This report describes the results of the program of research carried out at Harvard University during the period October 1, 1973 through August 31, 1975 utilizing the PDP-10 and various resources on the ARPANET during that period.

The work was divided into three major areas: Automatic Programming Research and Tools for Software Production; Network Research; and, Operating System Research.

In the first area, our major results have been related to the enhancement of the ECL Programming System and the utilization of ECL as the basis for tools for software production. We have also experimented with a number of applications of ECL. Finally, a number of efforts have been concerned with various aspects of the question of program optimization.

During the period considerable use has been made of the ARPANET and a major programming system developed (PRL on the PDP-11/45) using a variety of tools and resources at several sites on the net.

Our efforts in the operating systems area have been rather modest with work concentrated primarily on revising system architectures for higher level languages.

Finally, the last few months have seen the beginning of design work on various components of a Program Manipulation System -- a system devised to integrate the various tools for program development, optimization, and maintenance.
SECTION II

INTRODUCTION

This report describes the results of the program of research carried out at Harvard University during the period October 1, 1973 through August 31, 1975 utilizing the PDP-10 and various resources on the ARPANET during that period.

The major area of effort has been that of developing tools for software production and investigating various aspects of automatic programming, particularly those having to do with program transformation and optimization. During the period the ECL system has been considerably enhanced and a number of new tools developed based on ECL. The system has also been used for production problems by at least one government agency.

A second area of interest has been in the use of the ARPANET and various resources available at several locations on the net. Perhaps the major accomplishment here was in tying together the resources available at several sites to provide the tools which we used to implement a major programming system -- a full PPL system for the PDP-11/45 computer.

The third area, that of operating systems research, has been concerned primarily with the question of machine architectures for higher level languages.

The sections following are devoted to the various research areas in which we have been working in the course of the contract period. In each we have attempted to provide a brief review of the problems with which we have been concerned, cite the accomplishments during the contract period, and provide reference to the bibliography where the reports, papers, and memoranda which contain the detailed results are listed. We would note that not all the research done during the contract period has been written up at this point in time; it is our hope that the work will continue and these results will be reported in the coming months.
SECTION III
AUTOMATIC PROGRAMMING AND TOOLS FOR SOFTWARE PRODUCTION

1. Construction of Tools

1.1 Development of the ECL System

General Improvements

As part of the general effort to improve the usability of ECL for other tasks in this contract, a number of new features were added during this contract period. The error reporting and trapping facility was greatly expanded. The number of specific errors was increased from fifty to one hundred and twenty-four. Error messages of varying degrees of verbosity keyed to each specific error were put into an error message file, expanding the text of the error messages from about 5000 characters to 23,000 characters, and, for each error, appropriate user accessible parameters are provided. By revealing the precise nature of error, these new diagnostics have greatly facilitated the rapid debugging of programs. In addition, they have been of great help to those just learning the ECL language.

Direct access I/O routines were added to the system allowing both random reading and writing of given bytes of a file. These routines were of great utility in allowing the error message file to be indexed and the specific message for a given error to be rapidly accessed. Also, by remembering the byte position at which routines are defined in files to be compiled, it has now become possible to segment the compilation of large packages efficiently. The direct access I/O features were also of great use in the implementation of paged procedures.

In addition, the CASE statement, more powerful selection semantics, parallel DECLS, and DCL mode validation were added, and these features documented in the new ECL manual [manual]. The ECL system assembly language code was modularized, and monitor dependent code isolated in one module in order to make the process of producing a pure TEX version of ECL in the future easier. A document describing the internal representation of ECL data types was produced to enable better maintenance, and to aid in implementing ECL on other machines [Conrad].

(a) The ECL Compiler

The ECL compiler has been tuned and improved during the contract period. Its new features are principally documented in [manual] and [opt-final], so
they will only be summarized here.

A number of compiler options have been added to increase the efficiency of compiled code in situations where critical simplifying assumptions about the program or its data are not otherwise available. For example, expression data (list structures that can be both manipulated and evaluated) are very common in ECL; however, they must normally remain uncompiled. A means has now been provided for specifying which expression data values will not be modified and may therefore be compiled. As another example, options now make possible the elimination of run-time checks curing access of data components and pointer referents, so that thoroughly debugged production programs are not burdened with redundant type checking.

