corresponding constants of motion,

$$p_z^2 = p_x^2 + p_y^2 ,$$
$$\theta = \tan^{-1} \left( \frac{p_y}{p_x} \right) - \frac{\Omega_0 m}{p_z} z ,$$
$$p_H = p_z ,$$
$$x_g = x - \frac{p_y}{\Omega_0 m} ,$$
$$y_g = y + \frac{p_x}{\Omega_0 m} ,$$

(10)

which are, respectively, the transverse momentum, the azimuthal phase angle relative to a fixed cyclotron helix, the parallel momentum, and the
x and y locations of the guiding center, defined as functions of the Cartesian components of position \((x,y,z)\) and momentum \((p_x, p_y, p_z)\).

The nonrelativistic cyclotron frequency is \(\Omega_0 = eB_0/m_0c\). Considering Eq. (10) as a transformation from Cartesian to constant-of-motion phase space, that is, defining \(g^{(0)} = f(0)\) and \(g^{(1)} = f(1)\), where \(g^{(0)}\) and \(g^{(1)}\) are functions of the variables defined in Eq. (10) as well as \(z\) and \(t\), the Vlasov equations can be written as

\[
\left( \frac{3}{a} + \frac{p_y}{\gamma m_0} \frac{3}{a} \right) g^{(1)}(z) = e \left[ \delta \epsilon + \frac{1}{\gamma m_0 c p_x} \delta p_x \right] g^{(0)}(z) .
\]

Here the unperturbed distribution function is assumed independent of \(\theta, x, y,\) and \(p_y\). The relativistic factor \(\gamma\) is defined as \(\gamma^2 = 1 + (p^2_x + p^2_y + p^2_z)/(m_0c)^2\).

Using Eqs. (3) and (10) and introducing the expansion

\[
g^{(1)} = \tilde{g}^{(1)} e^{-i\omega t} + c.c.,
\]

in Eq. (11), the first order linear homogeneous differential equation for \(\tilde{g}^{(1)}\) can be integrated, yielding

\[
g^{(1)} = \frac{1}{4} eA_0 \frac{\gamma m_0}{p_y} \exp \left[ i \frac{\gamma m_0 \omega}{p_y} z \right] \times \left\{ (1 + e)e^{i\theta} \left[ \frac{e^{i\xi_{1+} z} - 1}{i\xi_{1+}} D_+ - \frac{e^{i\xi_{1-} z} - 1}{i\xi_{1-}} D_- \right] \\
- (1 - e)e^{-i\theta} \left[ \frac{e^{-i\xi_{2+} z} - 1}{i\xi_{2+}} D_+ - \frac{e^{-i\xi_{2-} z} - 1}{i\xi_{2-}} D_- \right] \right\} g^{(0)} .
\]

The differential operators, \(D_+\) and \(D_-\), acting on \(g^{(0)}\), and the relative wavenumbers, \(\xi_{1\pm}\) and \(\xi_{2\pm}\), are
\[ D_+ = \frac{\omega}{c} \frac{\partial}{\partial p_\perp} + \frac{k}{\gamma m_0 c} \left( p_\perp \frac{\partial}{\partial p_{\|}} - p_{\|} \frac{\partial}{\partial p_\perp} \right) \]

\[ \xi_{1+} = \pm \frac{(\Omega_0 + \gamma \omega) m_0}{p_{\|}} \]

\[ \xi_{2+} = \pm \frac{(\Omega_0 - \gamma \omega) m_0}{p_{\|}} . \]

The constant of integration in Eq. (13) is such that \( \bar{g}^{(1)} = 0 \) at \( z=0 \), corresponding to an unperturbed entering beam.

The perturbed distribution function, obtained in Eq. (13), can be used to evaluate the Fourier component of the current density,

\[ \bar{J} = -\frac{e}{m_0} \int \frac{dp}{\gamma} \bar{g}^{(1)} \ dp . \]

Performing the integration over \( \theta \) in Eq. (15) gives

\[ \bar{J} = -\frac{1}{8} e^2 A_0 n_0 \int dp_{\perp} dp_{\|} \frac{p_{\perp}^2}{p_{\|}} \exp \left[ i \frac{\gamma m_0 \omega}{p_{\|}} z \right] \]

\[ \times \left\{ \left( \vec{e}_x + i \vec{e}_y \right) \exp \left[ -i \frac{\Omega_0 m_0}{p_{\|}} z \right] (1 + \epsilon) \left[ e^{i \xi_1^+ z - i \xi_1^-} D_+ - e^{i \xi_1^- z - i \xi_1^+} D_- \right] \right\} g_0 . \]

The beam density \( n_0 \) has been extracted for convenience from the distribution function, by defining \( n_0 g_0 = 2 \times g^{(0)} \), where \( g_0 \) is normalized to \( \int dp_{\perp} \int dp_{\|} g_0 = 1 \). Finally, multiplying \( \bar{J} \) by \( \sin(kz) \) and integrating over the length of interaction, yields the driving term required in Eq. (6).
\[
\int_0^L 4\pi c \overline{J} \sin(kz) \, dz
\]
\[
= i \frac{n}{q} e^2 A_0 n_0 c \int dp_\perp dp_\parallel \frac{p_\parallel^2}{p_\parallel^2}
\]
\[
x \left\{ (\hat{E}_x + i \hat{E}_y) (1 + \epsilon) \left[ \left( \frac{e^{-i\xi_1 M - 1} - L}{i\xi_1} - \frac{e^{-i\xi_1 M + 1}}{i\xi_1} \right) \frac{1}{i\xi_1+} D_+ - \left( L + \frac{e^{i\xi_1 M - 1}}{i\xi_1} - \frac{e^{i\xi_1 M + 1}}{i\xi_1} \right) \frac{1}{i\xi_1-} D_+ \right] 
\right.
\]
\[
- \left( \hat{E}_x - i \hat{E}_y \right) (1 - \epsilon) \left[ \left( \frac{e^{i\xi_2 M - 1} - L}{i\xi_2} + \frac{e^{i\xi_2 M - 1}}{i\xi_2} \right) \frac{1}{i\xi_2+} D_+ - \left( L - \frac{e^{i\xi_2 M - 1}}{i\xi_2} + \frac{e^{i\xi_2 M - 1}}{i\xi_2} \right) \frac{1}{i\xi_2-} D_+ \right] \bigg\} g_0,
\]
\]
where the boundary condition \( \sin(kL) = 0 \) has been used to eliminate terms similar to \( \exp[i(\xi_1+ - \xi_1-) L] \).

