## ACKNOWLEDGEMENTS

Dr. Joseph F. Janni of the Air Force Weapons Laboratory sponsored this study. I am greatly indebted to him for his continuing counsel, for his forbearance, and for making available such tremendous computer support at AFWL.

Deserving of special thanks are Mr. Harry Murphy and Mr. John Burgio of AFWL and Miss Cherise Jarrett of Computer Sciences Corporation for their outstanding programming support, without which this study would have been impossible.

A strong debt of gratitude is owed to Tsgt. George Radke of AFWL, whose advice was invaluable, and who kept me mathematically honest.

Particular thanks is also due to my faculty advisors, Majors Robert Davie and James Lange. Their cogent advice and timely direction kept me from going too far astray.

Thanks is extended to Miss Casey Anglada of AFWL and Mrs. Antoinette Aguilar of Tetra Corporation for word-processing the text and equations in final form, and to Mrs. Cindy McDonald for typing a preliminary version of this report in spite of my handwriting.

Finally, I wish to thank my wife, Helen, for her continued encouragement and for putting up with my extended sojourns in Albuquerque.

Roger S. Dewey

## ABSTRACT

A semi-empirical method for modelling the loss of electron fluxes in the earth's magnetosphere was developed. An equation for the integral-energy omnidirectional electron flux as a function of time and magnetic field strength was derived from pitch-angle diffusion theory.

This flux equation was the basis for a computer data-fitting program written at the Air Force Weapons Laboratory (AFWL) to fit the AFWL Trapped Electron Data Base. The program utilized a least-squares fit and incorporated random variations of the characteristic exponential loss times about their initial values. An improved table of initial loss times was compiled for use with the program.

The derived flux model showed substantial agreement with the empirical data base. Representative plots of computed flux over raw data are shown for  $L$ -values of 2.3 and 2.4.

# I. INTRODUCTION

## Objective

Modern technology, both civilian and military, depends greatly on the use of satellite systems. It is thus important to the Department of Defense to understand and predict the environment in which satellites may operate, in order to determine survivability and vulnerability requirements. One part of that environment is the electron fluxes which may exist in the trapping regions of the earth's magnetosphere. Such fluxes may arise from natural sources or from injection by high-altitude nuclear bursts. Because such fluxes have great capability for inflicting damage to sensitive satellite components, even at great distances from a burst, understanding their behavior is vitally important.

There are a large number of theoretical treatments in the literature which describe various electron loss mechanisms from the earth's magnetosphere. However, the empirical calculations of actual electron losses are often conflicting, and frequently are restricted in their areas of coverage.

Since the cessation of high altitude nuclear testing in 1962, loss studies have been limited to electrons injected into the magnetosphere by natural magnetic disturbances such as solar storms. Thus, much of the theory which has been developed since 1962 has had restricted opportunity for empirical testing.

The objective of this study is to produce an improved algorithm to calculate losses of electrons from the magnetosphere. The algorithm is semi-empirical, because it utilizes the Air Force Weapons Laboratory (AFWL) Trapped Electron Data Base (Ref. 37) measurement of electron fluxes (following the old high altitude nuclear bursts) to determine the characteristic loss times of those electrons.

The loss times thus determined and the algorithm for flux "decay" will then be incorporated by AFWL into the SPECTER computer code (Ref. 7-9) for improved flux calculations of satellite environments.

## Scope

This study is limited to investigation of one loss mechanism, pitch-angle diffusion, using a theoretical formalism developed principally by Shulz (Ref. 47,48). The study has also been necessarily limited to those regions of space and those energies covered by the satellites from which the data base was compiled. The loss equations thus developed in this study are only implicitly functions of energy,  $E$ , and  $L$ -coordinate (explained in Chapter II).

The sheer volume of data and the limited time for this study also limited the testing of the algorithm developed to a representative subset of the entire data base.

## **Approach**

A specific solution of the pitch-angle diffusion equation is derived using the method proposed by Shuls (Ref. 47). This solution is then fitted to the electron flux data using a least-squares fitting program written by AFWL, with the coordination of this author. The solutions are performed for integral fluxes (above threshold energy of the satellite detector) and for constant  $L$ -value. The solutions are thus explicitly functions of magnetic field strength,  $B$ , but implicitly functions of  $E$  and  $L$ .

Use of the AFWL/NTCTS computer facilities was essential to this study. Well over 72 hours of actual computer-processing time were used, and over 1000 computer-produced flux plots were examined.

## **Presentation**

A brief Background section is presented, which covers some physical relations and terminology used in the study of space physics. This section is used to establish uniform symbol notation, and to provide a common starting point for the reader unfamiliar with the specialized language of space physics. It may be skipped by the reader more familiar with the topic.

Chapter III outlines the theory used to develop the flux equations which were fitted to the data.

Following the theory chapter is a chapter outlining the method of data analysis. Descriptions are given of the data base and of the AFWL computer codes used in this study.

Representative results of the study are presented in Chapter V, in both tabular and graphic form. Again, the sheer volume of data makes inclusion of all plots and fitted values prohibitive.

Conclusions and recommendations for improvements for further study are presented in Chapter VI.

The Bibliography includes 65 sources and provides a comprehensive summary of existing literature of relevant topics about radiation trapped in the magnetosphere and of pitch-angle diffusion.

## II. BACKGROUND

The equation of motion of a charged particle in magnetic, electric, and external gravitational fields is:

$$m \frac{d^2 \vec{r}}{dt^2} = m \vec{g} + q \left( \frac{d\vec{r}}{dt} \times \vec{B} \right) + q \vec{E}$$

where

$$\begin{aligned} \vec{r} &= \vec{r}(t, \vec{r}_0, \vec{v}_0); \quad \frac{d\vec{r}}{dt} = \vec{v} \\ m &= \text{particle mass,} \\ \vec{g} &= \text{gravitational constant,} \\ q &= \text{charge,} \\ \vec{B} &= \text{magnetic field,} \\ \vec{E} &= \text{total electric field} \end{aligned} \quad (\text{Ref. 11:23-24.})$$

In a uniform magnetic field, a charged particle will move in helical fashion along and around the field lines with a cyclotron radius,  $\rho_c$ , (also called gyroradius or Larmor radius) about its "guiding center". The particle's motion may thus be separated into its rotation around the field line and the motion of its center of rotation, or guiding center, along the field line (Ref. 11:24-25).

The period of cyclotron rotation,  $\tau_c$ , is defined by (Ref. 39:5):

$$\tau_c = \frac{2\pi m}{qB} = \frac{2\pi \rho_c}{v_{\perp}}$$

where  $m$  is the relativistic mass:

$$m = m_0 \gamma = m_0 \left[ \frac{1}{\sqrt{1 - (v^2/c^2)}} \right]$$

and where  $v_{\perp}$  is component of velocity perpendicular to  $\vec{B}$ . The cyclotron frequency is simply  $2\pi$  over the period (Ref. 39:5):

$$\omega_c = \frac{2\pi}{\tau_c} = \frac{qB}{m}$$

The angle between a particle's local velocity,  $\vec{v}$ , and the magnetic field,  $\vec{B}$ , is its pitch-angle,  $\alpha$ , which is defined as:

$$\alpha = \arccos\left(\frac{v_{\parallel}}{v}\right) = \arcsin\left(\frac{v_{\perp}}{v}\right).$$

In a uniform static magnetic field,  $v_{\parallel}$  is constant and  $v_{\perp}$  is constant, and hence  $\alpha$  is constant. The particle will then move with a uniform circular motion around the field line and uniform rectilinear motion along the field line, resulting in a helical motion about the line, since

$$\begin{aligned} d\vec{p}/dt &= q\vec{v} \times \vec{B} = m\vec{a}, \\ \text{and} \\ m\vec{a}_{\parallel} &= q(\vec{v} \times \vec{B})_{\parallel} = 0. \end{aligned}$$

$$\begin{aligned}
 \dot{a}_\parallel &= 0, \\
 v_\parallel &= \text{constant}, \\
 \text{and} \\
 m\dot{a}_\perp &= q(\vec{v} \times \vec{B})_\perp, \\
 a_\perp &= (qv_\perp B)/m = \text{constant, which is a constant centripetal acceleration} \\
 &\quad (\text{Ref. 39:4-7; Ref. 11:23-36}).
 \end{aligned}$$

The concept of the first adiabatic invariant arises naturally from the guiding center approximation. The *first adiabatic invariant*,  $M$ , (also called the relativistic magnetic moment) is defined by:

$$M = \frac{\bar{p}_\perp^2}{2m_0 B} = \text{constant}$$

where  $\bar{p}_\perp$  is the particle's perpendicular momentum in the guiding center approximation. The assumptions implicit in calling  $M$  invariant are that the spatial variation of  $B$  is small compared to  $\rho_e$  and the time variation of  $B$  is small compared to  $\tau_e$  (Ref. 39:11-23).

If a particle has a constant velocity along a field line in the guiding center frame of reference, then

$$\frac{\sin^2 \alpha(s)}{B(s)} = \frac{\sin^2 \alpha_i}{B_i} = \text{constant}$$

where  $s$  is the arc length along the field line and  $i$  is any point on the field line. This assumes that the particle's kinetic energy remains constant as it follows the field line. If a particle enters the field at point  $B_i$  with pitch angle  $\alpha_i$ , its velocity along the field line is

$$v_\parallel(s) = v \cos \alpha(s) = v \cdot \sqrt{1 - \frac{B(s)}{B_i} \sin^2 \alpha_i}.$$

If the field is increasing in the direction of  $v_\parallel$ , then the "mirror point" of the particle, where its parallel velocity is zero, is

$$B_m = \frac{B_i}{\sin^2 \alpha_i} = \frac{B(s)}{\sin^2 \alpha(s)}$$

and the particle has a local pitch angle of  $90^\circ$  at that mirror point (Ref. 39:34-42).

When the magnetic field has a geometry like that of a dipole field, increasing at the poles and decreasing in the midpoint, then the particle is in the so-called "magnetic bottle", and is trapped between the mirror points. There is some minimum  $B$  value between the mirror points which is called  $B_0$ , the equatorial field strength. Using the guiding center approximation and approximating the earth's magnetic field by a dipole field, a particle trapped in the earth's field has three distinct motions. It circles rapidly about a field line, it bounces along the line between mirror points, and it drifts slowly in longitude around the earth. All three motions take place with different speeds, so they are distinct (Ref. 11:25; Ref. 29:34-65).

From the mirror point definition, and from the velocity equations, we see that

$$M = \frac{p_\perp^2}{2\pi m_0 B_m}$$

and that

$$v_\perp(s) = v \sin \alpha_i \sqrt{\frac{B(s)}{B_i}} = v \sqrt{\frac{B(s)}{B_m}}.$$

Note that the particle's mirror point depends only on its "injection" point and its injection pitch angle, not on its initial energy or velocity. A mirror point is a consequence of the field alone, and all particles injected at the same point with the same pitch angle will mirror at the same point on the field line. Of course, this is only true if no external forces are acting.

