The objective of this investigation was to produce experimental verification of the tearing instability theory proposed by Paris and coworkers. This theory states that ductile crack extension will occur in an unstable fashion whenever the applied tearing force is greater than the material tearing resistance. In this investigation, a series of compact specimens of aluminum, titanium, and steel alloys were tested in a very compliant test.
machine to generate a range of applied tearing forces. The material tearing resistance was measured from the $J_I$-R curves of the stable specimens and compared to the applied tearing force necessary to generate ductile tearing instability in each material. The Paris theory was found to accurately predict the onset of gross instability behavior. Some limited instability behavior was found, however, at values of tearing force less than the average material tearing resistance obtained from an unloading compliance $J_I$-R curve test. Limited instability behavior was characterized by repeated short steps of rapid but ductile crack extension, separated by regions of slow stable tearing.

ABSTRACT

The objective of this investigation was to produce experimental verification of the tearing instability theory proposed by Paris and coworkers. This theory states that ductile crack extension will occur in an unstable fashion whenever the applied tearing force is greater than the material tearing resistance. In this investigation, a series of compact specimens of aluminum, titanium, and steel alloys were tested in a variably compliant test machine to generate a range of applied tearing forces. The material tearing resistance was measured from the J-R curves of the stable specimens and compared to the applied tearing force necessary to generate ductile tearing instability in each material. The Paris theory was found to accurately predict the onset of gross instability behavior. Some limited instability behavior was found, however, at values of tearing force less than the average material tearing resistance obtained from an unloading compliance J-R curve test. Limited instability behavior was characterized by repeated short steps of rapid but ductile crack extension, separated by regions of slow stable tearing.

ADMINISTRATIVE INFORMATION

This report was prepared as part of the Surface Ship and Craft Materials Block Program under the sponsorship of Dr. H.H. Vanderveldt, Naval Ship Systems Command (SEA 05R15). The effort was performed at the David W. Taylor Naval Ship Research and Development Center under Program Element 62761N, Task Area SF 61-541-592, Project 20457, and Work Unit 2803-161.

INTRODUCTION

During the past few years, it has become increasingly common to characterize a material's resistance to static crack extension in terms of the J resistance curve (J-R curve) as introduced by Begley and Landes. The usual application of this J-R curve has been to extrapolate back to the crack initiation parameter, J_{IC}, which is then considered to be a material parameter. Crack extension is avoided in the structural element by limiting applied loads to values which keep the J integral (J) parameter at existing cracks below the material J_{IC} value.

*A complete listing of references is given on page 21.
In many applications, overloads can be envisioned which could reach or exceed the loading required to initiate ductile crack extension. An added requirement for structural integrity then is that the crack growth be stable and not self-propagating and that it cease immediately when the overload is removed.

To address this problem, Paris and coworkers have defined a tearing modulus quantity \( T \) as

\[
T = \frac{E}{\sigma_0} \frac{dJ}{da}
\]

where

- \( E \) = elastic modulus
- \( \sigma_0 \) = material flow stress
- \( da \) = change in crack length

A material tearing modulus, \( T_{\text{material}} \), can then be defined by taking \( dJ/da \) as the slope of the material \( J_{1-R} \) curve beyond \( J_{1c} \).

The applied tearing force, \( T_{\text{applied}} \), depends upon the material properties, \( E \), \( \sigma_0 \), and the value of \( dJ/da \) applied to the crack tip by the combination of crack geometry, type of loading, and structural stiffness. Calculations of \( T_{\text{applied}} \) have been accomplished by Paris and coworkers for several simple geometries.

The tearing instability theory of Paris states that a flawed member will tear stably when it is beyond \( J_{1c} \), and at its limit load, as long as \( T_{\text{applied}} < T_{\text{material}} \). Tearing instability will occur whenever \( T_{\text{applied}} \geq T_{\text{material}} \).