Equating Eqs. (6) and (17) yields a consistency condition between \( \omega_R, \Gamma \) and \( \epsilon \). This is the linear dispersion relation, which includes the positive and negative electron cyclotron interaction with both the forward and backward traveling waves. However, in general only one of these interactions is resonant, which we take throughout the remainder of this paper to be with the forward wave.\(^3\) Defining

\[
\xi = \xi_1+ = k + \frac{(\Omega_o - \gamma\omega) n_o}{p_\parallel},
\]
\[
\nu = \frac{1}{2} \xi L,
\]

one obtains from Eq. (17),
\[ \int_{0}^{L} 4\pi c \hat{f} \sin(kz) dz \]

\[ = i \frac{\pi}{4} e^{2A} \eta_0 c \int dp_\perp dp_\parallel p_\perp^2 (\hat{e}_x + i \hat{e}_y) (1 + \epsilon) \left[ \frac{iL}{\xi} + \frac{e^{-i\xi L}}{\xi^2} \right] D_4 g_0. \quad (19) \]

Comparing this equation with Eq. (6), it is seen immediately that consistency requires that \( \epsilon = 1 \), that is, only a circular polarization is compatible with the interaction. The dispersion relation now becomes

\[ (\omega_R^2 - k^2 c^2) + i \omega_R (2\Gamma + \frac{\omega_R}{Q}) \]

\[ = \frac{1}{16} m_0 L c^2 \omega_0 \int dp_\perp dp_\parallel p_\perp^2 p_\parallel^2 \left[ \frac{2\mu - \sin^2 \mu}{\mu^2} + i 2 \frac{\sin^2 \mu}{\mu^2} \right] D_4 g_0, \quad (20) \]

where \( \omega_0^2 = 4\pi e^2 n_0/m_0 \) and \( \mu \) is a complex quantity, defined in Eq. (18) and depending on \( \omega = \omega_R + i\Gamma \).

In a number of interesting special cases only the real part \( \mu_R \) of \( \mu \) is of significance. These cases are: (i) the (linear) steady state, \( \Gamma = 0 \), (ii) the conditions just above threshold, \( \Gamma \to 0 \), and (iii) when the beam is sufficiently weak, so that the imaginary part of \( \mu \) is negligible. In such cases, separate equations can be obtained for the frequency and growth rate,

\[ \omega_R^2 - (kc)^2 = \frac{1}{4} m_0 L c^2 \omega_0 \int dp_\perp dp_\parallel p_\perp^2 p_\parallel^2 \frac{2\mu_R - \sin^2 \mu_R}{(2\mu_R)^2} D_4 g_0, \quad (21) \]

\[ \omega_R (2\Gamma + \frac{\omega_R}{Q}) = \frac{1}{8} m_0 L c^2 \omega_0 \int dp_\perp dp_\parallel p_\perp^2 p_\parallel^2 \frac{\sin^2 \mu_R}{\mu_R} D_4 g_0. \]

Finally, for the special case of a monoenergetic beam, \( g_0 = \delta(p_\perp - p_{\perp 0}) \delta(p_\parallel - p_{\parallel 0})/p_{\perp 0} \), integration over \( p_\perp \) and \( p_\parallel \) gives
\[
\frac{1-n^2}{2} \left( 2 \frac{\omega \beta_{\perp 0}}{\gamma_0} + \frac{L}{\omega R^C} \right) D_{\mu} + 1 D_{Q} \left( \frac{R_n(\mu) - R_Q(\mu)}{2} \right), \tag{22}
\]

where the refractive index, \( n = kc/\omega R \), has been introduced, the quantity \( \mu_R \) is obtained from Eq. (18) in terms of the beam quantities \( \gamma_0 \) and \( p_{\perp 0} \) and the dimensionless velocities \( \beta_{\perp 0} = p_{\perp 0}/\gamma_0 m_0 c \) and \( \beta_{\perp 0} = p_{\perp 0}/\gamma_0 m_0 c \) were used. The operator \( D_{\mu} \) and the functions \( R_n \) and \( R_Q \) are

\[
D_{\mu} = \left[ n - 2 \frac{\beta_{\perp 0}(1-n\beta_{\perp 0})}{\beta_{\perp 0}} \right] + \left[ \frac{1-n^2}{2} \frac{\omega R L}{c} + n \mu_R \right] \frac{d}{d\mu_R},
\]

\[
R_n(\mu) = \frac{2\mu - \sin 2\mu}{(2\mu)^2},
\]

\[
R_Q(\mu) = \left( \frac{\sin \mu}{\mu} \right)^2.
\]

To complete the formalism we note that for the fields of Eq. (3) the total steady state field energy inside the interaction region, \( L \), is given by \( \int_0^L u dz = (\omega R A_0/2c)^2 L (1 + n^2)/n \), hence the efficiency of converting kinetic energy to radiation energy, per unit time, is

\[
\eta_k = \frac{1 + n^2}{2\gamma_0 (\gamma_0 - 1)} \frac{\beta_{\perp 0}^2}{\beta_{\perp 0}^2} \frac{e_{A_0}^2}{2mc^2} \frac{\omega R L^2}{c} D_{\mu} R_Q. \tag{24}
\]

We have thus completed the linear analysis of the interaction. The results are represented by Eqs. (22) and (24) for a monoenergetic beam and weak (or vanishing) growth-rate, as well as the general case given by Eq. (20). Let us consider now the significance of these equations,
in the limiting cases \( n \to 0 \) and \( n \to 1 \). The first of these cases, \( n \to 0 \), corresponds to the gyrotron mechanism. Referring to Eq. (24), the efficiency of the oscillator is proportional to the quantity

\[
D_{\mu Q} = -2 \frac{\beta \mu_0}{\beta^2_0} \left( \frac{\sin \mu R}{\mu R} \right)^2 + \frac{1}{2} \frac{\omega R}{c} \frac{d}{d\mu R} \left( \frac{\sin \mu R}{\mu R} \right)^2 .
\] (25)

The first term in the above expression is always negative, and its stabilizing effects are reduced if the ratio \( \beta^2_0 / \beta^2 \) is large. If this ratio is large enough for this term to be omitted, a positive energy conversion can be obtained if the derivative \( dQ/d\mu R \) is positive. This occurs in a number of intervals in the domain of \( \mu R \), the most prominent of which is \( -\pi < \mu R < 0 \), and the maximum of \( dQ/d\mu R = 0.54 \) is attained at \( \mu R = -1.3 \). Such negative values for \( \mu R \) correspond to \( \omega R > \Omega_0 / \gamma_0 \), hence the wave frequency must exceed the relativistic electron gyrofrequency.