The parallel velocity,  $v_{\parallel}$ , of the particle will be the maximum at  $B_0$ , where  $B(s)$  is the minimum. Thus, a trapped particle spends most of its time near the mirror points, and the least amount of its time transiting the equatorial field regions (Ref. 29:34-44).

The bounce period,  $\tau_b$ , of a trapped particle is generally much greater than its cyclotron period,  $\tau_c$ , and is defined by:

$$\tau_b = 2 \int_{s_{m_1}}^{s_{m_2}} \frac{ds}{v_{\parallel}(s)} = \frac{2}{v} \int_{s_{m_1}}^{s_{m_2}} \frac{ds}{\sqrt{1 - (B(s)/B_m)}}$$

where  $s_{m_1}$  and  $s_{m_2}$  are the mirror points on the field line.

As a particle in a dipole field like the earth's bounces along the field line, it also drifts perpendicularly to the field line, due to external forces, field gradients, and field curvature, as well as other effects such as time-dependent field changes. This drift is slow compared to the bounce period. As the particle bounces and drifts, it traces out a surface between its mirror points and around the earth, called a drift shell (Ref. 39:9-19).

The concepts of the second and third adiabatic invariants arise from the above behavior. If the forces acting on the particle remain almost constant over its bounce period, the *second adiabatic invariant*,  $J$ , is defined by

$$J = \oint p_{\parallel} ds = 4 \int_0^{s_m} p_{\parallel} ds$$

where  $p_{\parallel}$  is the momentum component parallel to  $\vec{B}$  and  $ds$  measures arc length from the equator (Ref. 45:12; Ref. 6:3-31). If the forces acting on a particle remain almost constant over its drift period, the *third adiabatic invariant*,  $\Phi$ , which is the magnetic flux enclosed by a drift shell, is defined by

$$\Phi = \oint \vec{A}_0 \cdot d\vec{a}$$

where  $\vec{A}_0$  is the magnetic vector potential and where the integration is performed over a curve,  $s$ , which lies in the drift shell. The third invariant,  $\Phi$ , is defined and computed for the drift shell of the guiding center, with constant field, and not for a drift shell which a particle may physically trace out under short-term conditions (Ref. 45:12; Ref. 39:76-79).

The guiding drift shell of a particle may also be referred to as an "invariant surface," which is composed of field lines which end at the mirror points. The three adiabatic invariants uniquely define an invariant surface (Ref. 6:3-31 to 3-32).

The more common set of parameters used to define a particle's position in the magnetosphere (or to define an invariant surface) is the  $B$ - $L$  coordinate system. The  $B$  parameter is magnetic field strength, and  $L$  is the McIlwain  $L$  parameter defined by  $L = r_0/R_E$  where  $R_E$  is the earth's radius ( $\approx 6371$  km) (Ref. 6:3-33) and (Ref. 39:53).

The value of  $L$ , therefore, is equal to the distance, in earth radii, of the equatorial point on a field line in a dipole field. If the field is not symmetric (not a perfect dipole), the invariant surface is not so well defined. However, for most field lines in the trapping

region of the earth's magnetosphere,  $L$  varies by less than one percent along the line, so the  $B$ - $L$  system is adequate. The less-than-exact symmetry of the earth's dipole field and outside forces may cause particle drift to deviate from a perfect azimuthal course. This means that its  $L$  value will vary in the course of a drift period. This variation of  $L$  values is not significant below  $L \approx 3$ , but may be so above that value. The average  $L$ -value of all intersecting invariant surfaces is called an  $L$ -shell. This  $L$ -value defines a set of surfaces along field lines, which may end at differing mirror points. The  $L$ -shells are considered to intersect the earth's surface, even though mirror points do not extend through the atmosphere to the surface (Ref. 6:3-33 to 3-35; Ref. 39:53).

The various mechanisms which operate to cause trapped particles to change  $L$ -shell or to be lost from the trapping region will necessarily violate one or more of the adiabatic invariants. For example, pitch-angle diffusion violates  $M$  or  $J$ , or both; and radial diffusion violates  $\Phi$  (Ref. 45:48). These concepts are discussed further in Chapter III.

### III. THEORY

While the motion of particles trapped in a magnetic field is well understood, the mechanisms of losses from magnetic fields such as the earth's magnetosphere are less well understood. It is generally agreed, however, that pitch-angle diffusion into the loss cone is one of the predominant mechanisms for removal of charged particles for mid-range  $L$ -values. The loss cone angle is the lower limit of pitch angle for trapped particles. Any particles with smaller pitch angles will mirror in the sensible atmosphere and will be lost by atmospheric scattering.

Roberts (Ref. 41) has noted that a pitch-angle scattering mechanism must be extant for pitch-angle diffusion to occur. Such a mechanism would necessarily violate one or more of the adiabatic invariants.

It is not the purpose of this study to ascertain the true source mechanism of pitch-angle diffusion. Such a study is beyond the scope of this paper. Indeed, the search for this mechanism has been going on for decades. Roberts (Ref. 41) has postulated that the "perturbation forces" causing such diffusion may result from turbulent ambient electric or magnetic fields or from collisions with other trapped or non-trapped particles. Lyons (Refs. 20-28) has formulated extensive theory based on resonant interactions of so-called "whistler" VLF waves with the trapped-particles' gyrofrequencies: "cyclotron-resonance". Regardless of the actual physical mechanism behind pitch-angle diffusion, its general treatment is mathematically the same, and the physical results are the same. (Ref. 41:308) This study follows the methods of Roberts (Ref. 41), Shulz and Lanzerotti (Ref. 45) and Shulz (Ref. 47) in assuming that pitch-angle diffusion is an operative process. One of the purposes of this study is the formulation of the equations necessary to validate that assumption against experimental data, and to perform that experimental validation.

It should be emphasized that, while pitch-angle diffusion is assumed in this paper to be the dominant loss mechanism for  $b$ -values and altitudes considered, it is not the only loss mechanism. Several investigators have formulated radial diffusion (cross- $L$ ) theories (for example, Walt (Ref. 58) or Tomassian (Ref. 54)), coulombic or collision-scattering-diffusion theories (for example, Wentworth (Ref. 60)) and multiple diffusion theories, such as combinations of pitch-angle, energy, and/or radial diffusion (for example, Walt (Ref. 58) and Lyons (Ref. 26)), all of which show some agreement with experimental data. In particular, atmospheric scattering is obviously a dominant force at very low  $L$  values (Ref. 30).

The introduction of multiple loss-mechanisms makes explicit solutions of any diffusion equation extremely difficult. To simplify the problem and render it amenable to the method of Shulz (Ref. 47), this study assumes that "as a rule, radial diffusion enables the radiation belts to become populated from an external source (or rearranges particles injected by an internal source), while pitch angle diffusion causes particle loss to an atmospheric sink" (Ref. 45:48).

Pitch-angle diffusion, while simple in concept, is complicated in detail. Roberts' (Ref. 41:307-337) treatment of the general mechanism is particularly descriptive:

At the magnetic equator, a particle's pitch angle,  $\alpha_0$ , is determined by

$$(1) \quad z = \cos \alpha_0 = \frac{P_{\parallel 0}}{\sqrt{(P_{\parallel 0}^2 + P_{\perp 0}^2)}} = \sqrt{1 - \left(\frac{B_0}{B}\right)}$$

where  $P_{\parallel 0}$  and  $P_{\perp 0}$  are the parallel and perpendicular components of the particle's momentum with respect to the field line at the equatorial value of  $B_0$ . Roberts next defines

$$(2) \quad W_{\parallel 0} = \frac{P_{\parallel 0}^2}{2m_0},$$

$$W_{\perp 0} = \frac{P_{\perp 0}^2}{2m_0}$$

where  $m_0$  is the rest mass. These are defined since the first adiabatic invariant,  $M$ , is proportional to  $W_{\perp 0}$ :

$$(3) \quad M = \frac{W_{\perp 0}}{B_0}$$

and, if  $W_{\parallel 0} < W_{\perp 0}$ , the second adiabatic invariant,  $J$ , is approximately proportional to  $W_{\parallel 0}$ :

$$(4) \quad J \approx \frac{\tau_B W_{\parallel 0}}{\gamma}$$

where

$\tau_B$  = the particle's bounce period,

$$\gamma = \frac{\text{relativistic mass}}{\text{rest mass}} = \frac{m}{m_0}$$

A particle's path may be defined by plotting its values of  $W_{\perp 0}$  and  $W_{\parallel 0}$  as in Figure 1.

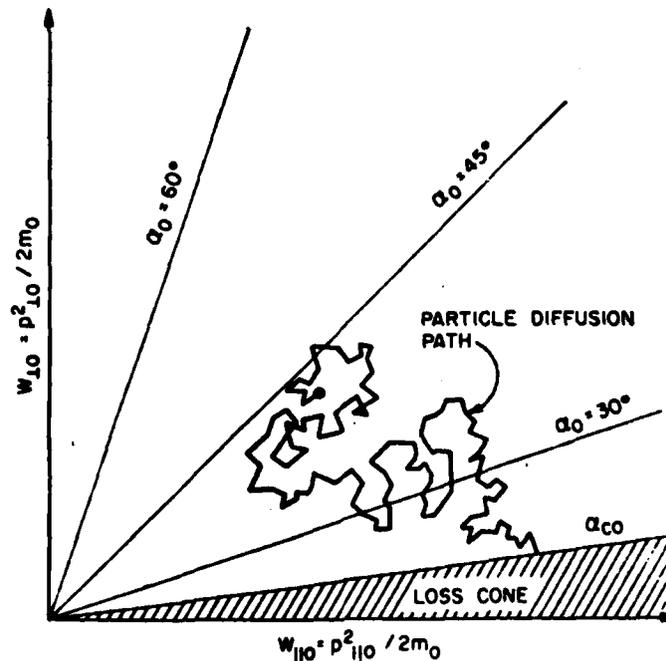

Fig. 1. Loss of a trapped particle by a random walk into the pitch-angle loss cone.

(Ref. 41:306)

Note that lines of constant equatorial pitch angle pass through the origin, because

$$\tan^2 \alpha_0 = \frac{W_{\perp 0}}{W_{\parallel 0}}$$

Any force which violates either  $M$  or  $J$ , the first or second adiabatic invariant, will produce "diffusion" of the particle's pitch angle as shown in Figure 1 as  $W_{\perp 0}$  and  $W_{\parallel 0}$  change with time. When a particle's equatorial pitch angle diffuses to the value of the loss cone angle,

$$(5) \quad z_0 = \cos \alpha_0 = \sqrt{1 - \frac{B_0}{B_{100}}}$$

where  $B_{100}$  is the value at 100 km altitude, then it is lost by atmospheric scattering. "The loss cone serves as a 'sink' for particles" undergoing pitch angle diffusion (Ref. 41:307).

