Artificial intelligence  Natural Language Processing
Production systems     Data fusion

Narrative data processing and database updating are examined from the viewpoint of interaction with other processes in an automated data fusion system. Methods are outlined for using production rules (if-then rules) in the processing of the narrative data and for integrating such a process with other rule-based data-fusion processes. Database updating methods which employ a "history file" are processed. An experimental rule-based program compares event reports for redundancies, combines reports of the same event and retires old data into a history file in a form useful for event reconstruction and evaluation. A number of related areas of investigation are suggested for future research.

1. INTRODUCTION

This report discusses two phases of investigations into the integration of data fusion techniques. One is the continuing investigations of the computer understanding of narrative data and the use of the processed data in an automated data fusion system. The discussion here concerns the feasibility of using production rules (if-then rules) in the processing of the narrative and the integrating of such a process with other rule-based data-fusion processes. The narrative data of particular interest are the narrative comments in RAINFORM messages, ASW (antisubmarine warfare) messages which can include natural language comments that amplify the formatted information. The other phase of investigations concerns the updating of the database of the data fusion system. In connection with these investigations, the concept of a "history file" is introduced.

1.1 Data Fusion System Model

This effort is part of a larger effort to develop automated data fusion techniques [1]. Under the larger effort, a conceptual model of an automated data fusion system (Figure 1-1) has evolved. The goal has been to identify the voids in the technologies required to support the various functions of the system and to devise techniques to fill these voids. Complementary interaction of individual fusion techniques has been the underlying design philosophy in the concept formulation of this integrated system.

The only component of the "final fusion" box of Figure 1-1 in experiments and investigations to date has been a "production system," a system which implements a number of if-then rules called "productions." (Systems of three different structures have been employed in the experiments.) In addition to various control and support mechanisms, a production system must have a database. However, this database is shown separately in Figure 1-1 because ideally it would be shared with other processes. (The components of the database are discussed in Section 1.2.) In particular, it is important that the natural language processing (NLP) functions and the database updating functions have access to the database, a need which is addressed in this report. Furthermore, it is envisioned at this point that the updating functions and some of the NLP functions (represented by the "NLP Control" box in Figure 1-1) should be performed within the same production system. Sections 3 and 4 discuss rule-based approaches to NLP and database updating, after a summary of present experimental NLP programs in Section 2.
One technique developed under the larger effort is PTAPS, a Platform-Track Association Production Subsystem [2], [3], [4]. PTAPS is a method of extending the capabilities of a production system applied to tactical data fusion, to enable the system to perform the higher order logical reasoning required to solve certain kinds of platform identification problems. PTAPS would exist as a subsection of the *Final Fusion* box of Figure 1-1.
1.2 Database

The database subsystem of the system shown in Figure 1-1 contains a "primary memory," a "secondary memory" and a "history file" and these are explained below. Additional domain knowledge could be contained in the NLP subsystems. Private or temporary memories also are needed at most levels of manipulation and computation.

**Primary Memory:** Primary memory is the storage of (a) all domain knowledge data needed by the production system, (b) input message data and (c) data created by the firing of production rules -- with the exception of infrequently needed domain knowledge and old, perishable data. This memory could be partitioned into multiple memories, each activated and deactivated as necessary.

**Secondary Memory:** Secondary memory is the storage of domain knowledge infrequently needed by NLP and fusion processes.

**History File:** History file is the storage of event data, as "understood" by the NLP subsystems and the final fusion subsystem.

A "history file" is needed to record events of tactical exercises and engagements in a manner useful in event reconstruction and evaluation. Good records are needed for assessment of fleet performance and readiness. Also, in determining the most probable enemy reaction to an operation under consideration, historical records of the enemy's strategies and reactions during earlier operations of a similar kind can be a valuable asset. The records can also be useful in estimating the probable outcome and losses of an operation and in deriving enemy capabilities.

All of the available data needed for good records will at some time be stored in the database of the tactical data fusion system envisioned for the future and now modelled on a small scale. Sophisticated knowledge-based system techniques are needed for selecting pertinent data, reconstructing events from them, and organizing the fused event records file for querying by other systems and humans. Here we consider the history file only from the aspect of entering into it partially fused event records from the data fusion system, which allows the data to be gracefully forgotten by the primary memory, but retrievable from the history file.
2. NLP OF PARTLY FORMATTED MESSAGES

2.1 NLP Investigations

Efforts to develop NLP techniques for processing Navy tactical narrative began with the study of a large collection of messages to determine the contextual problems, vocabulary statistics and syntactic characteristics of the natural language data. Reference [5] addresses these problems in terms of relevant NLP techniques, describing the techniques and giving sample "knowledge representations" of some of the narrative data.