Let us now turn our attention to the interaction with luminous waves, \( n \to 1 \). In this case, the efficiency of the resonator, referring to Eq. (24), is proportional to

\[
D_{\mu Q} = \left[ 1 - 2 \frac{\beta \mu_0}{\beta^2_0} (1 - \beta \mu_0) \right] \left( \frac{\sin \mu R}{\mu R} \right)^2 + \mu R \frac{d}{d\mu R} \left( \frac{\sin \mu R}{\mu R} \right)^2 .
\] (26)

This function is plotted in Fig. (2) for \( \beta_0 = 0.1 \) and (a) \( \beta_0 = 0.7 \), (b) \( \beta_0 = 0.425 \), and (c) \( \beta_0 = 0.35 \). A number of interesting features can be observed in Eq. (26). First it is noted that \( D_{\mu Q} \) (i.e., \( \eta \)) is an even function of \( \mu R \), therefore, contrary to the gyrotron mechanism, the interaction with luminous waves does not depend on the sign of the frequency mismatch, \( \Delta \omega = \omega R - \Omega_0 / \gamma_0 - k \nu_1 = -2 \mu R \nu_1 / L \). Instability occurs if either of two conditions are satisfied. The first is
Fig. 2 — The function $D_{\mu}R_{Q}(\mu_R)$, which is proportional to the linear efficiency, versus $\mu_R$, which is proportional to the resonator length, for $n=1$, $\beta_{||0} = 0.1$ and (a) $\beta_{\perp0} = 0.70$, (b) $\beta_{\perp0} = 0.425$, and (c) $\beta_{\perp0} = 0.35$. 

\[\beta_{||0} = 0.10\]
\[(a) \, \beta_{\perp0} = 0.70\]
\[(b) \, \beta_{\perp0} = 0.425\]
\[(c) \, \beta_{\perp0} = 0.35\]
and $\nu_R = 0$. If Eq. (27) is satisfied, the first term in Eq. (26) is positive, while the second term vanishes. Thus, contrary to the gyrotron mechanism, a positive efficiency can occur for $\Delta \omega = 0$, provided that Eq. (27) is satisfied. If Eq. (27) is well satisfied, the first term dominates up to the point $|\nu_R| = 1.166$, where $\tan \nu_R = 2 \nu_R$ and therefore

\[
- \nu_R \frac{dQ}{d\nu_R} = R_Q.
\]

Additional regions of instability occur when the second term is positive, provided that Eq. (27) is not too strongly violated. These regions cover the intervals $j\pi < |\nu_R| < a_j - 1/a_j$, where $a_j = (2j+1)\pi/2$, $j=1,2,3\ldots$, and the upper limit is a good approximation to the solution of $\tan \nu_R = \nu_R$. In these regions, $\nu_R \frac{dQ}{d\nu_R}$ reaches the maximum values $1/(1 + b_j)$ at $|\nu_R| = b_j - 1/(\sqrt{2} b_j)$, where $b_j = (4j + 1)\pi/4$, and $j$ is a positive integer.
III. NONLINEAR THEORY

The linear analysis established that the cyclotron interaction with plane waves results in instability, even for luminous waves, n=1. In this section the nonlinear equations of motion are obtained, both on the fast and slow spatial scales. These equations are investigated and constants of the motion are obtained. The application of these invariants permits the analytical study of the conditions for energy depletion, the trajectories in phase space and the exact scaling relations for the efficiency. A single first-order differential equation is found to be sufficient to describe the evolution of the particles.

The nonlinear equations of motion are studied under the action of a uniform axial magnetic field, \( B_z = B_0 \hat{e}_z \), specified by its nonrelativistic electron gyrofrequency, \( \Omega_0 = eB_0/mc \), and a steady state wave, whose vector potential is

\[
A = A_0 \left[ \hat{e}_x \sin(kz - \omega t + \phi_0) + \varepsilon \hat{e}_y \cos(kz - \omega t + \phi_0) \right]. \tag{28}
\]

Only the forward wave is included in Eq. (28). Adding to Eq. (28) a similar expression, with \( k \rightarrow -k \) and \( \phi_0 \rightarrow \phi_0 + \pi \), recovers Eq. (2). However, the backward wave has been omitted, since resonance with the forward component is assumed.

Although the natural independent variable for particle motion is time, it is convenient for oscillator configurations to adopt a Lagrangian representation, expressing the equations of motion in terms of the axial distance \( z \). Since \( dt = dz/v_z \), the phase of the wave as a function of \( z \) is given by
\[ \psi(z) = k \int_0^z \left( 1 - \frac{1}{n \beta_z(z')} \right) dz' + \psi_0 \]  

(29)

where \( \beta_z = v_z/c \). The equations of motion become

\[ \frac{d}{dz} (\gamma \beta_x) = A_0 \cos \psi \frac{d\psi}{dz} - \frac{\Omega_0}{c} \frac{\beta_y}{\beta_z} \]

\[ \frac{d}{dz} (\gamma \beta_y) = -\varepsilon A_0 \sin \psi \frac{d\psi}{dz} + \frac{\Omega_0}{c} \frac{\beta_x}{\beta_z} \]

\[ \frac{d}{dz} (\gamma \beta_z) = -k A_0 \left( \frac{\beta_x}{\beta_z} \cos \psi - \varepsilon \frac{\beta_y}{\beta_z} \sin \psi \right) \]

\[ \frac{d}{dz} \gamma = -k \frac{A_0}{n} \left( \frac{\beta_x}{\beta_z} \cos \psi - \varepsilon \frac{\beta_y}{\beta_z} \sin \psi \right) \]

\[ \frac{d}{dz} x = \frac{\beta_x}{\beta_z}, \quad \frac{d}{dz} y = \frac{\beta_y}{\beta_x} \]

where \( A_0 = eA_0/mc^2 \), \( \beta_x = v_x/c \), \( \beta_y = v_y/c \) and \( \gamma^2 = (1 - \beta_x^2 - \beta_y^2 - \beta_z^2)^{-1} \). Note that the first four of Eq. (30) are interrelated by the definition of \( \gamma \). In addition, the equations for \( x \) and \( y \) can be integrated, in conjunction with the equations for \( \gamma \beta_y \) and \( \gamma \beta_x \), respectively, to yield the constants of the motion

\[ I_x = \gamma \beta_x - A_0 \sin \psi + \frac{\Omega_0}{c} y \]

\[ I_y = \gamma \beta_y - \varepsilon A_0 \cos \psi - \frac{\Omega_0}{c} x \]