Roberts makes two very important points about pitch-angle diffusion as a loss-mechanism:

- (1) with no source, the entire radiation-belt would be depleted of particles,
- (2) the loss cone approximation is just that, since the atmosphere is not sharply defined at 100 km. However, if atmospheric pitch-angle scattering is not the primary focus, the loss cone approximation may be useful. "Naturally, when the loss-cone concept is used, detailed agreement between theory and experiment cannot be expected in the region near the edge of the loss cone" (Ref. 41:308).

Both Roberts (Ref. 41) and Shuls and Lanzerotti (Ref. 45) develop the pitch angle diffusion equation from the Fokker-Planck equation using a particle distribution function,  $f$ .

The Fokker-Planck equation is a formalism which arose from the study of Brownian motion, and which is used frequently in transport theory (Ref. 42:308). The characteristic Fokker-Planck equation for trapped particles (which ignores radial diffusion) is:

$$\frac{\partial f}{\partial t} = - \frac{1}{\gamma p} \frac{\partial}{\partial E} \left[ \gamma p \left( \frac{dE}{dt} \right)_{\nu} f \right] + \frac{1}{z T(y)} \frac{\partial}{\partial z} \left[ z T(y) D_{zz} \frac{\partial f}{\partial z} \right] + \frac{1}{\gamma p} \frac{\partial}{\partial E} \left[ \gamma p D_{EE} \frac{\partial f}{\partial E} \right]$$

where the first term, subscripted  $\nu$ , represents non-stochastic (mean) energy loss to the atmosphere, the second term represents pitch-angle diffusion, and the third term represents range-straggling (energy diffusion). The term  $T(y)$  is defined below, and the  $D_{EE}$  and  $D_{zz}$  terms are the characteristic diffusion coefficients;  $\gamma$  is relativistic mass ratio (Ref. 45:55-58).

Roberts uses a distribution of particles in a "tube" of force about a field line, and Shuls and Lanzerotti use a phase-space density distribution function which is essentially equivalent to Roberts'. Since this study follows the methods of Shuls (Ref. 4") and Shuls and Lanzerotti, a discussion of phase space is necessary (Ref. 45:15-22).

Any moving particle can be described by specifying its three position coordinates and its three canonical momentum components. This completes a six-dimension "phase-space" in which a particle can travel in time.

If there exists a system of a large number of particles in phase-space, the system can be described by a six-dimensional distribution function  $f(\vec{p}_i, \vec{q}_i, t)$  where

- $\vec{p}_i$  ( $i = 1, 2, 3$ ) are canonical momentum components,  
 $\vec{q}_i$  ( $i = 1, 2, 3$ ) are position coordinates, and  $t$  is time.

Thus,  $\int d^3\bar{p} d^3\bar{q}$  is the number of particles instantaneously occupying 6-D volume  $d^3\bar{p} d^3\bar{q}$ . According to Liouville's theorem, the phase-space volume containing the system of particles moves incompressibly through phase-space.

Since  $\bar{p}$  is an awkward quantity to deal with physically, Shulz and Lanzerotti note that  $\bar{p}$  transforms to the more familiar  $\bar{p}$  as

$$(6) \quad \bar{p} = \bar{p} + \left(\frac{q}{c}\right)\bar{A}$$

where  $\bar{A}$  is the electromagnetic vector potential.

Hence,  $f(\bar{p}, \bar{q}, t) = f(\bar{p}, \bar{r}, t)$  since  $\bar{q} = \bar{r}$  and the  $\bar{p}$  to  $\bar{p}$  transformation has a unit Jacobian. The position-momentum distribution function  $f(\bar{p}, \bar{r}, t)$  defines the particles occupying the 6-D volume  $d^3\bar{p} d^3\bar{r}$  at any given  $t$ . The pitch angle diffusion equation is given in terms of a phase-space distribution function which is numerically equal to the more easily-definable position-momentum distribution function (Ref. 45:15-22). At constant energy and  $L$ -shell, and under the action of some source  $\bar{S}$ , the diffusion equation in phase-space can be written

$$(7) \quad \frac{\partial \bar{f}}{\partial t} = \frac{1}{x T(y)} \frac{\partial}{\partial x} \left[ x T(y) D_{xx} \frac{\partial \bar{f}}{\partial x} \right] + \bar{S}$$

where  $T(y)$  is the quarter-bounce integral path length function of  $y = \sqrt{1-x^2}$  where  $x = \cos \alpha_0$ . The quarter bounce integral gives the length of the trajectory of a particle (in units of  $R_0$ , the distance to the equatorial crossing) from the equator to the mirror point. The exact definition of  $T$  is

$$T = \int_0^{\alpha_m} \frac{ds}{\cos \alpha}$$

where  $s$  is the distance along the field line and  $\alpha$  is the local pitch angle (Ref. 10:4029-4030).

$D_{xx}$  is the bounce-averaged diffusion coefficient as a function of  $x$  (Ref. 41 and Ref. 45). The boundary conditions are that  $\bar{f} = 0$  at  $x = x_c$  (some cutoff value) and  $\bar{f}(x=0)$  is finite.

Shulz and Lanzerotti (Ref. 45:162) rewrite the above as

$$(8) \quad \frac{\partial \bar{f}}{\partial t} = \frac{1}{x} \frac{\partial}{\partial x} \left[ x D_{xx} \frac{\partial \bar{f}}{\partial x} \right]_E - \frac{x}{y} D_{xx} \frac{T'(y)}{T(y)} \left[ \frac{\partial \bar{f}}{\partial x} \right]_E + \bar{S}$$

and further approximate that the second term is negligible for  $x \ll 1$  since  $x^2 + y^2 = 1$ . If  $T(y) \approx T(1)$ , the second term disappears and the equation is a diffusion equation in cylindrical coordinates. (These approximations are not used in this work. This development is used to aid in understanding the exact solutions which follow from Shulz (Ref. 47)). If  $D_{xx}$  and  $\bar{S}$  are then independent of  $x$ , and if  $\bar{f}(x, t) = X(x) T(t)$ , the eigenfunctions of (8) are Bessel functions of order zero. The general solution to (8) would then be

$$(9) \quad \bar{f}(x, t) = \bar{f}_{\infty}(x) + \sum_n a_n(t) J_0 \left( \kappa_n \frac{x}{x_c} \right)$$

where  $\bar{f}_{\infty}$  is the steady-state solution

$$(10) \quad \bar{f}_{\infty}(x) = \left( \frac{\bar{S} x_c^2}{4 D_{xx}} \right) \left[ 1 - \left( \frac{x}{x_c} \right)^2 \right]$$

The  $\kappa_n$  are the zeroes of  $J_0$  ( $n = 1, 2, \dots$ ) and the  $a_n(t)$  vary as  $e^{-(t/\tau_n)}$ , where  $\tau_n = z_n^2 / (D^2 \kappa_n^2)$ . Thus, the pitch angle distribution (and hence the directional or omnidirectional flux) is shown to be the sum of a steady state and higher order eigenmodes (Ref. 45:160-168).

The steady state can be thought of as the "normal" or "quiet-time" value of flux which exists in equilibrium with the source  $\bar{S}$ . An "injection" of particles would then result in a perturbed distribution function with several eigenmodes, each with a characteristic decay-time  $\tau_n$ . The higher order modes decay faster, and eventually only the fundamental mode would remain, which would decay exponentially to reach the steady state (after "infinite" time) (Ref. 41 and 45). There is ample evidence that such a process does indeed occur. Roberts (Ref. 41) cites Explorer XV data for the 28 October 1962 Russian explosion as an example. Rosen and Sanders (Ref. 43) also note that decay is faster immediately after solar magnetic storm activity than during quieter periods. The similarities in Figures 2 and 3 illustrate the way in which a decay of higher eigenmodes (Figure 2) can approximate the temporal evaluation of an actual electron distribution (Figure 3).

The primary difficulties with the above discussion arise from the approximations that:

- (1)  $T(y) = T(1) = \text{constant}$
- (2)  $z^2 \ll 1$  (or  $y \approx 1$ )
- (3)  $D_{zz}$  varies little (or not at all) with  $z$ .

Roberts (Ref. 41:311) uses the argument that the full spiral path (and hence  $T(y)$ ) varies only by a factor of 1.4 as  $z$  varies from 0 to 0.9 and by 1.9 as  $z$  varies from 0 to 1. Shulz and Lanzerotti (Ref. 45:163) use the simplifying assumptions that  $T(y) \equiv T(1)$  and  $D_{zz}$  is independent of  $z$ . Both use the assumption that  $z^2 \ll 1$ .

The present study requires that  $z$  be allowed to vary from 0 to  $z_e$  (up to near 1) in order to adequately examine the AFWL trapped electron data base (Ref. 37). In addition, if  $z$  is not small, the approximation that  $T(y) \equiv T(1)$  is a poor one, since  $y$  is not close to 1.

The function  $T(y)$  can be shown, within 0.57% to be approximated as (Ref. 10:4030)

$$(11) \quad T(y) \approx T(0) - [T(0) - T(1)]y^{3/4}$$

where  $T(0) = 1 + \left[ (\ln(2 + \sqrt{3})) / (2\sqrt{3}) \right] \approx 1.3802$  and  $T(1) = (\pi\sqrt{2})/6 \approx 0.7405$  (Ref. 45:19).

Obviously, if  $z$  approaches 1,  $y$  approaches 0 and the  $T(y) \equiv T(1)$  approximation becomes invalid.

The three limiting approximations are removed in the treatment of Shulz (Ref. 47) by introduction of a new "canonical" variable  $z$  such that:

$$(12) \quad z = Z(y) = \int_0^z x' T(y') dx' = \int_y^1 y' T(y') dy'$$

and a corresponding diffusion coefficient

$$(13) \quad D_{zz} = [z T(y)]^2 D_{zz}$$

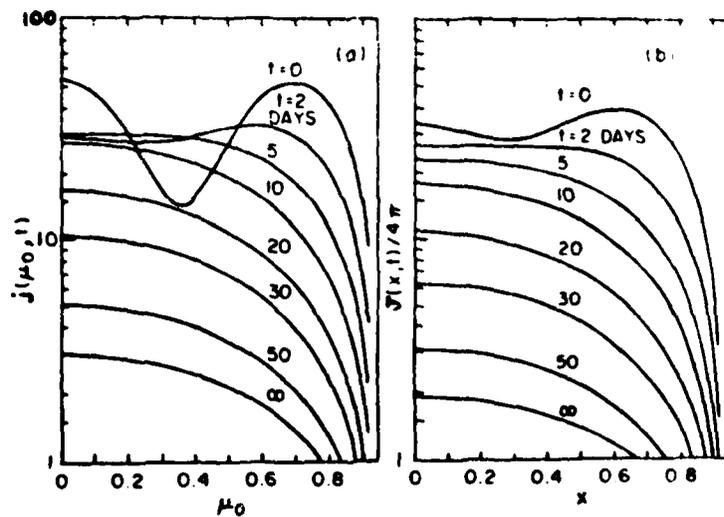

Figure 2. Postulated Decay of Higher Flux Eigenmodes to the Steady State by Pitch-Angle Diffusion (Ref. 41:313).