A variety of declarations about free variables may be used, causing them to be "frozen" to given constant or shared values, or else providing information about their modes and dynamic behavior. Other declarations allow the programmer to control the accessibility of local and global names in his production package, creating precisely the environment he wants its user to see.

Two methods now exist by which procedure calls may be eliminated during compilation for efficiency. The call may be replaced by an expression derived from the procedure body by substituting actual expressions for formal parameters. Or a user-defined routine may be invoked during compilation to supply a replacement derived from the given actual arguments. These substitution features are useful for efficient integration of user-defined mode behavior functions with compiled code.

An optional optimization phase has recently been added to the compiler. The optimizer is designed to remove the sorts of redundancy that most commonly arise in ECL programs, while staying within the strict resource limits that usually govern use of the compiler. Although ECL's semantic flexibility complicates the data flow analysis problems of redundancy removal, the optimizer incorporates a simple data invalidation detection scheme that enables significant improvements without elaborate analysis.

The user interface to the compiler, the collection of programs that help the programmer develop the actual declarations that bind his routines into a production package, has been expanded and smoothed. The use of ECL's program editor in this package building process
has permitted many features that improve the human engineering of the interface to be added quickly and inexpensively. Using a new data module linking package, facilities have been added that permit compiling large programs in limited storage, either through separately compiled modules linked at loading time or by partitioning the program dynamically during compilation.

(b) User-Defined Data Types

The notion of user-defined data types was clarified and strengthened by the addition of several features. First, user-defined generation functions are now used consistently throughout the system in all instances of generation. Second, the user generation function is now used as a left hand conversion function by taking conversion to be a case of generation by example. Third, through the addition of user-defined apparent dope vectors, it is now possible to model sequences conveniently even though the actual implementation is done with objects (such as pointers) which have no dimensionality. The double colon operator which allows the specification of extended modes was changed to take keywords followed by an argument to allow flexibility in defining the behavior of these modes.

(c) Free Storage Management

The compactifying garbage collector and the "fastmode" or "freecount" storage allocation method made possible by the compactifying garbage collector became an integral part of the CCL system early in the contract period. It has made possible to handle such larger problems in a smaller period of time because the compactifying garbage collector enables "fragmentation" of storage to be corrected by consolidating discontinuous free storage regions into one large contiguous free area. Because of this ability to undo the damaging effects of "fragmentation", it has been possible to allocate pages of core storage without doing a garbage collection every time the storage free list becomes empty. This ability to allocate storage freely without damaging side effects has cut typical garbage collection time figures by a factor of from five to ten times [Connor 2].

The compactifying garbage collector has also allowed the addition of expandable stacks to the CCL
system. By allowing stack overflows to be trapped, and the stacks to be lengthened without losing the context of the program being run, the number of failures of programs to run because of stack overflow has been greatly reduced. This ability of programs to adjust their stacks as they run is particularly important because it is difficult in advance to determine the stack requirements of a particular program with varying sets of data.

A CEXPR (compiled procedure) paging mechanism was implemented in order to run larger programs in smaller core sizes. The basic method used was to prepare a small "little brother" for each CEXPR to be paged which determines whether its "big brother" is already in core or whether it must be read in from a disk file. The "little brother" contains the file name and byte position of its "big brother" in the paging file, and by use of the recently implemented direct access I/O routines, the "big brother" may be rapidly brought into core. Routines to flush other CEXP Rs not currently in use and to add the freed space to the system's free list without a garbage collection were also written. This paging mechanism has been successfully used to page the ECL editor, a very large program, which only needs small subsets of its many routines to be in core at any given time.

Despite initial promise, the attempt to implement the Bobrow-Legbreit control model revealed serious questions relating to its overall effect on the efficiency of the ECL system. Basically, the fact that new nomenclature (named variables) may be introduced in any ECL statement (as contrasted to LISP) points to the possibility of very high overhead if the Bobrow-Legbreit control model is directly implemented. The matter is treated in more detail in the reference, "Bobrow-Legbreit Control Model Reconsidered" [Conrad 31].

(d) SPECL Compiler

The SPECL (Systems Programming in ECL) project is intended to extend the use of ECL into areas normally reserved for so-called "implementation languages." It is a dialect of ECL that can be compiled to machine code that runs without the support of ECL's runtime facilities. It offers the opportunity to "contract" ECL for special applications, since SPECL-produced code can be augmented by just the runtime support (such as storage management or I/O) that is actually needed.
SPECL also offers access to the implementation of operators and the choice of underlying data representations at the hardware level. For example, suppose a programmer wants to implement doubly linked lists using a minimum of storage for the links. One trick is to give each element a single link field containing the bitwise exclusive-or of the access of its predecessor with that of its successor. Given pointers to any two successive elements it is then a simple matter to move forward or backward along the list.