The objective of this investigation is to evaluate the validity of the Paris tearing instability theory by testing a series of compact specimens in a test apparatus of variable compliance. A range of materials including aluminum, titanium, and steel alloys were chosen to encompass a broad range of elastic moduli. Both side-grooved and non-side-grooved specimens were tested because earlier work demonstrated that this geometry modification had a distinct effect on the material \( J_{1-R} \) curve, tending to give lower \( T_{\text{material}} \) values when side grooves were present. Application of a range of \( T_{\text{applied}} \) values would allow the determination of whether or not the \( T_{\text{material}} \) value was geometrically dependent; if not, which \( T_{\text{material}} \) more accurately predicted the instability conditions. Two crack lengths were studied to
verify the accuracy of the expression for $T_{\text{applied}}$ over a range of this variable, elastic modulus, flow stress, and machine stiffness.

For each material, standard single specimen $J_{I}$-R curves were developed using a stiff test machine and the technique of Joyce and Gudas\textsuperscript{7} to characterize $T_{\text{material}}$ for each material tested. Then, by increasing the test machine compliance, $T_{\text{applied}}$ was increased until it exceeded the $T_{\text{material}}$ value, at which point the previously stable specimens would be expected to fail in a rapid, unstable, but ductile fashion. Previous work of this type has been completed for one type of steel using bend specimens by Paris et al.\textsuperscript{8} For all tests, the $J$ integral size criteria\textsuperscript{9} were met to keep the tests initially in the region of $J$-controlled growth.\textsuperscript{10}

For the compact specimen geometry, $T_{\text{applied}}$ was calculated in a compliant test machine using the general analysis scheme outlined by Paris et al,\textsuperscript{2} assuming elastic, fully plastic material behavior. The details of this analysis are described in this report.

**MATERIALS AND EXPERIMENTAL METHOD**

The experimental tearing instability analysis study was performed on a series of 36 IT compact specimens machined in the T-L orientation. These plate materials, which were chosen to encompass a wide range of elastic moduli, included Al 5456 H117 aluminum, Ti-3Al-2.5V titanium alloy, HY-130 steel, and as-quenched ASTM A533B steel. The mechanical properties of the materials are presented in Table 1. All specimens were tested at room temperature except the as-quenched A533B which was tested at 150°C. The tests were performed with a screw-driven Tinius Olsen tensile machine modified with a variable-stiffness titanium spring in the load train as shown in Figure 1. The spring was composed of two titanium beams in series loaded in three-point bending. The spring stiffness was a function of the span distance between the two rollers.

All the $J_{I}$ fracture tests were conducted using a single specimen computer-interactive unloading compliance method using a mini-computer for data acquisition and analysis as developed by Joyce and Gudas.\textsuperscript{7} The results of each unloading compliance test were plots of load versus load-line crack-opening displacement, load versus test machine-head displacement, and a $J_{I}$-R curve which included corrections for crack growth\textsuperscript{11} and for specimen rotation.\textsuperscript{12} The expression for $J_{I}$ incorporating the crack growth correction is as follows:

\[ J_{i+1} = \left[ J_i + \left( \frac{a_{i+1}}{b} \right) \frac{A_i + A_{i+1}}{B_N} \right] \left[ 1 - \frac{1}{b} \right] (a_{i+1} - a_i) \]

where \( \cdot = 2 + (0.522) b/W \) for compact specimens

\( W \) = specimen width

The computer program was modified to calculate machine compliance and \( T_{\text{applied}} \) using the machined stiffness, applied \( J_1 \), and crack length from each unloading. Machine compliance was calculated by measuring the total system crosshead deflection versus applied load during the initial loading of a specimen, then subtracting the compliance contribution of the specimen. In addition to the digitally recorded data, an analog plot of load versus crosshead displacement was recorded during each test. This plot supplemented the load versus load-line crack-opening displacement (COD) curves and was used to identify instability events during the test. Table 2 is the test matrix for the tearing instability investigation which summarizes the material, specimen geometries, and ranges of \( T_{\text{applied}} \).

The \( T_{\text{material}} \) values listed in Table 2 were calculated from conventional \( J_1 \)-Integral tests in two ways. The first method was to use a least squares linear regression analysis as prescribed by Clarke et al., up to a crack extension of 1.5 mm, and the second method was to use a similar method but to include all test points up to a crack extension of 5 mm.

**TEARING FORCE ANALYSIS**

This section presents the derivation of an expression for the tearing force \( T_{\text{applied}} \) for a compact specimen loaded in a compliant test machine.