These integrals can be used to assess the assumption of transverse uniformity implied by Eq. (28).
An additional invariant can be obtained from Eq. (30) by noting the equations for $\gamma \beta_z$ and $\gamma$. This invariant is

$$I_1 = \gamma(n - \beta_z),$$  \hspace{1cm} (31)

and its invariance is associated with the plane wave nature of the fields. When $n=0$, this invariant describes the conservation of axial momentum in the cut-off frame of the gyrotron. If $n > 1$, $I_1$ is proportional to the conserved particle energy in the wave frame. The significance of this invariant is that it indicates the possibility of complete energy depletion, $\gamma=1$, if the initial particle properties are such that $I_1 = n$. Denoting these initial properties with a subscript zero, the necessary condition for complete energy depletion is

$$\gamma_0 = \frac{n}{n-\beta_{zo}}.$$  \hspace{1cm} (32)

Introducing the definition of $\gamma_0$, Eq. (32) can be written as

$$\beta_{zo}^2 = 2 \frac{\beta_{zo}}{n} \left(1 - \beta_{zo} \frac{n^2+1}{2n}\right),$$  \hspace{1cm} (33)

where $\beta_{zo}^2 = \beta_{zo}^2 + \beta_{yo}^2$. An interesting observation is that when $n=1$, Eq. (33) reproduces the condition for the vanishing of the first term in the linear dispersion relation (see Eq. (26)). It should be noted that Eq. (32) or (33) represents only a necessary condition for complete energy depletion. The sufficient condition depends on whether the state of complete energy depletion is accessible by the particles. We will return to this point later.
The introduction of the invariants reduces the system of Eq. (30) formally to two coupled integro-differential equations for \( \gamma \beta_x \) and \( \gamma \beta_y \). Following the usual procedure, we define

\[
\beta_x = \beta_\perp \sin(\psi + \chi), \\
\beta_y = \beta_\perp \cos(\psi + \chi),
\]

where \( \beta_\perp, \psi \) and \( \chi \) are functions of \( z \) varying slowly over a cyclotron period. Substituting Eq. (34) into Eq. (30) results in trigonometric functions with arguments \( \chi \) and \( 2 + \chi \). The \( 2 + \chi \) terms phase-mix in a few wavelengths, hence the slow spatial scale equations are

\[
\frac{d}{dz} \left( \gamma \beta_\perp \right) = \frac{1+c}{2} k (1 - \frac{1}{n^2 z}) \Omega_0 \sin, \\
\frac{d}{dz} \left( \gamma \beta_z \right) = -\frac{1+c}{2} k \frac{\beta_\perp}{n^2 z} \Omega_0 \sin, \\
\frac{d}{dz} \chi = -k \left[ 1 - \frac{1}{n^2 z} (1 - \frac{\Omega_0}{\omega \gamma}) \right] + \frac{1+c}{2} k \frac{1}{\gamma \beta_\perp} (1 - \frac{1}{n^2 z}) \Omega_0 \cos, \\
\frac{d}{dz} \gamma = -\frac{1+c}{2} k \frac{\beta_\perp}{n^2 z} \Omega_0 \sin \chi.
\]

The above equations are interrelated by the definition of \( \gamma \) and the invariance of \( I_1 \). In addition, Eq. (35) possesses an additional invariant, given by

\[
I_2 = (\gamma \beta_\perp)^2 - (\gamma \beta_\perp) (1+c) \Omega_0 \cos - 2 \frac{\Omega_0}{kc} n \gamma.
\]
It can be seen that when \( n=0, c=0 \) and \( \beta_z \to 0 \), the combination \( I_2 + I_1^2 + 1 + (\Omega_0/\omega)^2 \) gives the corresponding gyrotron type invariant in the cut-off frame. \(^1\) Also, when \( n > 1 \), then \( I_2 \) transforms in the wave frame to the corresponding second invariant. \(^3, 34\) Furthermore, using the fast length scale Eq. (30), the derivative of \( I_2 \) is

\[
\frac{dI_2}{dz} = -(1-c) kA_0 \left[ \left( 1 - \frac{1}{n\beta_z^2} \right) - \frac{\Omega_0}{\omega} \right] \gamma \beta_z \sin(2\psi + \chi)
+ (1 - \frac{1}{n\beta_z^2}) - \frac{l+c}{2} A_0 \sin(2\psi) \right].
\]

\( (37) \)

Hence \( I_2 \) is invariant also on the fast length scale, provided \( c=1 \).

The determination of the two invariants, \( I_1 \) and \( I_2 \), allows us to study the trajectories in phase space. The appropriate coordinates for the two-dimensional representation are \( \chi \) and \( \gamma \). Using the definition of \( \gamma \) and the invariance of \( I_1 \) and \( I_2 \) to eliminate \( \beta_z \) and \( \beta_{\perp} \) in terms of \( \gamma \) and \( \chi \) (and the initial conditions, denoted by subscript zero), we find that

\[
\cos \chi = \frac{(1-n^2) (\gamma-\gamma_0)^2 + 2(\Delta\omega_0/\omega) \gamma_0 (\gamma-\gamma_0) + (1+c) A_0 \gamma_0 \beta_{\perp 0} \cos \gamma_0}{(1+c) A_0 \left[ (1-n^2) (\gamma-\gamma_0)^2 + 2(1-n\beta_{\perp 0}) \gamma_0 (\gamma-\gamma_0) + (\gamma_0 \beta_{\perp 0})^2 \right]}.
\]

\( (38) \)

where \( \Delta\omega_0 = \omega - \Omega_0/\gamma_0 - kv_{z0} \).

We are primarily interested in the case of luminous waves, \( n=1 \).