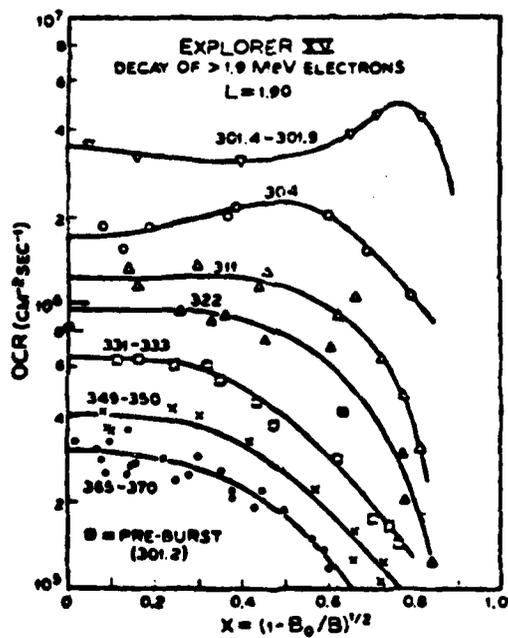

Figure 3. Temporal evolution of 1.0 MeV Electrons from the Russian 3 Burst (Ref. 41:319).

Using (11) in (12) and performing the integration:

$$\begin{aligned}
 z &\approx \int_y^1 y' \left[ T(0) - [T(0) - T(1)]y'^{11/4} \right] dy' \\
 &\approx \int_y^1 \left[ T(0)y' - [T(0) - T(1)]y'^{15/4} \right] dy' \\
 &\approx \frac{1}{2}T(0)y'^2 - \frac{4}{11}[T(0) - T(1)]y'^{11/4} \Big|_y^1 \\
 (14) \quad z &\approx \frac{T(0)(1-y^2)}{2} - \frac{4[T(0) - T(1)][1-y^{11/4}]}{11}
 \end{aligned}$$

where  $Z(0) = 16/35$  and  $Z(1) = 0$  (Ref. 46:5213).

Using (7), (12) and (13), the diffusion equation becomes:

$$(15) \quad \frac{\partial \bar{J}}{\partial t} = \frac{\partial}{\partial z} \left[ D_{zz} \frac{\partial \bar{J}}{\partial z} \right] + \bar{S}.$$

Shulz (Ref. 47:6) states that (15) is a "canonical" diffusion equation in that there is no Jacobian factor which fails to commute with  $D_{zz}$  as was the case in (7).

The assumptions which now must be made are:

- (1)  $D_{zz}$  is some "suitably simple function of  $z$ " (Ref. 47:6) so that exact eigenfunctions  $g_n(x)$  may be specified,
- (2)  $\bar{S}$ , the distributed natural environment source, is independent of  $z$ .

Assumption (1) is the limiting assumption, since if the function of  $z$  is very complex, the diffusion equation becomes extremely difficult to solve. Assumption (2) is both simple and reasonable, however. The source of the natural environment must be close to constant in order to be the "driver" of quiet-time equilibrium. It must also be distributed fairly closely to the steady-state quiet time distribution for the same reason.

Shulz (Ref. 47:7) states that even if  $D_{zz}$  is not of a functional form to yield exact eigenfunctions, there may be a  $\bar{D}_{zz}$  which resembles  $D_{zz}$  "closely enough" and for which exact eigenfunctions  $\bar{g}_n(x)$  (resembling  $g_n(x)$ ) are known.

The following derivation of the exact eigenfunctions and the corresponding omnidirectional differential-energy flux arises directly from Shulz (Ref. 47).

The first assumption by Shulz is that

$$(16) \quad D_{zz} = \left( \frac{z}{z_0} \right)^\sigma D_{zz_0}$$

where  $\sigma$  is some number, not necessarily an integer, less than 2, and where  $D_{zz_0}$  is the value of  $D_{zz}$  at some  $z_0 < 16/35$  where  $f$  vanishes. Roberts (1969) also uses this assumption.

This form of  $D_{zz}$  allows a basis set of orthogonal eigenfunctions to be shown for the interval of interest:  $0 \leq z \leq z_0$ . Following the notation above, we seek some  $D_{zz}$  and

eigenfunctions  $g_n(z)$  which "closely resemble" the true functions and which satisfy

$$(17) \quad \frac{d}{dz} \left[ D_{zz} \frac{d \bar{g}_n(z)}{dz} \right] + \bar{\lambda}_n \bar{g}_n(z) = 0$$

for

$$\bar{D}_{zz} = \left( \frac{z}{z_0} \right)^\sigma \bar{D}_{zz},$$

with the substitution

$$\bar{g}_n(z) = z^\alpha w(\beta z^\xi)$$

where

$$\xi = 1 - \frac{\sigma}{2},$$

$$\alpha = \frac{1 - \sigma}{2}$$

and

$$\beta = \sqrt{\frac{\bar{\lambda}_n z_0^\sigma}{\bar{D}_{zz} \xi^2}}$$

then (17) becomes Bessel's equation. The exact eigenfunctions of (17) are given by

$$(18) \quad \bar{g}_n(z) = \frac{\sqrt{\frac{2-\sigma}{z_0}}}{J_\nu'(\kappa_{\nu n})} \left( \frac{z}{z_0} \right)^{(1-\sigma)/2} J_\nu \left( \kappa_{\nu n} \left( \frac{z}{z_0} \right)^{(1-\sigma/2)} \right)$$

where  $\kappa_{\nu n}$  are the  $n$ th zeroes of the Bessel function  $J_\nu$  of the order  $\nu$ , where

$$\nu = \frac{\sigma - 1}{2 - \sigma}.$$

The  $\bar{g}_n$  given by (18) are normalized so that

$$(18) \quad \int_0^{z_0} \bar{g}_n \bar{g}_m dz = \delta_{nm}.$$

The eigenvalues of (18) are given by

$$(19) \quad \bar{\lambda}_n = \left( \frac{\kappa_{\nu n}}{2z_0} \right)^2 (2 - \sigma)^2 \bar{D}_{zz}.$$

Shulz and Boucher (Ref. 48:6) state that, since particles are not lost at  $z = 0$  (but rather at  $z = z_0$ ), the diffusion current must go to zero at  $z = 0$ . A diffusion current at  $z = 0$  would imply diffusion of pitch angles (and hence mirror points) into the equator, which is not reasonable. The condition of no diffusion current at  $z = 0$  corresponds to  $\lim_{z \rightarrow 0} D_{zz} \bar{g}'_n(z) = 0$ .

Shulz and Boucher (Ref. 48) use the series expansion of  $J_\nu$  from Abramovic; and Stegun (Ref. 1) to show the limit as  $z$  approaches zero. This author shows the limit directly for the special case eigenfunction ( $J_{-1/2}$ ) which is used in this report. The derivation is shown in Appendix A.

In order to arrive at the differential-energy omnidirectional flux, Shulz (Ref. 47) assumes that  $\bar{j}(z, t) \rightarrow \bar{j}_\infty(z)$  as  $t \rightarrow \infty$ ; that is, the solution distribution function has some steady-state value. This also assumes that  $\bar{S}$  is constant in time, but not in  $x$  or  $z$ . The  $\bar{j}_\infty$  distribution is necessary in order to expand  $\bar{j}$  as a series of eigenfunctions in the flux equation. To arrive at an expression for  $\bar{j}_\infty$  we start by setting  $\partial \bar{j} / \partial t$  to zero in (15) and integrating twice, which gives:

$$(20) \quad \bar{j}_\infty(z) = \int_x^{z_0} \frac{1}{D_{x'x'}} \int_0^{z'} \bar{S}(z'') dz'' dz'$$

Expanding  $\bar{S}$  as a series of orthogonal eigenfunctions gives:

$$(20a) \quad \bar{S}(z'') = \sum_{n=0}^{\infty} a_n \vartheta_n(z'')$$

and using orthogonality (18a) with (20a) gives:

$$(20b) \quad a_m = \int_0^{z_0} \bar{S}(z''') \vartheta_m(z''') dz'''$$

Substituting (20a) into (20) gives

$$(20c) \quad \bar{j}_\infty(z) = \int_x^{z_0} \frac{1}{D_{x'x'}} \int_0^{z'} \sum_{n=0}^{\infty} a_n \vartheta_n(z'') dz'' dz'$$

Rearranging the order of summation and integration in (20c) gives:

$$(20d) \quad \bar{j}_\infty(z) = \sum_{n=0}^{\infty} a_n \int_x^{z_0} \frac{1}{D_{x'x'}} \int_0^{z'} \vartheta_n(z'') dz'' dz'$$

Now integrating (17a) twice gives:

$$\vartheta_n(z) = \int_x^{z_0} \frac{1}{D_{x'x'}} \int_0^{z'} \lambda_n \vartheta_n(z'') dz'' dz'$$

or since  $\lambda_n$  is a constant,

$$(20e) \quad \frac{\vartheta_n(z)}{\lambda_n} = \int_x^{z_0} \frac{1}{D_{x'x'}} \int_0^{z'} \vartheta_n(z'') dz'' dz'$$

Substitution of (20e) into (20d) gives:

$$(20f) \quad \bar{j}_\infty(z) = \sum_{n=0}^{\infty} a_n \frac{\vartheta_n(z)}{\lambda_n}$$

Substitution of (20b) into (20f) gives:

$$(21) \quad \bar{j}_\infty(z) = \sum_{n=0}^{\infty} \frac{\vartheta_n(z)}{\lambda_n} \int_0^{z_0} \bar{S}(z') \vartheta_n(z') dz'$$

where  $\bar{S}(z')$  is positive (hence a source).