For the specimen and test configuration shown in Figure 2, a fixed \( T_{\text{applied}} \) is applied and held rigidly so that

\[ \Delta_{\text{TOT}} = \Delta_{\text{EL}} + \Delta_{\text{PL}} + \Delta_{\text{M}} = \text{Constant} \]

where \( \Delta_{\text{TOT}} \), \( \Delta_{\text{EL}} \), \( \Delta_{\text{PL}} \), and \( \Delta_{\text{M}} \) are the total, elastic, plastic, and machine displacements, respectively.

</table>

*All tests conducted at room temperature except A533B tests.
During crack extension then, the sum of the differentials of $\Delta_{EL}$, $\Delta_{PL}$, and $\Delta_M$ must be zero, i.e.,

$$d\Delta_{EL} + d\Delta_{PL} + d\Delta_M = 0$$

For the compact specimen, the elastic displacement component can be evaluated from the relationship

$$\Delta_{EL} = \frac{P}{BE} F\left(\frac{a}{W}\right)$$

where, from Saxena and Hudak,\textsuperscript{13}

$E$ = elastic modulus  
$B$ = specimen thickness  
$P$ = applied load
The plastic displacement component can be expressed as

$$
\Delta_{PL} = \delta_t \cdot g \left( \frac{a}{W} \right)
$$

(7)

where, from Merkle and Corten,

$$
g \left( \frac{a}{W} \right) = \left( \frac{2W}{W-a} + (\alpha - 1) \right) \frac{\delta_t}{1 + \alpha}
$$

(8)

where \( \delta_t \) = crack opening stretch

$$
\alpha = \left\{ \left[ 4a^2 + 4a(W-a) + 2(W-a)^2 \right]^{1/2} - (a+W) \right\} (W-a)
$$

(9)

The testing machine is assumed here to behave like a linear elastic spring, so the testing machine displacement is given simply by

$$
\Delta_M = \frac{P}{K_M}
$$

(10)

where \( K_M \), the machine stiffness, is a constant.

Assuming now that the load is at the specimen limit load, gives

$$
P = P_L = \sigma_o BW h \left( \frac{a}{W} \right)
$$

(11)

where, from Merkle and Corten,

$$
F \left( \frac{a}{W} \right) = \left( \frac{l + \frac{a}{W}}{l - \frac{a}{W}} \right)^2 \left[ 2.16299 + 12.219 \frac{a}{W} - 20.065 \left( \frac{a}{W} \right)^2 \\
- 0.9925 \left( \frac{a}{W} \right)^3 + 20.609 \left( \frac{a}{W} \right)^4 - 9.9314 \left( \frac{a}{W} \right)^5 \right]
$$

(6)
\[ h \left( \frac{a}{W} \right) = \left( 1 - \frac{a}{W} \right) \alpha \]  
(12)

with \( \alpha \) given by Equation (9). The final relationship needed is, from Paris \( ^{15} \) and Rice \( ^{16} \), that the crack tip opening displacement is proportional to \( J \) as

\[ \delta_t = \alpha * \frac{J}{\sigma_0} \]  
(13)

where \( \alpha * \) is a constant \( \approx 1 \) for plane stress and \( \approx 0.7 \) for plane strain.

Taking the differentials of Equations (5), (7), and (10), substituting into Equation (4), and rearranging gives the relationship

\[
T_{\text{applied}} = \frac{E}{\sigma_0} \frac{\partial J}{\partial a} = -\frac{W}{a^* g(a/W)} \left\{ \frac{\partial}{\partial a} \left[ h \left( \frac{a}{W} \right) f \left( \frac{a}{W} \right) \right] + \frac{E}{K_M} \frac{\partial h \left( \frac{a}{W} \right)}{\partial a} \right\} 
\]

\[ + \frac{\alpha * J E}{\sigma_0} \frac{\partial g \left( \frac{a}{W} \right)}{\partial a} \]  
(14)

where by differentiation of Equations (6), (8), and (12)

\[
\frac{\partial f}{\partial a} = \frac{2}{W} \left[ 2.16299 + 12.219 \frac{a}{W} - 20.065 \left( \frac{a}{W} \right)^2 - 0.9925 \left( \frac{a}{W} \right)^3 \right] 
\]