In this case, Eq. (38) takes on a rather simple form. The resultant equation is

\[
qC_w - q^2 \cos \chi = \text{const} ,
\]

\( (39) \)
where \( C_w \) is a constant proportional to the ratio of the initial frequency mismatch and the wave amplitude,

\[
C_w = \frac{\gamma_0 \beta_{z0}}{1 - \beta_{z0}} \frac{\omega - k v z_0 - \Omega_0 / \gamma_0}{\omega (1 + \varepsilon) A_0},
\]

and \( q \) is a linear function of \( \gamma \),

\[
q = 2 \frac{1 - \beta_{z0}}{\gamma_0 \beta_{z0}^2} (\gamma - \gamma_0) + 1.
\]

It can be seen that \( q=1 \) corresponds to the initial condition, \( \gamma = \gamma_0 \), hence the constant in Eq. (39) is equal to \( C_w - \cos \chi_0 \). In addition, depletion of the perpendicular or of the parallel energy, correspond to \( q=0 \) and \( q=C_d \) respectively, where

\[
C_d = 1 - \frac{2 \beta_{\perp0} (1 - \beta_{z0})}{\beta_{\perp0}^2},
\]

is a constant characterizing the anisotropy of the distribution. When \( C_d = 0 \), complete depletion of the energy is possible, see Eq. (33).

For a positive frequency mismatch, that is, when \( C_w > 0 \), the phase space trajectories, obtained from Eq. (39), are shown schematically in Fig. (3). The arrows indicate the direction of particle motion. Both open and closed trajectories are possible in principle. The separatrix between these two families of curves is shown by the broken bell-shaped curve, described by the equation \( q C_w^2 - \cos^2 \chi = 0 \) and defined only in the interval \( |\chi| < \pi/2 \). The largest value of \( q \) on the separatrix is at \( \chi = 0 \), \( q = C_w^{-2} \). The vortex, or 0-point, of the closed trajectories is at \( \chi = 0 \), \( q = (2 C_w)^{-2} \).
Fig. 3 — Trajectories in phase space coordinates $q, \chi$. The dashed curve is the separatrix. The dashed straight lines give the initial values, $q=1$, for (a) $C_w > 1$, (b) $0.5 < C_w < 1$, and (c) $0 < C_w < 0.5$. 
For the curves in Fig. (3) to represent actual electron trajectories, they must intersect the initial condition line, \( q_0 = 1 \). The location of this line can be obtained in relation to the value of \( C_w \). If \( C_w > 1 \), then the peak of the separatrix lies below the line \( q_0 = 1 \) (line (a)), and all particles are untrapped. Trapped particles exist if \( C_w < 1 \), but always more than half of the initial phase angles \( \chi_0 \) correspond to untrapped particles. Lines (b) and (c) in Fig. (3) describe the initial conditions, \( q_0 = 1 \), if \( 0.5 < C_w < 1 \) and \( 0 < C_w < 0.5 \), that is, above and below the vortex, respectively.

When \( C_w < 0 \), the phase space trajectories are obtained from those in Fig. (3) by a reflection about the line \( \chi = \pi/2 \). The trajectories for \( C_w > 0 \) and \( C_w < 0 \) are shown in Figs. 4(a) and (b). Because of this symmetry, any particle, trapped or untrapped, in Fig. 4(a) has a corresponding particle in Fig. 4(b), which executes identical changes in \( q \) (or \( \gamma \)). This recovers and extends to the nonlinear regime the linear result that the evolution is independent of the sign of the frequency mismatch (or \( C_w \)). The phase plot in Fig. 4(c) corresponds to exact synchronism, \( C_w = 0 \). In this case the separatrix reduces to the lines \( \chi = \pi/2 \) and \( \chi = -\pi/2 \) and all particles are semi-trapped. In this case the relative phase \( \chi \) is bounded, while the energy, or \( q \), is bounded only from below. Whether the initial evolution in this case corresponds to net particle energy loss or gain depends on whether \( C_d > 0 \) or \( C_d < 0 \), as has been shown in linear theory. However, it is clear from Fig. 4(c) that eventually all particles, regardless of their initial phase, will gain energy and will be tightly bunched in \( \chi \) (but not in energy), about \( \chi = -\pi/2 \). Accordingly, this configuration can be the basis for a particle
Fig. 4 — Comparison of phase space trajectories when (a) $C_w > 0$, (b) $C_w < 0$, and (c) $C_w = 0$. 
accelerator. The details of such an application are currently under study and will be discussed in a separate publication.

The determination of the two invariants, $I_1$ and $I_2$, which connect the three independent momentum components, makes possible the description of the electron evolution in terms of only one quantity, say $q$ (i.e., the energy). When the index of refraction is unity, i.e., $n=1$, the corresponding differential equation is

$$\frac{dq}{d\zeta} = - \text{sgn}(\sin \chi) \left[ q - (q C_w - C_w + \cos \chi_0)^2 \right]^{1/2}$$

where $\text{sgn}$ is the sign function and the reduced length $\zeta$ is defined as

$$\zeta = \frac{2(1+\varepsilon)A}{\gamma_0^2 \beta_0} \left( \frac{1-\beta z_0}{\beta \beta_0} \right)^2 k(z-z_0).$$

It can be seen that Eq. (43) is immediately integrable. The inversion of the resulting expression is straightforward only when $C_w=0$, $C_d<0$. This case is, however, uninteresting, since it corresponds to energy gain by the electrons.

In spite of the difficulties associated with the inversion of the integral of Eq. (43), useful information can still be obtained. It is noted that the solution of Eq. (43) has the form

$$q = q(\zeta_{\text{max}}, \chi_0, C_w, C_d),$$

where $\zeta_{\text{max}}$ is the value of $\zeta$ corresponding to the length $L$ of the interaction region in Eq. (44). In our Lagrangian representation, the efficiency is given by $\eta = -\langle \gamma - \gamma_0 \rangle / (\gamma_0 - 1)$, hence
\[ n(\zeta_{\text{max}}, C_w, C_d, C_n) = C_n (1-\langle q \rangle) , \]  

(46)

where the angular brackets denote an ensemble average over \( \chi_0 \) and the coefficient \( C_n \) is defined by

\[ C_n = \frac{\gamma_0 \beta_0^2}{2(\gamma_0-1)(1-\beta_2 \gamma_0)} . \]  

(47)

The efficiency, therefore, does not depend on the seven parameters \( k, \xi, \epsilon, L, \beta_{z_0}, \beta_{\gamma_0}, \Omega_0 \) arbitrarily but only on \( \zeta_{\text{max}}, C_w, C_d \) and \( C_n \). Further simplifications arise by the fact that \( C_n \) is just a multiplier of the efficiency expression. Large values of \( C_n \) are possible for a wide range of beam properties, as can be seen in Fig. (5). In this figure contour plots, \( C_n = \text{const} \), are presented. In addition, Fig. (6) presents contour plots of \( C_d = \text{const} \).