Shulz and Lanzerotti (Ref. 45:39-40) point out that the directional flux  $j(E; \vec{r}) = p^2 f(p_{\parallel}, p_{\perp}; \vec{r})$  where  $f$  is the same distribution function as in this paper. Shulz (Ref. 47)

points out that  $j$  must be integrated over all angles in the unit sphere in  $p$ -space to obtain the omnidirectional flux  $J$ :

$$(22) \quad J = 4\pi p^2 \int_0^{\cos \alpha_0} j d(\cos \alpha).$$

Since

$$\frac{\sin^2 \alpha}{B} = \frac{\sin^2 \alpha_0}{B_0}$$

and

$$y^2 = \sin^2 \alpha \left( \frac{B_0}{B} \right),$$

it follows that

$$\cos \alpha = \sqrt{1 - y^2 \left( \frac{B}{B_0} \right)}$$

and that

$$d(\cos \alpha) = \frac{-\frac{1}{2}(B/B_0) d(y^2)}{\sqrt{1 - y^2(B/B_0)}}.$$

Now since

$$\cos^2 \alpha = 1 - \frac{B}{B_0}(1 - x^2) = 1 - \frac{B}{B_0}(y^2)$$

if  $\cos \alpha = \cos \alpha_0$ ,  $y^2 = y_0^2$ ; if  $\cos \alpha = 0$ ,  $y^2 = B_0/B$  and (22) becomes

$$J = 4\pi p^2 \int_{(B_0/B)}^{y_0^2} \frac{-\frac{1}{2}(B/B_0) j d(y^2)}{\sqrt{1 - y^2(B/B_0)}}$$

which, upon combining terms and reversing the limits (-):

$$(23) \quad J = 2\pi p^2 \int_{y_0^2}^{(B_0/B)} \frac{(B/B_0) j d(y^2)}{\sqrt{1 - y^2(B/B_0)}}.$$

Integrating (23) by parts

$$\int u dv = uv - \int v du \quad \text{where } u = j$$

$$dv = \frac{(B/B_0) d(y^2)}{\sqrt{1 - y^2(B/B_0)}},$$

$$v = -2 \sqrt{1 - y^2 \left( \frac{B}{B_0} \right)}$$

gives:

$$2\pi p^2 \left[ -2 \sqrt{1 - y^2 \left( \frac{B}{B_0} \right)} j \right]_{y_0^2}^{(B_0/B)} + \int_{y_0^2}^{(B_0/B)} 2 \sqrt{1 - y^2 \left( \frac{B}{B_0} \right)} \frac{\partial j}{\partial (y^2)} d(y^2)$$

and since

$$\frac{\partial j}{\partial (y^2)} = \frac{\partial j}{\partial z} \frac{\partial z}{\partial (y^2)}$$

will give (since the definite integral evaluates to zero, because  $\bar{f}$  is 0 at  $y_c$  by definition):

$$(24) \quad J = +2\pi p^2 \int_{y_c}^{(B_0/B)} 2\sqrt{1-y^2} \left(\frac{B_0}{B}\right) \frac{\partial f}{\partial z} \frac{\partial z}{\partial(y^2)} d(y^2).$$

But, from (12),  $dz = -y T(y) dy$ . So

$$\frac{dz}{d(y^2)} = \frac{-y T(y) dy}{d(y^2)} = \frac{-y T(y) dy}{2y dy} = \frac{-T(y)}{2}.$$

Hence, (24) ultimately becomes:

$$(25) \quad J = -2\pi p^2 \int_{y_c}^{(B_0/B)} \sqrt{1-y^2} \left(\frac{B}{B_0}\right) T(y) \frac{\partial \bar{f}}{\partial z} d(y^2).$$

Shulz then expands  $\bar{f}$  as a weighted series of eigenfunctions:

$$(26) \quad \bar{f} = \bar{f}_\infty(z) + \sum_{n=0}^{\infty} A_n(E, L; t) \bar{g}_n(z).$$

This allows the flux  $J$  in (25) to be written:

$$(27) \quad J = 2\pi p^2 \left[ -\int_{y_c}^{(B_0/B)} \sqrt{1-y^2} \left(\frac{B}{B_0}\right) \bar{f}'_\infty(z) T(y) d(y^2) - \sum_{n=0}^{\infty} A_n(E, L; t) \int_{y_c}^{(B_0/B)} \sqrt{1-y^2} \left(\frac{B}{B_0}\right) T(y) \bar{g}'_n(z) d(y^2) \right].$$

The following two expressions are derived in Appendix B.

$$(28) \quad \bar{f}'_\infty(z) = \sum_{n=0}^{\infty} \frac{\bar{g}'_n(z)}{\lambda_n} \int_0^{z_c} \bar{S} \bar{g}_n(z') dz',$$

$$(29) \quad \bar{g}'_n(z) = \frac{\sqrt{(2-\sigma)/z_c}}{J'_\nu(\kappa_{\nu n})} \left\{ \left( \frac{1-\sigma}{2z_c} \right) \left( \frac{z}{z_c} \right)^{-(\sigma+1)/2} J_\nu \left( \kappa_{\nu n} \left( \frac{z}{z_c} \right)^{1-(\sigma/2)} \right) + \left( \frac{z}{z_c} \right)^{(1-\sigma)/2} J'_\nu \left( \kappa_{\nu n} \left( \frac{z}{z_c} \right)^{1-(\sigma/2)} \right) \left[ \frac{\kappa_{\nu n}}{z_c} \left( 1 - \frac{\sigma}{2} \right) \left( \frac{z}{z_c} \right)^{-(\sigma/2)} \right] \right\}$$

The actual form of the flux equation awaits the choice of  $\sigma$ , which also determines the dependence of  $D_{zz}$  on  $z$ . Shulz uses  $\sigma = 0$  for purposes of comparison of several computational methods. This choice is also attractive because it makes  $D_{zz}$  independent of  $z$  (see 17(b)) which was a major assumption to begin with:

$$(30) \quad D_{zz} = D_{zz}.$$

This choice is made in the present study for the above reasons and also for the sake of simplicity in computations.

With  $\sigma = 0$ , the Bessel functions within eigenfunctions become order  $-1/2$ , which can be simply written as:

$$(31) \quad J_{-1/2}(R) = \sqrt{\frac{2}{\pi R}} \cos(R),$$

$$(32) \quad J'_{-1/2}(R) = -\sqrt{\frac{2}{\pi R}} \sin(R) - \frac{\cos(R)}{\pi R^2 \sqrt{2/(\pi R)}}$$

and the zeroes  $\kappa_n$  occur at  $(2n+1)(\pi/2)$ .

This simplifies (32), since the second term will always be zero if  $J'_{-1/2}(\kappa_n)$  is evaluated at  $\kappa_n = (2n+1)(\pi/2)$ .

Equation (32) becomes

$$(33) \quad \begin{aligned} J'_{-1/2}(\kappa_n) &= -\sqrt{\frac{2}{\pi(2n+1)(\pi/2)}} \sin\left((2n+1)\frac{\pi}{2}\right) \\ J'_{-1/2}(\kappa_n) &= \sqrt{\frac{2}{\pi(2n+1)(\pi/2)}} (-1)^{n+1}. \end{aligned}$$

The integral with respect to  $z'$  within (28) would thus be evaluated as:

$$(34) \quad \begin{aligned} &\int_0^{z_c} \frac{\sqrt{2/z_c} \sqrt{z'/z_c} \sqrt{\frac{2}{\pi(2n+1)(\pi/2)(z'/z_c)}}}{-\sqrt{\frac{2}{\pi(2n+1)(\pi/2)}} \sin\left((2n+1)\frac{\pi}{2}\right)} \cos\left((2n+1)\frac{\pi}{2z_c} z'\right) dz' \\ &= \int_0^{z_c} \frac{\sqrt{2/z_c} \cos\left((2n+1)(\pi/2z_c) z'\right) dz'}{-\sin\left((2n+1)(\pi/2)\right)} \\ &= \frac{\sqrt{2/z_c} \sin\left((2n+1)(\pi/2)(z/z_c)\right)}{\left((2n+1)(\pi/2z_c)\right)(-1)^{n+1}} \Big|_0^{z_c} \\ &= \frac{\sqrt{2/z_c} \sin\left((2n+1)(\pi/2)\right)}{\left((2n+1)(\pi/2z_c)\right)(-1)^{n+1}}. \end{aligned}$$

The  $\bar{\lambda}_n$  in (28) would be evaluated as (from (19)):

$$(35) \quad \bar{\lambda}_n = (2n+1)^2 \left(\frac{\pi}{2z_c}\right)^2 \bar{D}_{zz}.$$

The flux equation (27), using (31), (33), (34), and (35), will then simplify to the following for  $\sigma = 0$ :

$$\begin{aligned}
(36) \quad J = 2\pi p^2 & \left\{ - \int_{y^2}^{(B_0/B)} \sum_{n=0}^{\infty} \frac{\tilde{S}\sqrt{(2/z_c)} \sin((2n+1)(\pi/2))}{(2n+1)(\pi/2z_c)(-1)^{n+1}} \frac{1}{(2n+1)^2(\pi/2z_c)^2 D_{xx}} \right. \\
& \cdot \frac{\sqrt{2/z_c}}{\sqrt{\pi(2n+1)(\pi/2)}} (-1)^{n+1} \left\{ \left( \frac{1}{2z_c} \right) \left( \frac{z}{z_c} \right)^{-\frac{1}{2}} \sqrt{\frac{2}{\pi(2n+1)(\pi/2)(z/z_c)}} \cos\left( (2n+1) \frac{\pi z}{2 z_c} \right) \right. \\
& + \sqrt{\frac{z}{z_c}} \left( - \sqrt{\frac{2}{\pi(2n+1)(\pi/2)(z/z_c)}} \sin\left( (2n+1) \frac{\pi z}{2 z_c} \right) \right. \\
& \quad \left. \left. - \frac{\cos((2n+1)(\pi/2)(z/z_c))}{\pi(2n+1)(\pi/2)(z/z_c)^2 \sqrt{\pi(2n+1)(\pi/2)(z/z_c)}} \right) \right. \\
& \left. \cdot \frac{(2n+1)(\pi/2)}{z_c} \right\} \sqrt{1-y^2} \left( \frac{B}{B_0} \right) T(y) d(y^2) \Big] \\
& - \left[ \sum_{n=0}^{\infty} A_n(E, L; t) \int_{y^2}^{(B_0/B)} \frac{\sqrt{(2/z_c)}}{\sqrt{2/(\pi(2n+1)(\pi/2))}} (-1)^{n+1} \right. \\
& \cdot \left[ \frac{1}{2z_c} \left( \frac{z}{z_c} \right)^{1/2} \sqrt{\frac{2}{\pi(2n+1)(\pi/2)(z/z_c)}} \cos\left( (2n+1) \frac{\pi z}{2 z_c} \right) \right. \\
& + \sqrt{\frac{z}{z_c}} \left( - \sin\left( (2n+1) \frac{\pi z}{2 z_c} \right) \sqrt{\frac{2}{\pi(2n+1)(\pi/2)(z/z_c)}} \right. \\
& \quad \left. \left. - \frac{\cos((2n+1)(\pi/2)(z/z_c))}{\pi(2n+1)(\pi/2)(z/z_c)^2 \sqrt{2/(\pi(2n+1)(z/z_c))}} \right) \right. \\
& \left. \left. \cdot \frac{(2n+1)(\pi/2)}{z_c} \right] \sqrt{1-y^2} \left( \frac{B}{B_0} \right) T(y) d(y^2) \right] \Big\}.
\end{aligned}$$