\[ + 20.609 \left( \frac{a}{W} \right)^4 - 9.9314 \left( \frac{a}{W} \right)^5 \]  
\[ + \frac{1}{W} \left( \frac{1 + \frac{a}{W}}{1 - \frac{a}{W}} \right)^2 \left[ 12.219 - 40.13 \left( \frac{a}{W} \right)^3 \right] \]

\[ - 2.9775 \left( \frac{a}{W} \right)^2 + 82.436 \left( \frac{a}{W} \right)^3 - 49.657 \left( \frac{a}{W} \right)^4 \]  
(15)
\[
\frac{\partial g}{\partial a} = \frac{\left\{ 1 + \frac{3\alpha(W-a)}{2a} \right\} [W-a + (W-a)\alpha]}{(W-a)^2 (1+\alpha)^2}
\]

- \[
\frac{\partial h}{\partial a} = \frac{1}{W} \frac{3\alpha(W-a)}{3a}
\]

Substitution of Equations (15) through (18) into Equation (14) gives the final form of \( T_{\text{applied}} \) used throughout this investigation, expressing the dependence of \( T_{\text{applied}} \) on \( J_1, E, \sigma_0, a/W, \) and \( K_M \) for the compact specimen.

RESULTS AND DISCUSSION

DESCRIPTION OF SPECIMEN INSTABILITY BEHAVIOR

During the loading of the specimens described in the text, three general types of load versus displacement behavior were demonstrated as shown in Figure 3. The results shown in Figure 3a were from a \( J_1 \)-R test performed in a rigid-test machine with the condition that \( T_{\text{material}} \) was much greater than \( T_{\text{applied}} \). The curve was constructed from digital data taken at 0.5 sec intervals. These data, regularly and closely spaced, reflect the stable response of the specimen to the constant crosshead rate used in all tests.
Figure 3 - Load Displacement Records for Three General Types of Tearing Behavior on HY-130 Steel
For the cases where \( T_{\text{applied}} \) approached \( T_{\text{material}} \) (but still less than \( T_{\text{material}} \)), the behavior shown in Figure 3b was observed. This behavior was characterized by repeated rapid steps of crack growth of relatively small magnitude, typically on the order of 0.1 mm to 0.5 mm, with larger steps being observed as \( T_{\text{applied}} \) more closely approached \( T_{\text{material}} \). The quick jumps of crack growth appeared as gaps in the load versus COD plot shown in Figure 3b. Each jump was accomplished in much less than the 0.5 sec data acquisition interval.

The specimens tested with \( T_{\text{applied}} > T_{\text{material}} \) produced the type of load versus displacement shown in Figure 3c. At or near maximum load, instability occurred producing an increment of crack extension large enough to either separate the specimen completely or leave only a small remaining ligament. This sudden unstable crack extension is shown in Figure 3c as the blank region to the right of the load displacement plot.

Figures 3a and 3b show that the load displacement records for stable specimens and specimens with limited instability are similar in shape in spite of the presence of the small instabilities. Likewise, the J-R curves obtained from stable and limited instability specimens are similar in shape as shown in Figure 4 for the aluminum alloy. This insensitivity of the \( J_{\text{R}} \)-curve to \( T_{\text{applied}} \) was seen for all materials tested.

Both macroscopic observation and scanning electron microscopic analysis of the fracture surface of all materials studied here showed that the fracture surfaces were fully ductile and very similar whether they resulted from the stable tearing fracture or the rapid instability. No evidence of cleavage was observed in any of the test samples either near the beginning of the unstable tearing or during the growth of the rapidly propagating crack.

VERIFICATION OF INSTABILITY THEORY

The results of the complete series of tests are plotted in Figures 5 and 6 with each point representing a single specimen. Solid points denote specimens which demonstrated instability to such a degree that the test was stopped. The half-filled data points represent specimens which demonstrated limited instability.
The open data points represent specimens that behaved in a stable fashion throughout the test as they would have been expected to behave in a standard stiff test machine. The only difference between Figures 5 and 6 is that the \( T_{\text{material}} \) plotted in Figure 5 were calculated from \( J_I - R \) curves with crack extension up to 1.5 mm while Figure 6 used \( T_{\text{material}} \) calculated from \( J_I - R \) curves with crack extension up to 5 mm.