SPECL is ideal for such an application since it permits the user to manage storage as he chooses and allows him to give machine code definitions for the necessary pointer operations. Access to the hardware level is isolated in code generation templates called Compiler Control Expressions (CCE). CCE’s tell the compiler how to implement a given operator, depending on the states of its operands. The descriptions of operand states serve as goals for the code generator as well as enabling code selection. The CCE’s contain enough information about register use and side effects that optimization of expressions containing user-specified operators need not be interrupted.

The compiler consists of three phases. The first labels the program tree with temporary storage requirements (for subtrees free of common subexpressions (CSE)) in a manner similar to the Sethi-Ullman method. Properties required for register allocation and assignment are attached to the tree: principally lists of variables potentially invalidated by assignments, variables whose addresses may be tracked by register allocation and a variety of minor properties necessary for code generation such as the number of locals declared in a block. An initial pruning of the possible code generation templates takes place as well.

The second phase operates on the tagged tree. It reorders computations to try to minimize the use of temporary storage. This step is necessary because the Sethi-Ullman algorithm does not allow for CSE’s. The method is heuristic and incomplete because the minimization problem is polynomial complete.

Register allocation and assignment are also performed during the second phase. Like minimization, the assignment problem is polynomial complete, and it will be handled heuristically.
The third phase is straightforward code generation.

Starting from a trial ordering of the expressions in each context (straight-line program section), the temporary-minimization procedure examines the variation in storage requirements over each context. The vicinities of peaks in the requirements are scanned for target positions that meet a simple numeric criterion based on the temporary usage and result size of the neighboring computations. Expressions are moved to these favorable positions in order to reduce overall storage use. Subtrees free of common sub-expressions move as units, subject to safety constraints. Most of the time used by this process is actually spent in recalculating the temporary requirements after a move.

Register allocation begins with live-dead analysis of variables and common sub-expressions and determines the minimum distance to next use for these items. This information suffices for optimal register allocation in straight line code, where branches are involved, however, a simple distance-to-next-use is not designated. Instead the allocator must compare distances with a heuristic. The best one would include information about relative probabilities of taking one branch over another. Lacking such information the choice may be made on a simple average, once the allocator decides which portion of the program the assignment process must determine which register for each such generation of a variable and must do it consistently at branches and join points of the program. It must also allow for occasional specific register assignments. Heuristics are needed to reduce the computation from a "try all assignments" approach. At present, we have only simple algorithms for this problem. As usual, the issue is the trade-off between the cost of the algorithm and the improvements in the code it makes.

In summary, then, SPECL will extend to the hardware level the methodology that will characterize code improvement at higher levels. Users will be permitted to become involved in the optimization of their programs, and they will not need to forsake good structure to achieve highly efficient performance.

(e) ECL Model

The original [Hedbrett 2] and updated definitions of the semantics of the ELI language were defined by giving an ELL-coded version of the interpreter. By the
fall of 1973, major revisions in the ECL system had rendered these out of date as well as incomplete. In the fall of 1973, work was started to develop a new model.

There are a number of motivations for this work. First, as was the case in the two theses cited above, this method of modelling has proved to be valuable both in development and documentation. Partial models have been coded on several occasions:

1. An updated model of portions of the interpreter was prepared for instructional purposes during fall, 1973.

2. The revised mode compiler was modelled [Conrad 2].

3. Modelling was used extensively in preparing the revised edition of the ECL programmer's manual [Manual].

4. The parser and parser window have recently been modelled.

In the first two instances, the main purpose was pedagogical. In the second instance, however, the model preceded the implementation of the revision of declaration semantics. Models have been an important guide in the current development of the PDP-11/45 implementation of ECL.

In spring, 1974 we started a long-term effort to develop a model for the entire ECL system; not just for the interpreter. The major goal of the model is to serve as a guide for implementations of ECL on other hardware systems. Accordingly, much of the design effort in the model has been the attempt to isolate as much as possible the machine-dependent aspects of the system (as has been done in the machine language code for the PDP-11 implementation of the system) while, at the same time, preserving maximum readability of the code. A major revision of the implementation strategy for the model took place in spring, 1975 to this end.