Before proceeding with the presentation of the results for the nonlinear efficiency, it is worthwhile to rewrite the linear efficiency, Eq. (24), in terms of the variables defined above. We use the definitions of \( C_d, C_w, C_n \) and note from the definition of \( \zeta \) that it is related to \( \mu_0 \) by

\[ C_w \zeta_{\text{max}} = -2(1-C_d)\mu_0, \]

where \( \mu_0 \) is defined in Eq. (18) in terms of the initial values. Then from Eq. (24) the expression for the linear efficiency is obtained,

\[ \eta_L = \frac{C_n}{C_w (1-C_d)} \mu_0^2 (C_d + \mu_0 \frac{d}{d\mu_0} \left( \frac{\sin \mu_0}{\mu_0} \right)^2) . \]

(48)

This expression has all the features expected from Eq. (46), since it involves a dependence on \( \zeta_{\text{max}} \) (through \( \mu_0 \)), as well as \( C_w, C_d \) and \( C_n \).
Fig. 5 — Contour plots for the efficiency coefficient $C_\eta$ vs. $\beta_{z_0} \beta_{\eta_0}$, the normalized transverse and axial electron velocities.
NORMALIZED AXIAL VELOCITY, $\beta_{zo}$

NORMALIZED TRANSVERSE VELOCITY, $\beta_{1o}$

Fig. 6 — Contour plots for the anisotropy constant $C_d$ vs. $\beta_{zo}$ and $\beta_{1o}$. 
Let us proceed now to solve for the nonlinear efficiency. Two numerical approaches are available, the first approach based on a numerical integration of the complete set of Eq. (30) to obtain the Lagrangian particle trajectories. The second approach requires the integration of Eq. (43) only. Both approaches have been used. In all cases, the agreement has been excellent. Equally excellent has been the agreement of the results with linear theory, when a sufficiently small amplitude or short interaction length has been employed in the simulations.

The dependence of the normalized efficiency $\eta/C_\eta = 1 - \langle q \rangle$ on the reduced distance $\nu_0$ is given by the solid curve in Fig. (7) for a distribution characterized by $C_d = -2.5$ and a wave characterized by $C_w = 1.4$. Comparing this curve with linear theory has shown that initially, up to $\nu_0 = 1.6$, the evolution is essentially linear. Beyond that point, the efficiency undergoes oscillations in $\nu_0$, reminiscent of the corresponding linear behavior, except that these nonlinear oscillations do not diverge, while the linear result of Eq. (48) predicted divergent oscillations. The location of the relative maxima of the efficiency vs. $\nu_0$ is however, in strikingly good agreement with linear theory. The first maximum is at $\nu_0 = 3.7$, and the corresponding optimized nonlinear efficiency is $\eta/C_\eta = 0.164$, approximately one half of the linear value $\eta_0/C_\eta = 0.300$. For these parameters, subsequent maxima correspond to negative values for the efficiency. The dashed curve corresponds to the values $C_d = -2.5$ and $C_w = 2.7$. This case will be discussed later.

The contour plots of Fig. (8) show the normalized nonlinear efficiency, $1 - \langle q \rangle$, at the first maximum (the one near $\nu_0 = 3.7$), for various values of the parameters $C_d$ and $C_w$. As can be seen from the Figure, large normalized efficiencies, e.g., $1 - \langle q \rangle \cdot 0.15$, are possible.
Fig. 7 — Spatial evolution of the normalized efficiency $1 - \langle q \rangle = \eta/C_\eta$ for $C_d = -2.5$ and $C_w = 1.4$ (solid curve), as well as for $C_d = -2.5$ and $C_w = 2.7$ (dashed curve).
Fig. 8 — Contour plots of the normalized efficiency $1<q>$ vs. the parameters $C_d$ and $C_w$ for an interaction length corresponding to the first efficiency maximum ($\mu_0 \approx 3.7$). The dotted curve gives the value of $C_w$ for maximum efficiency at any value of $C_d$. 

WAVE CONSTANT, $C_w$

BEAM DISTRIBUTION CONSTANT, $C_d$
over a wide range of beam distributions and ratios of frequency mismatch to radiation field amplitude. In addition, the dotted line in Fig. (8) gives the value of $C_w$ required for optimal operation at a given value of $C_d$. For such values of $C_w$, the normalized efficiency as a function of $C_d$ is given in Fig. (9). The overall maximum, $1 - \langle q \rangle = 0.165$, is obtained for $C_d = -2.2$, $C_w = 1.5$.

The results presented so far apply to the first maximum of the nonlinear efficiency, at a point near $\mu_o = 3.7$. This is not meant to imply that the first efficiency maximum is always dominant. For example, referring again to Fig. (7), it can be seen that increasing the value of $C_w$, causes the amplitude of the first efficiency maximum to decrease, and that of subsequent maxima to increase. When the point $C_w = 2.7$ is reached (dashed curve), for which $1 - \langle q \rangle$ maximizes near $\mu_o = 6.8$, the normalized nonlinear efficiency is equal to $1 - \langle q \rangle = 0.143$. For even higher values of $C_w$, it is the third, fourth, etc. efficiency maximum that dominates. The same behavior is observed if $-C_d$ is increased, keeping $C_w$ constant. Contour plots for the efficiency at the second and subsequent maxima are very similar to those of Fig. (8), except that the curves are shifted to slightly higher values of $C_w$ and $-C_d$. 