Equation (36) reduces to the following upon simplification and cancellation of terms:

$$\begin{aligned}
(37) \quad J = 2\pi p^2 & \left( \left[ \int_{y^2}^{(B_0/B)} \sum_{n=0}^{\infty} \frac{\tilde{S}(2/z_c) \sin((2n+1)(\pi/2)(z/z_c))}{D_{xx} (2n+1)^2 (\pi/2z_c)^2 (-1)^n} \cdot \sqrt{1-y^2} \left( \frac{B}{B_0} \right) T(y) d(y^2) \right] \right. \\
& - \left[ \sum_{n=0}^{\infty} \frac{A_n(E, L; t)}{(-1)^n} \int_{y^2}^{(B_0/B)} \sqrt{\frac{2}{z_c}} \sin\left( (2n+1) \frac{\pi z}{2 z_c} \right) \left( (2n+1) \frac{\pi}{2 z_c} \right) \right. \\
& \left. \left. \cdot \sqrt{1-y^2} \left( \frac{B}{B_0} \right) T(y) d(y^2) \right] \right).
\end{aligned}$$

The first term in Equation (37) represents a steady state value of the flux, and the second term represents a sum of eigenmodes. Each  $A_n$  (Ref. 45:162) has the form  $a_n(L)e^{-t/(\tau_n(E))}$ . As  $n$  increases, the  $\tau_n$ 's become shorter; i.e., the higher eigenmodes decay faster, so that eventually only the fundamental mode is left, which decays exponentially. At  $t = \infty$ , the fundamental mode has reached zero, and only the flux remaining is the steady state flux, which corresponds to the natural environment background.

The remaining substitutions in (37) are  $z_c$ ,  $z$ ,  $T(y)$ , and  $y_c$ :

$$(38) \quad \begin{aligned} y_c &= \sqrt{\frac{1}{L^3 \sqrt{4 - (3/L)}}}, \\ z &= Z(y) = \frac{1}{2}(1 - y^2)T(0) - \frac{4}{11}[T(0) - T(1)](1 - y^{11/4}), \\ z_c &= Z(y_c) = \frac{1}{2}(1 - y_c^2)T(0) - \frac{4}{11}[T(0) - T(1)](1 - y_c^{11/4}) \end{aligned}$$

(as shown in Equation (14))  $T(y)$  is given by Equation (11).

The variable of integration in (37) is taken as  $y$  rather than  $y^2$  for simplicity of integration.

The preceding derivation has explicitly followed Shulz (1981). However, Shulz did not show how the differential-energy flux related to the integral-energy flux. Shulz and Lanzarotti (Ref. 45:163) state that the integral flux "will then scale as" the differential flux, without derivation. Since the AFWL trapped electron data base (Ref. 37) exists primarily as omnidirectional fluxes integrated over broad energy bandpass, the relation must be derived.

It will be shown in the following and Lanzarotti (Ref. 45) are indeed correct: The differential-energy flux equation (37) will scale as the integral flux, and the energy dependence will be imbedded in the constants for the source and the eigenmodes.

From Roederer (Ref. 39:86), the integral energy omnidirectional flux can be written:

$$(39) \quad J_{>E} = \int_E^{\infty} J dE$$

where  $J$  is the differential-energy flux, as in the previous equations, and  $J_{>E}$  is the integral energy flux above threshold energy  $E$ .

A principal assumption will be that energy and pitch angle are both independent variables of the flux. Thus, (26) would really look like

$$(39 a) \quad \tilde{J}(z, E) = \tilde{J}_{\infty_1}(E) \tilde{J}_{\infty_2}(z) + \sum_{n=0}^{\infty} A_n(E, L; t) \tilde{y}_n(z)$$

and hence in (25)  $\partial \tilde{J} / \partial z$  would look like

$$(39 b) \quad \frac{\partial \tilde{J}}{\partial z} = \tilde{J}_{\infty_1}(E) \tilde{J}'_{\infty_2}(z) + \sum_{n=0}^{\infty} A_n(E, L; t) \tilde{y}'_n(z).$$

Using (27), (39a) and (39b), Equation (30) becomes, at a given  $L$ -shell:

(40)

$$J_{>E} = -2\pi \int_E^\infty p^2 \bar{J}_{\infty_1}(E) dE \int_{z_1}^{z_2} \bar{J}'_{\infty_2}(z) dz - 2\pi \sum_{n=0}^{\infty} \int_E^\infty p^2 dE A_{nL}(E) \int_{z_1}^{z_2} \bar{J}'_n(z) dz$$

where  $\bar{J}'_{\infty_2}(z)$  and  $\bar{J}'_n(z)$  represent all of the angular-dependent functions of  $x, y,$  or  $z$  shown in (25) through (27).

Using the previously stated assumption (Ref. 45:162-163) that  $A_{nL}(E)$  are of the form  $a_n(E)e^{-t/(\tau_n(E))}$ , (40) becomes:

$$(41) \quad J_{>E} = -2\pi \int_E^\infty p^2 \bar{J}_{\infty_1}(E) dE \int_{z_1}^{z_2} \bar{J}_{\infty_2}(z) dz - 2\pi \sum_{n=0}^{\infty} \int_E^\infty p^2 a_n(E) e^{-t/(\tau_n(E))} dE \int_{z_1}^{z_2} \bar{J}'_n(z) dz$$

at a given  $L$ -shell.

To "remove" the energy dependence of the decay-time terms, the expectation value of  $e^{-t/(\tau_n)}$  is computed, assuming that the second term in (41) represents a distribution-function of the energies.

$$(42) \quad \langle e^{-t/(\tau_n)} \rangle \approx \frac{\int_E^\infty p^2 a_n(E) e^{-t/(\tau_n(E))} dE}{\int_E^\infty p^2 a_n(E) dE}$$

Then (41) can be written, using (42):

$$(43) \quad J_{>E} = 2\pi \left[ - \int_E^\infty p^2 \bar{J}_{\infty_1}(E) dE \right]_L \int_{z_1}^{z_2} \bar{J}'_{\infty_2}(z) dz - 2\pi \sum_{n=0}^{\infty} \left[ \int_E^\infty p^2 a_n(E) dE \right]_L \langle e^{-t/(\tau_n)} \rangle_L \int_{z_1}^{z_2} \bar{J}'_n(z) dz.$$

Now since it is assumed that the energy and angular shape functions are separable, the  $\bar{J}_{\infty_1}(E)$  must include only those parts of (28) which have energy dependence. The only terms in (28) which could have any energy dependence are  $\bar{S}$  and  $\bar{\lambda}_n$ .

Shulz (Ref. 47:23) notes that, while  $\bar{J}_{\infty}(z)$  resembles  $g_0(z)$  in functional form,  $\bar{J}_{\infty}(z)$  will coincide exactly with  $g_0(z)$  only if  $\bar{S}$  is directly proportional to  $g_0(z)$ . For simplicity, the assumption is made in this study that  $\bar{S}$  is constant over the interval  $0 \leq z \leq z_c$ . In physical terms, this really corresponds to a steady-state isotropic source. It is known that the natural environment is not isotropic over either space or time, but the variations are generally small compared to the variations from an injection by a nuclear event.

Now if  $\bar{S}$  and  $\bar{\lambda}_n$  are the only terms in (28) which may have energy dependence, then  $\bar{J}_{\infty_1}(E)$  in (43) would correspond to

$$\sum_{n=0}^{\infty} \frac{\bar{S}(E)}{\bar{\lambda}_n(E)},$$

and since the only portion of the  $\bar{\lambda}_n$  which may have any energy dependence (from (19)) is  $D_{xx}$ , then  $\bar{J}_{\infty_1}(E)$  should be proportional to

$$\frac{\bar{S}(E)}{D_{xx}(E)},$$

where  $\bar{D}_{ss}(E)$  may be a constant in  $E$ . There may, of course, be some other functional energy-dependence included in  $\bar{J}_{\infty_1}(E)$  which is yet-undetermined.

Equation (43) is generally of the same functional form as equation (37) if the terms in square brackets in (43) correspond to the combined constant terms in (37) as demonstrated above and as shown in Appendix D. Equation (43) also bears out Shulz and Lanzerotti's (Ref. 45:163) prediction that the integral flux scales with the differential flux; i.e., the "pitch-angle shape" dependence is invariant for differential- or integral-energy fluxes.

Since it is impractical to evaluate an infinite number of terms in (37), only the terms up to  $n = 3$  will be shown. Shulz and Lanzerotti (Ref. 45:163) state that the higher modes vanish for  $n > 2$ . This in fact means that the higher modes decay so rapidly that modes higher than  $n = 3$  should not be seen except at very early times. The final form of Equation (43), taken to  $n = 3$ , is shown in Appendix C. This is the form of the flux equation used in the data analysis, except that fewer terms were used than are shown in Appendix C.

The general solution for the differential-energy flux (which, from (43), is directly proportional to the integral-energy flux), using Bessel functions of arbitrary order and with  $\sigma$ -dependence explicitly shown, is given in Appendix D.

## IV. ANALYSIS OF DATA

The AFWL Trapped Electron Data Base consists of a set of computer tapes of satellite counting data which have been assembled from historical archives (such as the National Space Sciences Data Center, NSSDC) (Ref. 37). The data cover injections of electrons from nine high-altitude nuclear detonations shown in Table I (Ref. 6:6-2).

The Data Base has been organized by Pfitzer into a coherent set of tapes which present, by satellite, net electron omnidirectional integral-energy (above threshold) fluxes as a function of time,  $B$ , and  $L$ -shell. The computed errors for each data point, in units of flux, are also given. The background which was subtracted to give net flux is also given (Ref. 37:11, 188-189).

Additional data have been collected by AFWL from plots published in early literature. These plots have been photographically enlarged, and the data points digitized and placed in computer files with formats similar to the Pfitzer data (Ref. 12:670-671, Ref. 31:646-468, Ref. 38:637-638).

The satellites which provided the data, and their orbital parameters, are shown in Table II (Ref. 44:41-45).

The analysis of the data base required development of three computer programs by personnel at AFWL, in coordination with this author:

- (1) "Program DTABASE" to read raw data, organize it for processing, and output it into uniformly formatted files (Ref. 15).
- (2) A program to plot the raw data and to plot flux curves generated by the fitting program.
- (3) "Program Electrofit", a fitting program to take data points from DTABASE at a given  $L$ -shell and energy and to fit them with the theoretical model developed in this study. It also generates flux curves using the fitted functions at predetermined times to compare with the raw data (Ref. 34).