(f) Editor

The ECL 11st structure editor (EDIT) is an in-core editor which operates on the internal representation of uncompiled routines and unevaluated data (that is, upon forms) rather than on character strings, as do conventional editors.
We have extended the editor to include a file editing facility (FIXIT). FIXIT allows a package consisting of one or more source files to be defined. It loads the package by parsing each file to construct a single block containing all of the commands in each source file in the package. At the same time, it constructs properties for each definition (that is, assignment command) in the file which relate the identifier and form which is bound to it at top level to the corresponding source file. The source files are similarly related to the package so that several packages may be in core at the same time. This process is equivalent to loading, except that the properties allow the file to be reconstructed for output.

A routine, FIX, may be used at any time during debugging to apply EDIT to any routine loaded or to the form representing any file loaded by FIXIT. In the latter case, upon exit from the editor, FIX regines the definitions in the file in case new or revised definitions have been edited into the file form. Finally, the routine LUIPE, applied to a package name, will write out new versions of any files in the package which have been edited or any of whose definitions have been edited.

1.2 Programmable Theorem Prover

A number of issues relevant to developing a programmable theorem prover were investigated, including techniques for specifying the behavioral properties of some data structure in an implementation independent manner which allows verification of the correctness of concrete implementations of the data structure. These results are described in [Spitzen & Heidelberg].

1.3 Measurement Package

A number of additional mechanisms for measuring and probing ECL programs have been completed during the contract period. A procedure which takes a specification of a class of data objects, that is, a mode specification, and returns the amount of space on a PDP-10 an object from that class will require, according to the ECL data packing conventions, is one such mechanism. We have also extended the basic metering facility to permit a (non-redundant) measure to be made of an arbitrary collection of statements within a procedure. As part of this extension we can now produce a profile display of the metering results for greater readability.
1.4 Closure Mechanism

Procedure closure [Herbreit 1] is a program transformation that replaces a procedure by an equivalent one in which the values of some formal parameters and free variables have been fixed and corresponding simplifications have been made.

It is a kind of optimization that becomes increasingly relevant as we learn more about "prefabricated construction" techniques for building large systems from standard components by tailoring them to special needs. It is well-suited to program development by stepwise refinement, an implementation discipline that appears to enhance reliability and maintainability of programs.

Just before and during the early part of the contract period, we constructed a preliminary procedure closure mechanism. The intent was two-fold. It was to provide immediate benefit to ECL users as a practical code-improvement tool, and it was to give us insight into the nature of incremental optimization techniques. As a practical tool, that preliminary closure program was not a success. It proved awkward and very inefficient to use. It was not released to the general ECL user community, and in its stead several features were included in the compiler (the ability to "freeze" few variables to constant or shared values or to fix their scopes; facilities for in-line procedure expansion and invocation; redundant expression optimization, and so on).

On the other hand, our experience with closure profoundly shaped our views of how the programming process can be automated. It has led us, in fact, to try to solve the problem by generalizing it. Some of the key difficulties were:

(1) Need for precise user guidance. As a semi-automatic tool, closure requires that simplifying assumptions be supplied from which to derive specializations. The restriction to assertions about the free variables and formal parameters of an entire procedure was too severe. In practice, one needs to guide the simplifier to particular program regions selected by pattern, by identifier scope, by the data types of constructs to be affected, and the like.

We have begun to satisfy this need for precise guidance in program transformation by the development of a Rewrite Mechanism [Jakes] and by recent improvements in the ECL program editor [Manual]. The Rewrite Mechanism is a pattern-directed transformation
facility that permits replacement rules to be associated with the lexical scopes for variables. Rewriting rules relax the restrictions that procedure closure imposes by generalizing the notion of procedure definition. They can encode simplifying assumptions that they will (in a future system) themselves be the object of simplifications. The ECL rewriter is also pattern-directed, and it is now fully programmable, so that user-defined transformation routines can be applied to pattern-selected program regions.

(2) Need for program investigation aids. Even though a program improvement tool may require user help to achieve significant results, it should not be assumed that the user is intimately familiar with the program being processed. In the important case that a library routine is being tailored to special requirements, quite the opposite may be true. Neither, facilities that help the user become familiar with a program package should be provided, so that he can be sure his simplifying assumptions about its behavior are valid.