An unclassified set of models of RAINFORM messages was constructed for NLP experiments. While the formats used in these messages were invented for this effort and the names, locations and times given in the actual messages were changed, the message models still exhibit the semantic and syntactic problems to be encountered by a message-understanding system. Several examples are given below. The first "word" of each line is the line name, or "identifier," and dictates the contents of the succeeding slots of the line. For example, the first line of each message is defined by

PRELIM/sender/month and day/msg #/msg type

where the message number starts at "1" each day for each sender. The various lines and the order in which they can occur in the message models are described in Reference [6].

PRELIM/TU 175.7/MAR 25/46/MISSION SYNOPSIS
Although not evident in these sample messages, most of the narrative information concerns routine operations or observations of minor importance. Furthermore, in the application of immediate concern here, the narrative information is not useful unless pertinent to the conditions of the production rules in the production system performing tactical data fusion. Processing all of the narrative lines can therefore be wasteful of computer resources. For this reason, the approach taken in this work has been to search the narrative lines for an indication of any of a number of relevant situations and, if there is an indication, to perform a follow-up analysis, aborting it whenever a determination is made that the situation discussed is not the one suspected.

An experimental NLP program based on this top-down approach, using keyword patterns as indicators of situations, was written in Interlisp and tested on a number of unclassified message models [6]. Narrative comments concerning certain overflight and geometry-reference situations pertinent to production system rules were successfully understood and were restructured into assertional statements read and used by STAMMER2 [7], a production system performing tactical situation assessment (TSA). The initial experimental results helped to demonstrate the feasibility of the technical approach. Since then, a new NLP program has been written [8] which has improved syntactic analysis portions and which can be extended easily to a large number of situations. The interface of these NLP programs with STAMMER2 is described in the next section.
2.2 Original Interfacing of NLP and STAMMER2

Before actual NLP begins, preprocessing functions convert the incoming message into a form suitable for further manipulation in Interlisp and interpret the information in the formatted lines. The sentences in the narrative parts are processed in specialized ways, and the "actor" or "object" is determined, where necessary, from formatted data or earlier narrative. The two kinds of situations recognized by the first NLP programs are an overflight of a friendly ship by a hostile aircraft and a referencing of the position of one ship with respect to another (e.g., "came within" and "in vicinity of"). In the sense that the analysis is aimed at identifying certain properties of events, the process is similar to filling slots in a frame [9] or script [10], and also bears resemblance to the "event template" technique [11] designed for processing the narrative portions of Air Force intelligence messages.

The production system chosen for initial experiments was STAMMER2, a development of NOSC [7]. The original STAMMER [12], A System for Tactical Situation Assessment of Multisource Messages, Even Radar, was developed to serve as a demonstration of the applicability of rule-based inference techniques to the problem of tactical situation assessment (TSA) and STAMMER2 is an improved version.

STAMMER2 accepts data in the form of two-node assertions, generally written as a triple (<relation> <node-a> <node-b>) and read "<node-b> is a <relation> of <node-a>" or "the <relation> of <node-a> is <node-b>." The assertion (SOURCE MESSAGE92 ENTERPRISE), for example, expresses the fact that the source of message 92 was the Enterprise. The relation "is" in STAMMER2 indicates that <node-b> "is a" <node-a>, and is expressed in assertional statement form as (<node-b> <node-a>). STAMMER2 also accepts and uses assertions containing more than two nodes, but these are currently used only internally and not for input data.

Computational functions called "oracles" provide an escape to LISP code for certain relations that are either difficult or tedious to represent as rules, and for relations that should only be calculated on demand (17), Section 2.5 of Volume 1). The oracles available in STAMMER2 are listed in Volume 2 of Reference [7]. Oracles can be used like assertions in the conditions of STAMMER2 rules. Among the simplest two-argument oracles that return either T or nil are SAME-AS, ROUGHLY-THE-SAME-AS, GREATER-THAN and LESS-THAN. Oracles that return an answer ("lastarg" oracles, where the last "argument" is returned as an answer) include SPEED, RANGE and COURSE.
Figure 2-1 illustrates the major functions and components of STAMMER2 and of the NLP system as structured in the original program. The relationships among the various components of STAMMER2 are too complex to describe here but are indicated with asterisks; the data flow is illustrated with arrows. The narrative processing generates temporary data kept as property lists and variable bindings to word lists, numbers, etc., and STAMMER2 generates similar temporary data; consider these data to be distributed among the support boxes.