The first two programs were written with limited input from the author. The third was written under close and extensive coordination with this author, as discussed in this chapter.

The DTABASE program, written by Miss Cherise Jarrett of Computer Sciences Corporation, reads the raw data files, in various formats created by Pfitzer (Ref. 37), satellite by satellite, and stores them in a three-dimensional array. The points are then ordered (within each energy group) by increasing time since burst. To generate a file of points at a specified  $L$ -value, each data point  $L$ -value is compared to the desired  $L$  and is recorded in the output file if a match occurs. Additional points are "created" by linear interpolation of two successive data points if they fall on both sides of the desired  $L$  and if the data points differ in time by no more than a specified value. The interpolation is performed in  $L$ ,  $B$ , time, flux, and error. The output file can be restricted to a specified time "window" and to a specified range of  $B$  values, if desired; however, the data were analyzed over the full range of  $B$  and over all times which existed in the Data Base. The program has the additional capability to " $B$ -average" data points at the same  $L$  if their individual  $B$  values are within a user specified limit of each other and they are within the required time difference. This procedure has the effect of eliminating "double" points, and was used for the majority of this study with a limit of one percent. Another capability of the program is to interpolate to a specified  $B$ -value in a manner analogous to the  $L$ -interpolation described above; this capability was unused in this study (Ref. 15:1-2).

Table I. High-altitude nuclear detonations.

Event	Altitude (km)	Time (U.T.)	Date	Latitude	Longitude	Approximate L-Value of Detonation	Yield	Characteristics of Band	Approximate Decay Time
Teak	76.8	13:50:05	1 Aug 1958	17°N	169°W	1.12	MT Range	Low Altitude	~few days

Explorer 4	7-26-58	10-6-58	10-23-59	110.1	163	1372 (Ref. 44:41-45)	50.1

In order to determine the optimum time difference to use for interpolation across the desired  $L$ -value, the DTABASE program was modified under direction of this author. The program now presents a summary table of the raw data points for each satellite, showing the frequency of occurrence of time differences between successive data points from 0.1 minute to 5.0 minutes, by tenths of a minutes. The cumulative percentage of points with a specified time difference or less is also shown. These summaries are presented for the bursts and satellites examined as Tables III through XIII (Ref. 15:67-70). Perusal of these tables showed that the optimum time difference for interpolation was 2.2 minutes, primarily to include the maximum number of points in the Starfish Telstar file. This time difference was used for all data examined in this study.

A final capability of DTABASE is to add data points to a specified  $L$ -value file by rounding points in  $L$  to the desired value. This procedure assumes that points which are closer to the desired  $L$  than some specified limit may be considered to occur at the desired  $L$ . Within the errors in satellite measurements, this procedure is reasonable, and in fact appears (by data comparison) to have been used by Roberts (Ref. 41:310), although he does not so explicitly state. This capability exists in the program, but was not used in this study (Ref. 15).

The plotting program was developed by Mr. John Burgio of AFWL to generate all the plots of raw data and fitted curves shown in this report. The program plots raw data points beginning at a specified start time since burst (in days) and covering the time period in a specified time "window" (shown in Figure headings as "TW"). The  $L$ -value, equatorial  $B$ -value, and  $B$ -cutoff values are also shown. If the  $B$ -range of points is restricted, the minimum and maximum values of  $B$  are shown. The equatorial  $B$  value is computed from  $L$  by the relation

$$B_0 = \frac{0.308}{L^3}.$$

The  $B$ -cutoff value was initially computed by using the dipole formula (Ref. 39:55)

$$y_c = \sqrt{\frac{1}{L^3 \sqrt{4 - (3/L)}}} = \sqrt{(B_0/B_{cut})}.$$

However, it was later determined that this approximation might be less than optimum; so a table of  $L$ -values versus  $B_{cut}$  was used and was linearly interpolated across the tabulated  $L$ -values to find the  $B_{cut}$  value. This table (Table XIV) was prepared by AFWL from the 48-term Jensen-Cain model of the magnetosphere (Ref. 16). It was found that use of Table XIV produced  $B_{cut}$  (or  $y_{cut}$  or  $z_{cut}$ ) values more indicative of the global cutoff values. This table was used thereafter in both the plotting program and the fitting program (discussed below). This procedure is reasonable in view of the use of the same Jensen-Cain model to produce the  $B$ - $L$  coordinates for the Pfitzer Data Base (Ref. 37).

The plotting program plots flux as a function of  $x = \sqrt{1 - (B_0/B)}$ . It also has the capability to plot flux data points versus time over all values of  $L$  and  $B$ , or flux versus energy at specified  $B$  or  $L$ . Next to the satellite name on each plot which has fitted curves is a number in square brackets which corresponds to the serial number of the run of the fitting program which produced the curves.

This author's input to the plotting program was limited to supplying header information and specifying layout and format.

The third program used in data analysis is "Program Electrofit," written by Mr. Harry Murphy of AFWL with the close coordination of this author (Ref. 34). Electrofit is a least-squares fitting program which uses the functions developed by this author (Appendix C)

to fit data points which are output from DTABASE in order to compute the characteristic decay times ( $\tau_n$ ) and linear amplitude constants ( $a_n$ ). These decay times and constants are determined at the specific energy and  $L$ -value which are input with the data.

Note: The Table may be interpolated for other *L*-values (Ref. 16).

The overall flow for the program is as follows (see Appendix E):

- (1) Use an initial guess for the fundamental decay time and the theoretical ratios of the higher-mode decay times to compute the starting decay times. The first guess at fundamental decay time is shown in Table XV as a function of  $L$  and energy. This table is interpolated in  $L$  and  $E$  for starting value.
- (2) Numerically compute the integrals of the functions shown in Appendix C at each data point using the initial guessed decay times. The integration is performed by a 12-point Gauss/Legendre Quadrature at each data point for each function. Only the fundamental decay mode and two higher modes were computed.
- (3) Compute the linear amplitude constants using a least-squares matrix-solving routine. Compute the standard error of the fit. The individual points are weighted by the reciprocal of their fractional errors, which have been normalized to an average value of one.
- (4) Optimize the initially computed  $y_{cut}$  value by using a "Golden Section Minimum" function. This section attempts to let the data determine the "best" cutoff value. If the data are not distributed down toward the loss cone, the Golden Minimum function will provide an erroneous  $y_{cut}$  value. Hence, the function specifies that the computed  $y_{cut}$  must be within  $\pm 10$  percent of the initial input value. If, in the iteration process, the function tries to exceed these limits, the initial guess of  $y_{cut}$  is specified as the correct value.
- (5) Repeat the steps (2) and (3) with the optimum  $y_{cut}$  value.
- (6) To determine the best combination of decay times and amplitude constants, the decay times are changed by a "random-walk" method, either increased or decreased. The amount by which the decay times may randomly vary is determined by using a cumulative normal probability distribution about the initial value.

The standard deviation used was estimated according to this author's best guess of the accuracy of the tables and curves shown by Stassinopoulos (Ref. 53:31-32, 40-44) and West (Ref. 63:50-54). The Stassinopoulos tables do not always correlate with each other or with the Stassinopoulos curves, and the West curves do not always correlate with the Stassinopoulos in the  $L$ -regions of overlap. The initial fundamental decay times in Table XV were computed by this author by interpolation of the tables and curves in Reference 53 and by reading and extrapolation of the curves in Reference 63. The author's estimates of their standard deviations are shown in Table XVI. Of particular note is the very low confidence in decay times at high  $L$  values (above 2.2) and at high energies (above 2.0 MeV). There have been few computations of decay times in these regions, and the results vary widely (Refs. 53, 63).

The effect of using the cumulative normal probability distribution and the above standard deviations is to restrict the "random-walk" of the decay times away from their initial values. The farther away from the initial "mean value" that the random value generator places the new decay time, the greater the "push" that is created back toward the mean for the next walk. The distance away, however, is defined in terms of the standard deviation, so that  $r$  values in which there is low confidence may vary by larger amounts than may  $r$  values in which there is greater confidence. The  $r$ 's are also restricted by the constraint that  $r_0 > r_1 > r_2$ .

With each change of decay times, steps (2) and (3) are repeated up to 96 times, in an attempt to get a "better" fit by reducing the standard error of the fit.

(Computed from Ref. 53:31-32, 40-41 and Ref. 63:50-54)

Table XVI

Percent Standard Deviation of Initial  
Fundamental Decay Times (in Table XV)

<i>L</i> -Range	1.02- 1.20	1.21- 1.40	1.41- 1.80	1.81- 2.20	> 2.20
Energy Range MeV					
$E \leq 0.6$	50	30	20	35	200
$0.6 < E \leq 2.0$	30	20	20	75	100
$E > 2.0$	50	20	50	100	100

(estimated from Ref. 53:31-32, 40-44 and Ref. 63:50-54)

- (7) If a better fit is found in less than 96 random walks, and if less than 32 "better" values have been found, steps (2), (3) and (6) are repeated up to 32 times, using the latest "best" decay times.
- (8) Up to five repeats of steps (4) and (5) may be carried out, but only if 32 "better" fits are found. Otherwise, only the first  $y_{cut}$  optimization is performed.
- (9) The program will always end at the point where 96 random-walks have failed to reduce the error of the fit from the previous "best-fit". The decay times,  $y_{cut}$ , and amplitude constants are printed for each "better" fit, with the final values being those of the "best" fit.
- (10) After the best fit is found, the program uses the fitted constants and decay times to compute fluxes, at specified times, from the equator to the best cutoff value. These specified times correspond to default times plus 1/2 time window in the program which plots raw data. Thus, the computed fluxes are used to generate curves which are plotted over raw data points at approximately the same times.

Variations in the program were tried in order to study the effects of the fitting process. The principal modifications were in the random decay-time variations.

The first modification was to fix the ratios of the  $\tau$ 's to their theoretical values of 1:1/9:1/25 (Ref. 48:16-19). The effect of this modification is to significantly reduce the degrees of freedom available to fit the data.

The second modification was a compromise between the above and complete freedom to random walk. This variation allowed  $\tau_0$  and  $\tau_1$  to vary freely (subject to the usual constraint that  $\tau_0 > \tau_1$ ), but  $\tau_1$  and  $\tau_2$  were fixed at their theoretical ratio of 25:9. The principal reason for this attempt was the very short time-span covered by some satellite/burst combinations. For example, the Russian 2 Burst covered only 4 1/2 days prior to the Russian 3 injection. If the data cover a time-span which is small compared to the fundamental decay constant, then the fitted value of that decay time may be suspect. However, if the time-span is not so small compared to the decay times of the higher modes, one should have more confidence in the fitted values of those decay time. Stated another way, the fit may not be sensitive to the fundamental, but may still be sensitive to the higher modes.