33

OPTIMAL NORMALIZED EFFICIENCY, $1 - \langle q \rangle$

BEAM DISTRIBUTION CONSTANT, $C_d$
IV. DISCUSSION

In the previous two Sections, we have considered the linear and nonlinear electron cyclotron interaction with (primarily) luminous waves. From that analysis, results have been obtained regarding the stability of these waves and the nonlinear steady-state performance. In this Section, we conclude with various aspects concerning the practical feasibility of a device based on this analysis. We show that this interaction has weak temperature requirements ($\delta \beta_{zo}/\beta_{zo} << 1$) and that excellent mode selection can be achieved. One example of a cyclotron maser is given and the use of this interaction as a free-electron laser is discussed. Finally, the possibility of improving the nonlinear efficiency (up to $\eta \approx 0.60$) is discussed.

(a) Temperature requirements.

Let us consider first the effects associated with a thermal spread, $\delta \beta_{zo}$ and $\delta \gamma_{0}$, of the beam electrons. The sharpness of the resonance in both linear and nonlinear theory is characterized by the parameter $\nu_{0}$, which can be written as

$$\nu_{0} = \pi \frac{L}{\lambda} \left[ 1 + \frac{\Omega/\gamma_{0} - \omega}{k c \beta_{zo}} \right], \quad (49)$$

where $\lambda = 2\pi/k$ is the radiation wavelength. From the dependence of the efficiency on $\nu_{0}$, it is seen that $|\delta \nu_{0}| \ll \pi/4$ is required. With regard to the parallel velocity, this translates to the requirement

$$\frac{\delta \beta_{zo}}{\beta_{zo}} \ll \frac{1}{4} \frac{\lambda}{L} \frac{k c \beta_{zo}}{|\Omega/\gamma_{0} - \omega|} \quad (50).$$
For conventional cyclotron maser operation, \( \omega \geq \Omega/\gamma_0 + k\beta z_0 \) and this requirement gives \( \delta \beta z_0/\beta z_0 \ll \lambda/4L \), prohibiting operation in a system longer than a few wavelengths. However, when \( \omega = kc \), the symmetry about \( \mu_0 = 0 \) allows a choice of operating point with \( \omega < \Omega/\gamma_0 + k\beta z_0 \). In particular, if the wave is suppressed (e.g., by a polygonal ray-path in a multi-mirror resonator) and the choice is made that

\[
\mu_0 = \pi \left( \frac{\lambda}{\lambda} + \frac{1}{4} \right),
\]

(51)

where a local maximum of the efficiency is located, the requirement is simply

\[
\frac{\delta \beta z_0}{\beta z_0} \ll 1.
\]

(52)

For the same operation, the requirement for \( \delta \gamma_0 \) is

\[
\frac{\delta \gamma_0}{\gamma_0} \ll \frac{1}{4} \beta z_0 \frac{\lambda}{L},
\]

(53)

which may be more restrictive.

As regards the other significant parameters of the interaction, the requirement \( |\delta C_d| \ll 1 - C_d \) gives a condition supplementary to Eq. (53),

\[
\frac{\delta \gamma_0}{\gamma_0} \ll (\gamma_0 \beta z_0)^2,
\]

(54)

while the condition on the parallel velocity is less restrictive than (52). Similarly, the condition \( |\delta C_w| \ll C_w \) is satisfied if the above conditions are satisfied, except that in the highly relativistic limit, \( \beta z_0 \gg 1 \), an additional condition is imposed, viz.
(b) Mode Selectivity.

Transverse and longitudinal mode selectivity can be dealt separately. We will not deal in any detail with the former. It is expected that by an appropriate design of the mirrors, only the lowest order transverse mode will be intercepted, while the higher order modes will suffer from diffraction losses.

As far as the longitudinal modes are concerned, we first seek to determine the number of modes that fill the positive gain curve segment, at whose peak the desired longitudinal mode is located. Since the half-width of the gain curve is \(|\delta \mu| \lesssim \pi/4\), it can be seen from Eq. (49) that the number \(\delta \lambda\) of longitudinal mode pairs (in addition to the mode at which operation is desired) within the positive gain segment is

\[
\delta \lambda \lesssim \frac{\beta_{zo}}{2(1-\beta_{zo})}.
\]  

Thus, no competing axial modes are present if \(\beta_{zo} < 2/3\). On the other hand, many modes will be excited in the case of a highly relativistic electron beam with \(\beta_{zo} = 1\).

An additional point to be considered is whether the operation of the device at a certain efficiency maximum is accompanied by the presence of a different longitudinal mode which might correspond to a value of \(\mu_0\) lying within a different positive segment of the gain curve. This question is particularly important when there are many wavelengths within the resonator. In that case, the operation is seen from Eq. (51) to
require a large value of $\mu_0$ and the broken line in Fig. (7) indicates that more than one gain segment corresponds to positive gain. Such undesired modes can be suppressed by the introduction of distributed feedback. Inherent means for mode selection are also available. Thus, it can be seen from Eq. (49) that if the choice

$$\beta_{zo} = \frac{1}{2j+1} \quad (57)$$

is made, where $j$ is an integer, then the closest potentially unstable mode falls at the next $(2j-1)$-th maximum of the gain curve. If $j$ is not too small, then it is expected that this maximum may correspond to negative gain, thus guaranteeing the absence of any competing modes.

(c) Example of cyclotron maser operation.

Before proceeding, it is necessary to present a numerical example, in order to demonstrate how our results can be applied to a particular design. We consider an interaction at the third maximum of the gain curve. As can be seen from Eq. (51), temperature effects are reduced by choosing a system length equal to $3\lambda$. The normalized efficiency at the third maximum is $\eta/C_{\eta} = -0.156$, for $C_d = -2.9$, $C_w = +3.0$ and $\mu_0 = +10.1$. A value $\beta_{zo} = 0.143 (=1/7)$ guarantees the absence of any competing modes (see Eq. (57)) and Eq. (53) gives the condition $\delta\gamma_0/\gamma_0 \ll 1.2\%$. From the definition of $C_d$, Eq. (42) (or, from Fig. (6)), it can be found that $\beta_{zo} = 0.25$, hence $\gamma_0 = 1.0433$ corresponding to a beam energy of 22.2 keV. Then from the definition of $C_{\eta}$, Eq. (47), or, from Fig. (5), it is found that $C_{\eta} = 0.88$. Therefore, the nonlinear efficiency is $\eta = 0.137$. For the above values and the definition of $C_w$ (Eq. (40)), the normalized vector potential of the
radiation field, assuming linear polarization, has the value $A_0 = 1.55 \times 10^{-2}$. The external magnetic field gives a gyrofrequency satisfying $\Omega_0/\omega = 1.055$ and the frequency mismatch is $\Delta\omega_0/\omega = (\omega - \Omega_0/\gamma_0 - kv_0)/\omega = -0.154$. Finally, by choosing a wavelength $\lambda = 2$ mm, this example requires an external magnetic field of $B_0 = 56.5$ kG for a radiation field amplitude of $E_0 = 833$ sV/cm (= 250 kV/cm) and frequency $\omega = 0.942 \times 10^{12}$ sec$^{-1}$ (= 150 GHz). For an incident beam current of 20 A, the radiated power is 61 kW.