Although in practice all pertinent formatted data would be made available to STAMMER2, in this experimental version only those data from messages containing pertinent narrative are made available, via a message file. The message file is filled with messages of the form (MESSAGE <assertion 1> <assertion 2> ... <assertion n>).
Figure 2-1: Original NLP system and its interaction with STAMMER2.
3. RULE-BASED NLP

3.1 Introduction

Much of the reasoning involved in processing the narrative lines can be expressed in the form of production rules. These can be, for example, pattern-action rules used in parsing, rules that use the formatted lines in understanding the narrative (e.g., if there is a ship S reported in the narrative and there is no formatted line consistent with S, then S is not hostile), and rules that infer activities (e.g., if the primary function of a hostile ship is reconnaissance and it remains in the area of a US ship, then its activity is probably reconnaissance). An examination of the following message is useful in demonstrating the difficulty of formulating good rules.

RELATIVELY SMALL AREA AND PINGED SONAR PRIOR TO SURFACING.
LOST CONTACT 192125Z0. DEPARTED AREA.
STOP

Consider the last sentence of the narrative -- "DEPARTED
AREA." The reader knows that the subject is the "crew" and that the area is not specifically the "45NM AREA" but some general area related to "ONSTA" (on-station) and the "RELATIVELY SMALL AREA." Depending on the extent of the TSA rules, the system may need to be capable of rejecting the interpretation "the sub departed the relatively small area." A useful rule for this sentence would be one that takes the subject of the previous sentence, "LOST CONTACT 19125Z0." If this rule had been applied to that previous sentence, though, the subject for both sentences would be "sub" instead of "crew." A very good rule for this message, but not necessarily for others, is one that suggests the subject is "crew" if none is given. Other possible subjects, taken from earlier narrative, are: ONSTA AIRCRAFT, TOI, ASW SHIP and AGI KRYM. The system may previously have concluded that the "TOI" (target of interest) is the sub and not the AGI, partly from the fact that no formatted line was given for the AGI. Other problems occur with other sentences. For example, the segment "PINGED SONAR PRIOR TO SURFACING" tells the reader that the visual sighting resulted from a surfacing of the sub, not just a sighting of a periscope or snorkel. The system should easily eliminate other platforms as the thing "SURFACING" by noting that the sub is the only one capable of surfacing.

One reasonable approach to dividing these kinds of ambiguity problems between an initial NLP unit and a production system which also deals with the larger picture of TSA is to have the initial NLP unit present to the production system, with each ambiguous conceptual structure, a list of candidate actions, actors, objects or whatever, and their respective initial probabilities or weights. The production system would use the formatted data and additional knowledge (as derived from prior sentences and messages) about the situation to select the most probable. The certainty of the decision would have to be high unless data certainty factors are carried in the TSA system.

A complete understanding of the information in message narrative requires a considerable amount of causal inferencing. For example, the narrative in the last message model in Section 2.1 includes the lines:

CREW SIGHTED SUB ON THE SURFACE TRACKING 150T/12KTS AND DROPPED BUOY PATTERN AROUND SAME. SUB PROMPTLY SUBMERGED.

The reader immediately realizes that the sighting of the sub was a contributing cause of the dropping of a buoy pattern and
that the crew's presence was a contributing cause of the sub's submerging and also that tactical and self-preservation considerations caused the sub to have as one of its goals the hiding of its location. It may be a very long time before a rule-based TSA system is capable of accepting and using conceptual structures having causal links of this kind, but an eventual operational system must have such a capability.

A major advantage of combining some of the NLP operations with TSA operations in a production system is that the NLP processes can share the production system's extensive database. For example, the properties (class, type, category, etc.) and most recent tracks of the platforms are needed by both the NLP and the TSA reasoning operations. The organization of a production system shared in this manner is discussed further in the next two sections.

3.2 Integration of NLP with STAMMER2

Figure 3-1 shows the major parts of a system which uses STAMMER2 to perform some of the NLP reasoning in addition to TSA reasoning. The files containing preprocessing functions, first-stage NLP functions and NLP oracles (LISP functions which would perform pattern matching and various other manipulations) would be loaded along with STAMMER2 files. Care would be needed initially to avoid giving a NLP function or variable the same name as a STAMMER2 function or variable. The rule-set would contain both NLP rules and TSA rules. The "message receipt" mechanism of STAMMER2 would require a small modification to permit the receipt of messages from multiple sources during a single run.