Figure 6 - $T_{applied}$ versus $T_{material}$ with $T_{material}$ calculated from the $J_R$ curve slope taken to crack extensions of 5.0 millimeters.

Figure 6 - $T_{applied}$ versus $T_{material}$ with $T_{material}$ calculated from the $J_R$ curve slope taken to crack extensions of 5.0 millimeters.
Both Figures 5 and 6 demonstrate the validity of the Paris tearing instability criterion, that when $T_{\text{material}} < T_{\text{applied}}$ unstable fracture behavior will occur. The two Figures 5 and 6 also show that all the $T_{\text{material}}$ calculated from $J_{\text{I}}$-$R$ curves with crack extension to 5 mm are more accurate measures of the material tearing modulus. This effect was more pronounced on specimens with 20 percent side grooves than on specimens with no side grooves.

The effect of 20 percent side grooves on the materials tested was to produce a different $T_{\text{material}}$ from the non-grooved specimens and, correspondingly, to require a different $T_{\text{applied}}$ to produce unstable behavior. Figure 6 thus shows that the $T_{\text{material}}$ produced with 20 percent side grooved specimens is a real change in the effective material behavior due to the change in constraint. Further research is necessary to prove that the constraint produced by side grooved models is the constraint present in very thick parts.

**DISCUSSION OF LIMITED INSTABILITY**

In previous work on tearing instability using bend bar specimens, Paris and coworkers did not report observing the wide range of limited instability behavior observed in this work. They did report one case of "marginal behavior" and two other cases termed "stable" that showed instantaneous load drops of about 5 percent just beyond maximum load and possibly some other load drops later in the test - in specimens with $T_{\text{applied}} = 0.6 - 0.8 T_{\text{material}}$.

To explain the observed range of limited instability, two possibilities seemed to present themselves. First it was conjectured that $T_{\text{applied}}$ would fall rapidly with the increased crack length thus re-establishing stability. The second possibility was that $T_{\text{material}}$ varied considerably about the average value obtained by the single specimen $J_{\text{I}}$-$R$ curve methodology leaving the possibility that occasionally $T_{\text{applied}}$ would exceed $T_{\text{material}}$ giving a limited instability behavior.

To investigate these alternatives, a load-line COD plot was obtained from a non-side-grooved specimen of the HY-130 alloy without any unloadings. Because this alloy was identical to the alloy used by Joyce et al. a "key curve" analysis could be applied to develop a $J_{\text{I}}$-$R$ curve for this specimen directly from the load displacement curve of the specimen. The resulting $J_{\text{I}}$-$R$ curve is shown in Figure 7. The key curve analysis result has a $(J,\Delta a)$ pair for each point on the original load displacement curve and thus it allows a determination of the variability in both $T_{\text{material}}$ and $T_{\text{applied}}$ during a test.
Using the J and $a/W$ values defined by the $J_I-R$ curve of Figure 7 allows calculating $T_{\text{applied}}$, which would have been present if the test had been run in a compliant test machine with the given stiffness. These results are plotted in Figure 8 and show that $T_{\text{applied}}$ does vary during a typical test, but only slowly, decreasing as $a/W$ and $J_I$ increase. No sudden and pronounced reduction in $T_{\text{applied}}$ occurs as the result of a slight increase in crack length. If the situation occurred where $T_{\text{applied}}$ was slightly above $T_{\text{material}}$ at maximum load, a small step of crack extension could occur with stability being reestablished when $T_{\text{applied}}$ fell below $T_{\text{material}}$. This phenomenon then could not re-occur during this test because $T_{\text{applied}}$ would only fall with further increases in $a/W$ or $J_I$.