(d) Free-electron-laser type operation.

An interesting variant to the study presented here is the possibility of using the interaction for the excitation of waves with a frequency shifted significantly above the gyrofrequency. It can be seen from the definition of $C_w$ that the frequency is given by

$$\omega = \frac{\Omega_{zo}}{\gamma_0 (1-\beta_{zo})} + C_w \frac{1+\epsilon}{\gamma_0^{\beta_{zo}}} \frac{eE_0}{mc}, \quad (58)$$

where $E_0 = \omega A_0/c$ is the amplitude of the electric component of the radiation field. The operating frequency is essentially given by the first term in Eq. (58). Defining the axial relativistic factor, $\gamma_{zo} = (1-\beta_{zo}^2)^{-1/2}$, the operating frequency is accurately given by

$$\omega = (1 + \beta_{zo})\gamma_{zo}^2 \frac{\Omega_0}{\gamma_0} \quad \text{ (59)}$$

and bears the same form as the free-electron laser frequency, employing a magnetic wiggler.
Since the relativistic gyrofrequency depends on the mass factor $\gamma_0$, the actual quantity that multiplies the nonrelativistic gyrofrequency to give the operating frequency is $I_1^{-1}$, where $I_1 = \gamma_0(1 - \beta z_0)$ is the first invariant. For high operating frequencies, it is required that $I_1^{-1} > 1$. This requirement, together with the desire that $C_n$ be not too much less than unity (in order to achieve adequate efficiencies) requires that $-C_d < 1$. Thus, as can be seen from Fig. (9), efficiencies of the order of 10% are to be expected. For example, $\omega/\Omega_0 = 10$ requires $I_1 = 0.1$. Taking $\gamma_0 = 50$, gives $\beta z_0 = 0.998$ and $\beta 40 = 0.06$. Then $C_d = -0.11$, giving $\eta/C_n = 0.102$, and $C_n = 0.917$, and the result is an efficiency $\eta = 9.36\%$. (Of course, higher efficiencies can be obtained by adopting efficiency enhancement schemes, as discussed in IV(e) below.) In this example, it is required that $C_w = 3.6$ and $\mu_0 = 3.6$. Choosing a wavelength of $\lambda = 0.2$ mm ($f = 1.5$ THz) and a system length $L = 1m = 5000 \lambda$, it is found that an external magnetic field of strength $B_0 = 47.5$ kGs is needed. Furthermore, assuming a beam current of $10 A$, the radiated power is equal to $P_{rad} = 23.4$ MW.

(e) Efficiency enhancement.

The nonlinear analysis of Sec. III shows that the performance of an oscillator operating with luminous waves is limited to efficiencies $\eta < 16\%$. Here we will outline briefly a scheme which can improve the performance of the interaction dramatically. We introduce a two-stage oscillator configuration, in which the first stage (the prebuncher) acts to pre-bunch the particles in their relative angle $\chi$, without significantly changing particle momentum. The second stage (the converter) converts the kinetic energy of the bunch to radiation energy. A 100% conversion
is possible, if the bunch is perfect and $C_d = 0$.

In the prebuncher we require a combination of a "large" frequency mismatch and "small" radiation field amplitude, such that $|C_{w1}| \gg 1$. In this stage the electrons are highly untrapped and only negligible energy exchange occurs. To first order $\chi$ is

$$\chi^{(1)} = \chi_0 + \left(C_{w1} - \frac{\cos \chi_0}{2}\right) \xi$$

(60)

where $C_d = 0$ has been assumed. For $\chi_0$ uniformly distributed in the interval $(0, 2\pi)$, Eq. (60) describes the formation of a bunch.

The extraction of particle energy occurs in the converter. From the discussion of Sec. III (see also Fig. (3)), it is recalled that a particle on the separatrix eventually loses all its kinetic energy, if $C_d = 0$, as is assumed here. Since the bunch has a spread in $\chi$ rather than in $q$, it is necessary to arrange the converter parameters so that $C_{w2} = 1$. With an appropriate choice of $C_{w1}$, the bunch will be centered at the peak of the separatrix. The center of the bunch will thus be able to convert all its energy to radiation energy, by choosing the appropriate length for the converter section. Examining the bunch coherence from Eq. (60) it can be estimated that efficiencies of the order of 60% are attainable.

As an example of a two-stage oscillator we consider the case $C_{w1} = 7.5, C_d = 0$, with a discontinuity in the radiation field amplitude, $C_{w2} = 1.0$, for $\xi > \xi_1$. The evolution of the efficiency for this case is shown in Fig. (10). The oscillatory curve gives the evolution when the first oscillator is sufficiently long, $\xi_1 \rightarrow \infty$. However, if the location of the discontinuity is appropriately chosen, the ensuing evolution is
Fig. 10 — Efficiency enhancement in a two-stage oscillator configuration. The oscillatory curve gives the nonlinear normalized efficiency vs. normalized distance for $C_{w1} = 7.5$ and $C_d = 0$ in a single resonator. The introduction of a second resonator with $C_{w2} = 1.0$ at $\zeta = \zeta_1$, shown by the small circles, improves the overall efficiency. The cases shown correspond to (a) $\zeta_1 = 0.90$, (b) $\zeta_1 = 1.72$, and (c) $\zeta_1 = 2.50$. 
characterized by substantially increased efficiency. Thus, for the choices $\zeta_1 = 0.90$, 1.72, and 2.50, shown in the figure by the small circles, the evolution of the efficiency in the second oscillator, where $C_{w2} = 1.0$, is shown by the curves (a), (b), and (c). This procedure yields the optimal values of the efficiency $\eta = 0.15$, 0.28, and 0.35 at the positions $\zeta_2 = 1.5$, 2.3, and 3.1, respectively. This clearly demonstrates the principle of efficiency enhancement in a two-stage oscillator.