Temporary data used in the processing of the partly formatted messages would be stored as property lists and as variable bindings to word lists, numbers, etc. (The equivalent temporary data exist for TSA operations in STAMMER2 -- consider the data to be represented in the support boxes.) The temporary data would be used or operated on by the oracles. Permanent and semi-permanent data would be stored as assertions in STAMMER2's primary database, both for NLP and TSA. When an oracle is called (as an evaluation of a rule condition), its arguments generally are retrieved from this primary database. An example of an oracle which would be needed is one that compares the capabilities of candidate platforms against a reported activity when a sentence about the activity does not fully identify the platform. Another example of a needed oracle is one that performs consistency checks with position data.
2ND-STAGE NLP AND TSA IN STAMMER2

**Figure 3-1:** Natural language processing shared by STAMMER2. The boxes represent components of a candidate experimental configuration.
The current version of STAMMER2 does not permit rules to be selectively activated or deactivated. If a partitioning of rules is needed for efficient operation, a modification enabling this should be attempted. Rule partitioning is a capability of Rosie, an alternative production system discussed in the next section.

3.3 Integration of NLP with Rosie

Rosie (A Rule-Oriented System for Implementing Expertise) is a development of The Rand Corporation. The most noticeable difference between Rosie and STAMMER2 systems is in the rule syntax -- Rosie rules are written in an English-like syntax while STAMMER rules are coded in statements involving assertions or oracles.

In an experimental configuration of a system using Rosie, a first-stage Interlisp program would restructure the message lines, extract pertinent formatted data, parse the narrative lines and then would create a temporary file containing data to be operated on in Rosie. As in the proposed system involving STAMMER2, the temporary data would include, for ambiguous conceptual structures, the candidate actions, actors, objects, etc., and their respective weights. Under a separate job, a ruleset in Rosie would read the file and store the data in Rosie syntax in the database, and NLP rulesets also activated for the purpose would perform further analyses. (Alternatively, some of the parsing could be performed with NLP rulesets employing Rosie's pattern-matching features.) Most of the manipulations performed via oracles in STAMMER2 would be performed in Rosie via "system rulesets," rulesets that access Lisp functions. As with the STAMMER2 version and its database of assertions, TSA and second-stage NLP activities would share a large database. Rosie syntax permits data to be stored in statements equivalent to STAMMER2 assertions and also in many other more complex syntax structures.

3.4 NLP in a Dedicated Production System

Little has been said, to this point, about the structure of the initial NLP unit in the experimental system configurations proposed in Sections 3.2 and 3.3. A rule-based approach would use packets of pattern-action rules similar to those constituting the grammar of Marcus' model of a parser [13]. Implementation of grammar rules would be awkward in STAMMER2 and Rosie and would best be accomplished in a system designed for and dedicated to NLP. Implementation of the "second-stage" NLP rules in this same system would be desirable, although access to the database of the
TSA system would be required. Implementation of all of the NLP rules in a single production system would permit expectation-based parsing using knowledge derived from the TSA database.

3.5 Conclusions

In addition to parsing, the computer understanding of tactical narrative from partly formatted messages will require reasoning processes which can establish cause and effect relationships between events, infer other events and activities, resolve ambiguities, etc. The implementation of frames and frame systems for situations of interest, including routine sequences of events, will permit the representation of some of the causal relationships, but a method has not yet been proposed to use these conceptual structures in a knowledge-based system performing TSA (tactical situation assessment). An adequate method of interpreting narrative data will require not only the facts from the message's formatted lines but also knowledge from an extensive database which includes properties, track histories and activities of platforms. The need for NLP functions to access the continually updated TSA database was a major consideration in the formulation of the system approaches outlined in this report.

Two systems proposed, one employing STAMMER2 and the other Rosie, would use linguistic knowledge in an initial NLP unit and domain knowledge in a production system already performing TSA. A better, but more difficult, approach would be to design a rule-based system suitable for both aspects -- syntactic and semantic/environmental -- of this special kind of NLP and to give the system access to the database maintained by a separate TSA system. A greater degree of expectation-based parsing can be achieved with this approach, since interaction is possible between the semantic/environmental processes and the syntactic processes.

In any near-term system, relatively few of the situations discussed in message narrative will be pertinent to the TSA rules implemented and, therefore, the number of situations that must be understood will be small. However, when the actor and/or object is not specified in a sentence concerning one of these situations, a complete understanding of that situation will sometimes require an understanding of a situation discussed in an earlier sentence. A system having a very high success rate would, therefore, require many times the number of frames of a system having a moderate success rate.
NOSC is involved in another program devised to develop a system for processing narrative tactical data. The system would query the message preparer to remove ambiguities before transmission. Although the system would not have access to the much greater collection of data at the data fusion site, it could remove many of the syntactic ambiguities concerning the action, actor and object, a problem discussed in Section 3.1. Data preprocessed by such a system would require significantly less processing by the data fusion system.

Studies of optimal system configurations will continue in conjunction with the work to extend the original NLP program.
4. DATABASE UPDATING

4.1 Introduction

This section discusses techniques for updating the database of the automated data fusion system described in Section 1.