To test the second possibility, an iterated quadratic polynomial fit procedure was used to evaluate the local slopes of the $J_I-R$ curve presented in Figure 7, and hence the local $T_{\text{material}}$ defined by Equation (1). In the technique used here,
the polynomial was fit to all \( J-a \) pairs in a fixed region of \( a \) instead of to a set number of data points. This procedure, applied to the \( J-R \) curve of Figure 7, gives the results shown in Figure 9. Here, even when fitting the polynomial over a relatively large region of 0.25 mm of crack extension, a wide band of \( T_{\text{material}} \) values is found ranging from 5 to 35. Overplotted on this Figure are the \( T_{\text{applied}} \) curves from Figure 7 which tend to bound the \( T_{\text{material}} \) scatter band. The implication of this plot is that a mixture of stable and unstable behavior should exist for this material for \( T_{\text{applied}} \) values ranging from 5 to 35. This effect is not unexpected considering the inhomogeneity of structural materials, producing in turn, irregular crack growth. The wide variation of \( T_{\text{material}} \) observed here is, however, somewhat surprising.
CONCLUSIONS

The following conclusions can be drawn from the work described in this report.

- Tearing instability was assured in a compact specimen if the $T_{\text{applied}}$ produced by the compliant-test machine exceeded the $T_{\text{material}}$ defined by a stable single specimen unloading compliance $J_{1}$-R curve for a similar specimen for the range of aluminum, titanium and steel alloys tested here.

- The least squares slope of the $J_{1}$-R curve from 0.15 mm beyond the blunting line to a crack extension of 5 mm provided the most accurate measure of $T_{\text{material}}$, which, here, was as far as the stable $J_{1}$-R curves were measured.

- Macroscopic and scanning electron microscopic analysis showed that the stable and unstable specimen's fracture surfaces were very similar. No evidence
of cleavage was observed on fracture surfaces of the unstable specimens.

- In all materials tested, a region of limited instability behavior was observed for a range of $T_{\text{applied}}$ below the average $T_{\text{material}}$ value, with a gradual reduction in the severity of the unstable behavior as $T_{\text{applied}}$ was reduced.

- For $T_{\text{applied}}$ less than one tenth the average $T_{\text{material}}$, no unstable behavior was observed in these tests.

- The existence of the limited instability region was apparently due to variability of $T_{\text{material}}$ about the average value obtained from the single specimen $J_1$-$R$ curve and not to variations in $T_{\text{applied}}$ resulting from the crack extension.

- The $J_1$-$R$ curves for the materials tested were unaffected by the value of $T_{\text{applied}}$ experienced by the compact specimen.

- The added constraint present in the side grooved specimens produced a $T_{\text{material}}$ value distinctly different from that of non-side-grooved specimens of the same material. Tearing instability was then controlled by the applicable $T_{\text{material}}$ in these specimens.

ACKNOWLEDGMENT

The authors wish to acknowledge Dr. Hendrikus H. J. Vanderveldt of the Naval Sea System Command (NAVSEA 05R15), for supporting this research.

DTRNEROC SERIES THREE TYPES OF REPORTS

1. DTRNEROC REPORTS, A FORMAL SERIES, CONTAIN INFORMATION OF PERMANENT TECHNICAL VALUE. THEY CARRY A CONSECUTIVE NUMERICAL IDENTIFICATION REGARDLESS OF THEIR CLASSIFICATION OR THE ORIGINATING DEPARTMENT.

2. DEPARTMENTAL REPORTS, A SEMIFORMAL SERIES, CONTAIN INFORMATION OF A PRELIMINARY, TEMPORARY, OR EXEMPLARY NATURE OR OF LIMITED INTEREST OR SIGNIFICANCE. THEY CARRY A DEPARTMENTAL ALPHANUMERICAL IDENTIFICATION.

3. TECHNICAL MEMORANDA, AN INFORMAL SERIES, CONTAIN TECHNICAL DOCUMENTATION OF LIMITED USE AND INTEREST. THEY ARE PRIMARILY WORKING PAPERS INTENDED FOR INTERNAL USE. THEY CARRY AN IDENTIFYING NUMBER WHICH INDICATES THEIR TYPE AND THE NUMERICAL CODE OF THE ORIGINATING DEPARTMENT. ANY DISTRIBUTION OUTSIDE DTRNEROC MUST BE APPROVED BY THE HEAD OF THE ORIGINATING DEPARTMENT ON A CASE-BY-CASE BASIS.