As a step toward such a facility, we have implemented a program that studies free variable reference patterns in an ECL package (Wensens). The information is displayed in a skeletal rendering of the program that also exhibits its recursive calling structure.

(3) Need for a data base supporting stepwise development. Large-scale software seems to be most reliable and least expensive when it is produced in careful increments, each of which specializes some aspect of an abstract algorithm into more concrete terms. Optimization should be involved at each step, or vital information may be lost in the clutter of low level detail. If the program must be reanalyzed each time an optimizer is invoked, the cost is likely to be extremely high and disciplined implementation may disintegrate. Rather, the optimizer should be able to make incremental improvements without full reanalysis by maintaining a data base of information about the program acquired through user assertion, measurement, and analysis. Since implementation often proceeds by trial and error, the data base should include a history of the development and the user should be able to undo decisions, revise them, and then repeat unaffected portions of the implementation.

(4) Need for a common store of general-purpose optimization techniques. The closure experiment was an attempt to achieve a limited class of code improvements with limited resources. It demonstrated the difficulty
of trying to factor global program analysis into a set of independent tools without gross duplication of effort. Instead, automatic programming tools should be integrated around a single, general-purpose semantic analyzer, so that all can share a common representation, a common data base, and a store of analytical and manipulative expertise.

To answer these needs, a new program manipulation system is under development. Its basis will be a full Symbolic Evaluator for ECL programs. This analyzer will maintain a Program Data Base to support incremental optimization and to preserve the refinement history of the user's program as its implementation progresses.

These facilities will not be cheap. Deep analysis of practical programs is costly to obtain and to maintain. They can be viewed, however, as an investment whose dividends will be the relative simplicity of coding special-purpose tools, like closure, better code generators for ECL and SPECL, and a data representation optimizer, to the kernel system.

2. Applications

2.1 Parallel Processing

The SYNER system has been developed during the contract period. The SYNER system permits a high level specification of problems in concurrent control in the SAL specification language, which has been designed and implemented. The SYNER synthesizer then generates ECL runnable code which enables concurrent processes to communicate with each other in the manner specified. A technique has now been developed whereby the correctness of the specification can be verified.

Currently code generated to effect the synchronization is written for use with the ECL control extension facility (Frenner's CI), and the adoption for a code generator for Hoare's monitors (CAC, Oct. 1974) is written but not implemented. In addition a code generator forijkstra's P and V semaphore operations is being developed. Initial results for this code generator are very encouraging; in many cases generated code is equivalent to that which would be hand-written.

The results of this work are described in Griffiths 23.

2.2 and 2.3 Data Type Optimization
The extension to ECL to accommodate sets, tuples, stacks, and queues has been done. The extension includes new notational facilities (in the case of sets) for more natural specification of operations. We have used the more behavior facility to specify the intended behavior of objects from the classes of data objects. In the case of sets we have implemented several different underlying machine representations for objects. In each case we have defined the necessary primitive operations. We have not yet solved the problem, however, of (mechanically) choosing efficient representations for objects, taking into consideration the access patterns and other primitive operations. (e.g. insertions, deletions) on the objects. This is a more difficult problem than anticipated though it still promises high pay-off.

2.4 Compound Objects and Operations

We have developed the foundations for exploring the customizing of general-purpose algorithms for the domain of matrices. We have implemented a package of basic general-purpose operations and defined a collection of representations for matrices, with particular concern for sparse matrices. The package will use information about algebraic properties (in particular algebraic identities) of the matrices and do some optimization of the operations taking into account these properties. It will also define for the user some non-basic operations, like transitive closure, permitted by the properties. The package includes a number of notational extensions to facilitate the user's writing of iterations (e.g. \( i[I,j] \) to specify the selection of the \( i \)th row) and partitions of a matrix. Several underlying representations have been implemented for sparse matrices and we are just now at the stage of considering the interaction among representations and optimizations over them.

2.5 Resource Management

A linkage loading and dumping facility (LINK) has been added to the system which is more general than those in previous systems. While the earlier version of the system allowed a package to be compiled in several modules, which were then loaded together for execution, linkage between different modules was effected by invocation of the interpreter. In order to eliminate this interpretation at run-time, a reference to a routine external to the package being compiled may be replaced at load-time by a pointer to an external (to that particular compilation) routine, affording exactly as tight binding as would have been the case if the two routines had been compiled together.
External references are defined to the compiler by a compiler driver list, external pairs, which contains the identifiers and names of external routines and/or data. Following compilation, the linkage dumper traces all compiled routines in order to locate all external references in the compiled code. The results of compilation are then dumped, together with tables which allow the linkage loader to link separately-compiled modules to each other and, where required, to routines and data which are already loaded.