4.2 Events

The term "event" will be used in a very general sense here, to refer to an activity, a determination of platform location, a signal intercept, or even a static situation. Some typical kinds of events are: refueling, search, sonobuoy laying, communication, radar detection, harassment, attack, damage assessment, and low fuel supply.

An event which is reported to have occurred or maybe to have occurred will be called an "actual" event. Those events which are only speculated or suspected to have occurred will have low confidence values associated with them. (There may be several different interpretations of an event, each with a confidence value, and these cases must be handled a special way in the database.)

A "virtual" event will refer to an event which has not occurred (at the time of the report) and may be a planned or requested activity, a prediction of enemy activity, etc.

Some virtual and actual events may be "supporting" events, e.g., the launching of aircraft may be in support of an attack of an enemy ship.

Examples of Narrative Reports of Virtual Events

Planned/Requested/Ordered Events

- Will strike Kobchik with airborne aircraft when hostilities commence.
- Have requested E-2 coverage 1800-2000T to ensure continuous locating data on Vietnamese units.
- Intend make sweep of area with active sonar.
Peterson directed to prosecute Victor with LANPS and HS.

Pegasus currently enroute to attack Zhevny with gun. [The event concerning Pegasus being enroute is a supporting active event.]

Intend use eight strike aircraft from 0130T launch from SSSC in effort to locate two Kyndas. [If the 0130T launch has not yet occurred, it becomes a supporting virtual event to the virtual event(s) of locating the Kyndas.]

Predicted/Expected Events

- Increased reconnaissance expected within 48 hours.
- Increased air surveillance activity can be expected first light 7 Nov.
- Anticipate approximately 60 aircraft are available for impending operations.

4.3 Event Records

The following is an outline of a procedure for creating and retiring event records.

a. For each event, whether an actual or virtual event, enter into the primary memory an event record of the appropriate kind for that event and link that record, as needed, with associated event records. (A "link" is formed by entering an assertion indicating the relationship and having as nodes or name-elements the two event-record labels.)

b. If another report of the same actual event occurs, update or correct the event record, as needed, and record the additional information source in that record. If the new report is not sufficiently correlated with a similar report, enter the new report into the primary memory and link the two with an assertion indicating the potential redundancy relationship.

c. If the event is an actual event, and a sufficiently similar virtual-event report is in the primary memory, then
(1) Link the actual-event record to the virtual-event record with an assertion which relates their respective labels and indicates the predictive relationship.

(2) If the virtual event is related to other events, e.g., a supporting relationship, connect the respective linking assertions instead to the actual event.

(3) Store the virtual-event record in the history file;

(4) Delete the virtual-event record from the primary memory.

d. If an active-event record has remained in the primary memory over a certain period of time (e.g., 1-2 days, depending on the event type), then

(1) Store the event record in the history file;

(2) In the primary memory, replace the event record with an event summary -- a minimum sized structure serving to indicate the nature of the event so its record can be retrieved from the history file if needed.

After a longer period of time,

(3) Delete the event summary from the primary memory.

e. If a virtual-event record has remained in the primary memory well past its expected time of occurrence, then

(1) Store the event record in the history file;

(2) Delete the event summary from the primary memory (optionally leaving for a time an assertion indicating its existence).
4.4 Experimental Results

Experiments were performed in Rosie for three kinds of events: aircraft launches, sightings and attacks. Rulesets were written for

- Comparing actual-event reports with virtual-event reports and other actual-event reports
- Combining actual-event reports found to be sufficiently similar
- Retiring event reports into a history file.

These three functions are implemented, respectively, in the files "W-Update," "W-combine" and "W-Copy," listed in the appendix. The appendix begins with a typescript of an example involving these files and three others listed in the appendix—WMsg1, WMsg2 and WMsg3, which enter messages in Rosie syntax, each message describing several events. The second message describes virtual events which predict the actual events described in the third message. The third message was entered another time (as Message #4) to see if reports of the same event would be correctly correlated. The messages represent the result of the initial processing of formatted and/or narrative data, discussed in earlier sections. The acts of starting the updating process (steps 13, 35 and 39 in the typescript) and the copying process (steps 45 and 46) are shown as human actions in the typescript, but can be performed easily by a "master" ruleset that decides when an action is appropriate.

The messages used in the example assume that aircraft launches support sightings and attacks. We also could have assumed that sightings support attacks. This decision usually would be made at an earlier stage, though one occurring during the message-understanding process. One of the useful functions of support relationships between events is that of providing lower bounds to times when event times are not given. A major future use is in the initial processing of the raw message; e.g., the NLP subsystems (see Figure 1-1) will have access to the data and may use them in cause and effect reasoning and in creating expectations.

The criteria used for comparing event times and other attributes and for assigning scores to the matching of attributes were somewhat arbitrary and highly oversimplified and should be
specified much more carefully in a real application. For example, when assigning a score for equivalence between two attributes, the case where they are identically equal should receive a higher score. Also, a variety of other factors would need to be considered, such as weapons, sensors and ranges. The prediction-match and redundancy-match scores were printed out only for evaluation of the program and such information would probably be optional for an operator. Other experiments, not shown, involved changing the attributes of events to varying degrees and observing the resulting scores.

In the initial experiments, the representation of events permitted multiple actors and multiple objects or victims, since sometimes co-located targets are sighted and attacked or two platforms participate in an attack. (The ruleset "Function count for attribute of event" in the file "W-Update" was involved in these experiments and is no longer needed.) Allowing multiple actors and objects/victims created serious difficulties, both in comparing event records and in retiring only the fulfilled part of virtual events. It was concluded that event records should have only one actor (which can be a "group" in the case of carrier aircraft, for example, where individual aircraft are not specified) and only one object or victim. When the object or victim is specified in a message as a composite and individual targets are reported in a later version, the initial event report can be split into more specific event records. A similar splitting can be made when a group named as the actor is later more fully defined, with the possible exception of aircraft. Additional rulesets will be needed for recognizing the need for splitting and accomplishing it. Also, event records involving simultaneous cooperative actions should be linked together with assertions indicating the relationship.

Experiments with a history file used the multiple database feature of Rosie, while an actual system would store such data offline. The ruleset (in the file "W-Copy" of the appendix) used in these experiments may accomplish the storing process in an inefficient manner, but it was written when the multiple database feature was first implemented and no documentation was available.

Rule 3 of "Procedure Update for New Event" in the file "W-Update" relates sightings to tracks in a form compatible with other programs in Rosie (tactical situation assessment rules and PTAPS rules). A round-about redundancy is created in that the sighted platform will be the object of the sighting and will also have a track which, in turn, has that sighting as one of its reports. However, the convenience of being able to run the
updating rulesets with other rulesets should compensate for the extra assertion. Step 44 illustrates the result of this rule for "TRACK #1."

4.5 Conclusions

It was observed from many examples of tactical narrative messages that the events described could be put in either of two categories: (1) those that occurred or were thought to have occurred and (2) those that were planned, ordered or predicted. These two categories of events are here termed "actual" events and "virtual" events, respectively.

Data concerning a virtual event are pertinent to the tactical situation picture until the predicted or planned event actually occurs (unless it is cancelled), at which time an event record of the actual event should replace the event record of the virtual event. To do this, first a method is needed to determine that the actual event was indeed "predicted" by the virtual event. Also, a method is needed to identify redundant reports and to update earlier event records, since the same event often is reported several times at different levels of reporting and rarely in an identical manner.

As a beginning step in developing these methods, simple versions of event records were created for three kinds of events: aircraft launches, sightings and attacks, and experimental programs were written to compare event records, to combine redundant actual-event records and to retire into a "history file" the event records which were no longer needed.

Early experiments indicated that to facilitate the updating and history-recording processes, event records should not have more than one actor or more than one object or victim, even at the expense of using several related event records to represent one event having several participants. (Whether or not to allow multiple sensors, multiple weapons, etc., has not yet been addressed.) This single actor or object/victim can be the name or label of a group, however, when the composition of the group is unimportant or unknown. In the latter case, if the group is later specified, usually it may be better to split the event report into one for each "member" of the group.

No attempt has been made yet to compare and combine redundant virtual-event reports, although this probably should be done.
Redundancy of virtual-report events will be less of a problem, since virtual events are not reported at as many levels of reporting as actual events and since their event reports generally will be retired to the history file much sooner than actual-event reports. The process of comparing virtual-event records will be more difficult than comparing actual-event records, though, since successive versions of a planned event may change.

The question of when to retire event records into the history file needs additional attention. One approach would be to calculate for each record, upon its creation or reorganization, a date-time of retirement, and then periodically sweep out all records whose times have expired. Some exceptions would have to be made, however; e.g., when an old sighting was the last sighting of a platform, its record should be kept much longer.

There is a variety of other problems that also need investigating. For example, an event record may be found to be a redundant version of two other event records which are contradictory to each other. A repetition of an event can be a problem; e.g., two attacks involving the same actor and victim may occur at times which are relatively close and not both specified precisely. In this case, clues such as "second" or "another" from the narrative are important. Further experiments will no doubt reveal many other problems.
5. SUMMARY AND RECOMMENDATIONS

In past efforts under this project, we have modelled an automated data fusion system and have experimented with its component processes, particularly natural language processing (NLP) and rule-based higher-order logic. In the recent work described in this report, we have centered our attention on the database of the system.