The link dumper may, in fact, be used to separate a mass of loaded routines and data into separate files, together with information required for linkage loading, independent of use of the compiler. Due to the manner in which routines and data are represented in core, such separation can be effected for any data objects which are bound to identifiers at top level or on the name stack. Thus, for instance, if a data table consisted of, among other things, a sequence of routines, different routines might be dumped into different files with the resulting files being reloadable. A forthcoming version of the package will extend this behavior to arbitrary data objects which are not necessarily related to a compilation.

3. Related Research Efforts

3.1 Property Extraction

Property extraction is a generic name for a set of techniques for efficiently extracting from some set of programs a collection of properties which enable program transformation and optimization. During the contract period a prototype system to explore the technique was developed and reported in [Scherlis]. Work is continuing.
SECTION IV
DATA STORAGE AND TRANSFER

4.1 Use of the DATACOMPUTER

Experience with the use of the DFTP (Datacomputer File Transfer Program) developed by CCA has shown that a more automatic method of file archiving and retrieval, while feasible, is probably not worth the development effort required. We have also investigated the feasibility of referencing files stored on the Datacomputer from ECL programs. While this facility is easily implementable in ECL, given recent improvements in the input-output and error-handling facilities, the result would be to overburden the currently limited number of network ports on CCA-TELEX at very little gain to our own operation. Therefore, no actual development work has been undertaken in this area.

4.2 Datacomputer and Datalanguage Development

Except for several consultations with CCA, no work has been done in this area. Our current attitude with regard to conversion of data stored on the Datacomputer is that, in the absence of economic justification in the case of any particular application, the actual computations required should take place at other sites. Such conversions may be done with significantly less overhead by a facility which knows both the source and target data types than is possible at a centralized facility which must deal with a far larger set of data types and formats.

4.3 Graphics Studies

The development of a sophisticated graphics system was undertaken. The objectives of this effort were to experiment with the viability of graphics processors with graphics instructions sets capable of directly interpreting a high level data structure to produce graphical output. This approach is to be contrasted with the classical real-time compilation of a data structure into some low-level object format suitable for execution by a graphics controller.

A system that would support research in micro-programmed graphics instruction sets was designed and partially implemented. It consisted of a graphics processor (DPF-11/40) linked to a local processor (PDP-11/10) and a PDP-10 host machine. The DPF-11/40 was extensively modified to be a dynamically micro-programmable graphics processor.
He added a writeable control store, hardware micro-program development aids, and (partially implemented) registers accessible at the micro-program level which drive display hardware. A special interface allows the two PDP-11s to share the same address space. A high-speed parallel channel was built to permit fast access to the PDP-10.

A large amount of software development stands in the way of the relatively small amount of hardware work necessary to complete the system. The investigation was conducted by a one-half time research assistant until his time was preempted by his thesis research. The project is currently inactive, pending the availability of students with appropriate interests and background.
SECTION V

SYSTEM ARCHITECTURE FOR HIGH-LEVEL LANGUAGE

The problem of implementing complex computations as embodied by, say, high-level languages has customarily been attacked in relation to classical machine architectures. These architectures have been and persist in being rather arbitrary in that they do not, in any formalized way, reflect the nature of the computations that are anticipated.

The problem of constructing machine architectures that are appropriate to specific computational problems, (in particular ELI programs), is currently being investigated. The objective of this effort is to develop formal methods by which one may take a representation of a desired computation and transform it into an implementation that capitalizes on the specific nature of the computation.

The approach being pursued represents the computation, (e.g. the ELI interpreter), within a formalism that introduces no overhead and exhibits all potential concurrency. This representation, resembling an infinite Petri net, is then subjected to a series of transformations that reduce it to a finite form, and in particular, a form with properties making it readily implementable by some set of hardware primitives. Each transformation is chosen by the system designer and has a quantitative effect on performance that may be readily perceived.

This research is aimed at developing a system that derives increased representational and execution efficiency from the fact that ELI is the lowest level of machine language and determining the facilities and characteristics such a system should possess as a whole.