Knowledge about recent events, conceptually represented in a continually updated database, can be of considerable value in understanding incoming narrative. It can provide expectations, causes and enabling conditions useful in evaluating candidate interpretations of narrative data. The database also contains long term data, such as assertions about platform attributes and capabilities, which the NLP subsystem requires. For these reasons, access is highly desirable to the system's database by the NLP subsystems. Also, it appears that a rule-based approach should be taken in using the data to guide or control the processing of the narrative. Several ways of doing this were outlined in Section 3.

Other investigations in FY81 concerned the updating of the database of the data fusion system. An experimental program, written in Rosie (Rule-Oriented System for Implementing Expertise, a development of The Rand Corporation), compares event reports for redundancies, combines reports of the same event and retires old data into a history file in a form useful for event reconstruction. Section 4 discusses the experimental results and conclusions.

If the NLP controlling subsystems, the database updating subsystem and the final fusion processes are all to be rule-based processes which share the same database, as it appears they should be, they will require the same kind of rule interpreting mechanism. Furthermore, these processes ideally would be implemented in the same rule-based system, to facilitate coordination and interaction.

In conjunction with continuing investigations in the areas discussed in this report, several related areas should receive attention. One is the organization of the history file. A study of the potential uses of the history file and the kinds of information needed for each should influence the design of the database updating processes which create the history file. Another area is the employment of event records in the database.
to understand new events and link their records with those of other events in a chain of events. For example, a report of an attack should create an expectation of a report of damage and permit a relational linking of the attack record with the damage record in a script representation. In some cases the reasoning needed to relate events can be used at the NLP stage and in other cases the same reasoning is needed at the database updating stage. Still another potential area of investigation is the use of event records to automatically modify status data concerning supplies and capabilities. Reports of missiles used in attacks could be used to update the missile inventory counts kept for both friendly and hostile platforms. (The detection of redundant reports is especially important in this case.) A report of a damaged system should alter the list of operational systems on a platform. The updating of status records in such situations is another possible application of a rule-based system.

The areas of needed investigation described in this report and also other important ones not discussed will require research efforts many times greater than can be supported under this research project. We encourage other researchers working in artificial intelligence and natural language processing to consider these data fusion problems in their design of new systems and techniques.

'CONSTELLATION did launch AIRCRAFT at 220630' is a description of AIRCRAFT-LAUNCH #1.
220630 is a time of AIRCRAFT-LAUNCH #1.
AIRCRAFT-LAUNCH #1 is an aircraft-launch.
AIRCRAFT-GROUP #1 is an aircraft of AIRCRAFT-LAUNCH #1.
AIRCRAFT-LAUNCH #1 is actual.

<55> attack #3?
[ ATTACK #3 ]
MESSAGE #2 did report ATTACK #3.
ATTACK #3 did predict ATTACK #6.
AIRCRAFT-LAUNCH #2 will support ATTACK #3.
ATTACK #3 is an event.
'VARYAG will be attacked after 221120 by AIRCRAFT from CONSTELLATION' is a description of ATTACK #3.
AIRCRAFT-GROUP #2 is an actor of ATTACK #3.
PLATFORM #2 is a victim of ATTACK #3.
ATTACK #3 is an attack.
ATTACK #3 is virtual.

<56> logout.
Procedure Update for new-event.

Locals xmatch.

[1] If the new-event is actual,
   for each virtual event (ve) which does
   describe_an_event_of_the_type of the new-event,
   let the xmatch be
   the prediction-match of ve with the new-event
   and (if the xmatch >= 25,
       assert ve did predict the new-event)
   and (if the xmatch < 25 and the xmatch >= 20,
       assert ve did somewhat_predict the new-event)
   and send {return,
   "The prediction-match of ", the new-event, " with ", ve, " is ",
   the xmatch, return}.

[2] If the new-event is actual,
   for each actual event (ae)
   which does describe_an_event_of_the_type of the new-event,
   if ae ^= the new-event,
   let the xmatch be
   the redundancy-match of ae with the new-event
   and (if the xmatch >= 25,
       go combine ae with the new-event
       and forget about ae
       and assert ae is an event
       and ae was combined with the new-event)
   and (if the xmatch < 25 and the xmatch >= 20,
       assert the new-event does resemble ae)
   and send {return,
   "The redundancy-match of ", the new-event, " with ", ae, " is ",
   the xmatch, return}.

[3] If the new-event is an actual sighting
   and there is an object (plat) of the new-event
   and plat is a platform,
   (if there is no track of plat,
       create a track whose platform is plat
       and which is a track of plat)
   and assert the new-event is a report of (the track of plat).

[4] Deny the new-event is unprocessed.

End ruleset.
Predicate event1 does describe_an_event_of_the_type of event2.

[1] Match the event1 against
   {anything (bind typel to the name), " #", anything}
and match the event2 against
   {anything (bind type2 to the name), " #", anything}
and (if typel = type2 conclude true).

End ruleset.

Function prediction-match of virtual-event with actual-event.

Locals mintime, scorel, score2, score3, score4, scoretotal, mintime, xdelta.

[1] Let the scorel be 0 and the score2 be 0 and the score3 be 0
   and the score4 be 0 and the mintime be -1.

[2] If the virtual-event is an aircraft-launch
   and there is an aircraft (vac) of the virtual-event
   and there is an aircraft (aac) of the actual-event
   and there is a base (vb) of vac
   and there is a base (ab) of aac,
   (if vb = ab, produce 0)
   and (if vb = ab, let the scorel be 15).

[3] If there is a planned-time (pt) of the virtual-event
   and there is a time (t) of the actual-event,
   let the xdelta be the time_difference of <t, pt>
   and (if the xdelta > 120 or the xdelta < -60, produce 0)
   and (if the xdelta < 60 or the xdelta < -15, let the score2 be 5)
   and (if the xdelta <= 30, let the score2 be 10)
   and (if the xdelta = 0, let the score2 be 15).

[4] If there is no planned-time of the virtual-event
   and there is a time of the actual-event,
   for each event (se) which will support the virtual-event,
   if (there is a planned-time (st) of se
       or there is a time (st) of se),
   let the mintime be the maximum of <the mintime, st>.
[5] If the mintime > 0
and there is a time (t) of the actual-event,
let the xdelta be the time_difference of <t, the mintime>
and (if the xdelta < 0 or the xdelta > 240, produce 0)
and (if the xdelta < 180, let the score2 be 5)
and (if the xdelta < 90, let the score2 be 10).

[6] If there is an actor (actor1) of the virtual-event
and there is an actor (actor2) of the actual-event,
if actor1 is an equivalent of actor2,
let the score1 be 5,
otherwise produce 0.

[7] If there is an object (object1) of the virtual-event
and there is an object (object2) of the actual-event,
if object1 is an equivalent of object2,
let the score3 be 10,
otherwise produce 0.

[8] If there is a victim (victim1) of the virtual-event
and there is a victim (victim2) of the actual-event,
if victim1 is an equivalent of victim2,
let the score3 be 10,
otherwise produce 0.

[9] Produce the score1 + the score2 + the score3 + the score4.
End ruleset.

Function redundancy-match of event1 with event2.
Locals score1, score2, score3, score4, xdelta.

[1] Let the score1 be 0 and the score2 be 0 and the score3 be 0
and the score4 be 0.

[2] If the event1 is an aircraft-launch
and there is an aircraft (acl) of the event1
and there is an aircraft (ac2) of the event2
and there is a base (bl) of acl
and there is a base (b2) of ac2,
(if bl = b2, produce 0)
and (if bl = b2, let the score1 be 10).
[3] If there is a time (t1) of the event1 and there is a time (t2) of the event2, let the xdelta be the absolute-value of the time_difference of <t2, t1> and (if the xdelta > 90, produce 0) and (if the xdelta < 60, let the score2 be 5) and (if the xdelta < 30, let the score2 be 10) and (if the xdelta = 0, let the score2 be 15).

[4] If (there is no time of the event1 or there is no time of the event2), for each event (el) which did support the event1, if there is an event (e2) such that (e2 did support the event2 and e2 does describe_an_event_of_the_type of el), (if el = e2 let the score2 be 10) and (if el does resemble e2 and the score2 = 10 let the score2 be 5).

[5] If there is a latitude (lat1) of event1 and there is a latitude (lat2) of event2 and there is a longitude (lon1) of event1 and there is a longitude (lon2) of event2, if the absolute-value of (lat1 - lat2) < .01 and the absolute-value of (lon1 - lon2) < .01, let the score2 be the score2 + 5, otherwise produce 0.

[6] If there is an actor (actor1) of the event1 and there is an actor (actor2) of the event2, if actor1 is an equivalent of actor2, let the score1 be 5, otherwise produce 0.

[7] If there is an object (object1) of the event1 and there is an object (object2) of the event2, if object1 is an equivalent of object2, let the score3 be 10, otherwise produce 0.

[8] If there is a victim (victim1) of the event1 and there is a victim (victim2) of the event2, if victim1 is an equivalent of victim2, let the score3 be 10, otherwise produce 0.

[9] Produce the score4 + the score3 + the score2 + the score1.

End ruleset.
Predicate thing1 is an equivalent of thing2.

[1] If the thing1 = the thing2 conclude true.