In this analysis, not all  $L$ -values covered by the satellite in Table II were examined. Over 1000 plots of flux versus  $x$  were examined at various  $L$ -values for the satellite/burst combinations of Tables I and II. In many cases, the satellite orbits were of such high inclination (toward polar) that data were not available close to equatorial  $B$ -values. Because of this, and because of the very large volume of data, those satellite/burst/ $L$  combinations which provided the most consistent coverage from the equator to the loss cone were chosen for study.

Generally, the data fell into three regions of  $x$ -space (with some overlap). Region I was from the equator to the point where flux dropped off sharply into the loss cone ( $x = 0$  to  $x \approx 0.6$  or  $0.8$ ). Region II was the area where the flux "turned the corner" from a rather "horizontal" curve to a rather "vertical" curve into the loss cone ( $x \approx 0.7$  to  $0.9$ ). Region III was the loss cone region, where the flux levels dropped sharply to the cutoff value ( $x \approx .9$  for a typical  $L$ -value).

Representative plots of raw data in the three regions are shown in Figures 4 through 8. These plots are typical in that data seldom cover all three regions in a short time-span. Gaps in the data appear because of satellite orbital coverage and because of lack of on-satellite recorders. When a satellite lacked a recorder, data were collected only as the satellite passed above the radio horizon of a ground tracking station. Figure 9 is an eight-hour plot of typical satellite coverage over all *B-L* space.

Figures 10 (a) through (g) shows raw data from Explorer XV over the time period of the Russian 2 and 3 bursts, at times corresponding to those shown in Figure 3, for comparison. It is apparent that fewer points are plotted from the AFWL data base in Figures 10 (a) through (g) than were plotted by Roberts in Figure 3 for the 1.9 Mev electrons, even though the satellite and time periods of coverage were the same. These discrepancies are not resolved in this study, although the previously alluded-to  $L$ -rounding procedure may account for the differences.

The temporal progression of flux after one burst from one satellite (Telstar), at a typical  $L$ -value of 1.9, is shown in Figures 11 (a) through (h). Again, typical gaps in coverage of Regions I, II, and III are readily apparent over the 90 days shown.

As previously noted, only fundamental and two higher eignemodes ( $f_0, f_1, f_2$ ) are used to fit the satellite data (Appendix C). The third eigenmode ( $f_3$ ) is not used because Shulz and Lanzerotti (Ref. 45:163) suggest that the modes greater than two rapidly vanish. Initially, the steady-state function ( $f_\infty$ ) was used along with the fundamental, but this solution was found to be "competing" with the fit for the fundamental, in the sense that the linear constants tended to be roughly equal in magnitude and tended to alternate in sign. Shulz (Ref. 47:22-23) indicates that the  $f_\infty$  and  $f_0$  functions should resemble each other in shape. Also, Pfitzer (Ref.37) has subtracted the background from all flux data, and the background should approximate the steady-state,  $f_\infty$ , solution. For these reasons, the steady-state solution was not used in the data fit.

## V. RESULTS AND DISCUSSION

Figures 12 and 13 show the typical temporal progression of raw data at two representative  $L$  values,  $L = 2.3$  and  $L = 2.4$ . Included on those figures are the flux curves calculated from the amplitude coefficients and decay times fitted to that data by Electrofit. As previously noted, the curves shown on any given figure may vary slightly in time from the individual data points, since the curves represent only the one time-instant corresponding to the start time plus one-half the time window of the plot. Figures 12 and 13 represent maximum freedom of the fit, since each  $\tau$  is free to vary independently of the other  $\tau$ 's.

Figure 14 shows the same temporal data progression with different fitted curves. The curves in this figure were calculated under the restriction that the ratios of the  $\tau$ 's were fixed at the theoretical values of 1:1/9:1/25; hence, only  $\tau_1$  was really varying in a random sense.

Figure 15 shows similar data progression and fitted curves where the  $\tau$ 's were allowed to freely vary, subject to the constraint that  $\tau_0 > \tau_1 > \tau_2$ . Also, this was an initial run with 500 tries for convergence, vice 96 tries. In addition, the computed flux was used in the iteration process to eliminate non-physical (negative) solutions. The solution was restricted to being positive at four different times and at five different equatorial pitch angles. Although this is an initial run with only a small amount of data used, it indicates that the recommendations in Chapter VI should be pursued.

Table XVII shows the fitted linear amplitude coefficients and exponential decay times (in days) at constant Energy and  $L$ -shell for a representative subset of the data examined in this study. The sheer volume of resultant fits and calculated curves made it impossible to include all results in this report. The values shown in Table XVII were computed with the  $\tau$ 's allowed to vary freely.

Figures 12 and 13 are considered representative of the results of the fitting model. It is apparent from examination of Figures 12 and 13 that the pitch-angle diffusion theory and flux computation method developed in this report are consistent with experimental measurements. Higher eigenmodes are readily discernible at the lowest energy in the Figures or the first five days, and are not visible at later times. These higher eigenmodes are not discernible in the plots at the higher energies; Table XVII shows that these modes are present, but at much lower levels, in some cases. The calculated curves show a reasonable fit to the data even at late times, consistent with the assumption of exponential decay.

Examination of Figures 14 and 15 shows that some inconsistencies remain to be resolved in the use of this fitting method. The calculated flux curves for the low-energy data points also appear to be slightly lower than optimum, while the high-energy data appears to be fitted better by the model. This may be partially explained by the existence of many lower data points in the vicinity of the loss cone which tend to "drag down" the overall fit. Any change in the cutoff value significantly affects the fit by shifting the "vertical" portion of the curve toward or away from those points. However, this cannot account for the entire difference of the curves from the data. The energy dependence may be treated less than optimally in the choice of functional solution made in this study. If the chosen functional solution is not the correct one, it may be nevertheless close enough to correct to give a reasonable fit at high energy, but be significantly in error at lower energy. A different functional solution may fit the lower-energy groups better and yet still fit the high-energy electrons as well. Recommendation for the use of other functions is made in Chapter VI.

The short time-spans covered by most of the data sets in the Trapped Electron Data Base have not allowed adequate determination of  $\tau_0$ . The values of  $\tau_0$  presented in Table XVII are suspect for this reason. However, more confidence is held in the values of  $\tau_1$  and  $\tau_2$  computed by this study. In most data sets studied, the time period of the data was long enough compared to the values of  $\tau_1$  and  $\tau_2$  to compute reasonable values. More consistency between data sets was found for  $\tau_1$  and  $\tau_2$  than was found for  $\tau_0$ . Of course, then  $\tau_0$  may be simply computed by multiplying  $\tau_1$  by the theoretical ratio corresponding to the solution.

## VI. CONCLUSIONS AND RECOMMENDATIONS

### Conclusions

The pitch-angle diffusion theory and flux calculation method developed in this study are reasonably consistent with experimental data in most cases. The method shows promise as a way of calculating improved decay times over a broad region of the magnetosphere, particularly for higher energy electrons. Additionally, a comprehensive summary table of the best available literature values for  $\tau_0$  has been prepared (Table XV). A complete table covering such a broad range of energy and  $L$  has not heretofore been compiled.

Time and computer limitations have precluded examination of the entire data base. However, the overall efficiency of the model developed in this study has been demonstrated. It is expected that improved predictions of fluxes and improved inputs to the AFWL SPECTER Codes (Ref. 7-9) will be available as a result of this work. This will enhance the capability for calculation of satellite operational environments, and will improve the ability to predict satellite survivability and vulnerability.

### Recommendations

The following recommendations for further study are proposed to improve the model developed in this study, and to resolve the problem of non-physical solutions for some data sets. At the direction of this author, several of these recommendations are presently being implemented at the Air Force Weapons Laboratory.

- (1) Incorporate an estimation of the error in the magnetic field value,  $B$ , of individual data points. This corresponds to a "horizontal" error bar on the plots such as Figure 12. It is known that errors exist in the computation of the  $B$  value associated with each data point, and this error would prove significant in the region of the loss cone. Improved weighting of the data points with the combined errors should improve the fit.
- (2) Utilize the  $L$ -rounding procedure of Chapter IV to add data points to each  $L$ -value considered. This should aid in filling gaps in the data, which necessarily will improve the fit.
- (3) Discard the highest eigenmode if the fitted value of its decay time is less than 0.25 day, and fit the data with only the fundamental and one higher mode. A value of 0.25 day is not reasonably fitted within the errors in the Trapped Electron Data Base. This mode would be essentially lost within the first day in any case.
- (4) Perform an "energy-scaling" of the data to combine data from different satellites. This involves assuming some form of energy spectrum, such as  $e^{-(E/E_0)}$ , including an estimate of the error in the assumed value of  $E_0$ . The new flux would be simply the old flux multiplied by a factor  $e^{-(E_{new}-E_{old})/E_0}$ . If the error in the old flux were 50 percent (a value consistent with the Data Base) and the error in  $E_0$  were 25 percent, and if  $E_0 \approx 1.1$  (a fission spectrum), then the resultant error in the shifted flux would be less than 1 percent different from that of the old flux, when shifting from 660 KeV to 500 KeV. Thus, it should be possible to combine data sets and fill the gaps in data to achieve a better fit. However, the limitation of the assumed spectrum still exists.

- (5) Utilize only late-time data where it is available, and fit only the fundamental mode to it, under the assumption that higher modes will have decayed away. Then, with the fundamental mode constrained, go back to early time data and attempt to fit higher modes, if any. This recommendation is of limited value because only two data sets cover a significant period of time: Starfish/Telstar and Russian 3/Explorer 5. However, it may provide a better value of  $\tau_0$  than is presently available at some  $L$  values.
- (6) Revise the fitting functions to other Bessel function solutions than the  $J_{-1/2}$  solution and compare results. This was performed only on one other functional solution,  $J_0$ , with only one small data set, and the results showed no improvement over the present study. However, to be certain that the author has not simply chosen the wrong functional form, more functional forms must be investigated.
- (7) In the fitting program, constrain the directional flux to physical reality at each iteration (i.e., compute flux at each iteration and reject non-physical solutions at each iteration, rather than after converging on a final solution). This should converge to a physically real solution if it converges at all; however, significant increases in computer processing time may accrue.
- (8) Increase the number of tries for a solution from 96 to 200 and reduce the number of outer loops from 32 to 10 or 15. This may improve the convergence of the least squares error, if non-physical solutions are also rejected at each iteration.
- (9) Compare the background subtracted from the flux with the latest available natural environment, to ascertain the correctness of the background subtraction. If significant differences are found, the background should be re-added to the flux and the natural environment subtracted.
- (10) A suggestion proposed by Professor D.G. Shankland, Air Force Institute of Technology, involves a significant modification to the fitting method. This method involves an interpolating function, or measure of "roughness" of the fit, which may be made arbitrarily smooth. The advantage of this method is that no limiting assumptions need be made about the data. The chief disadvantage is that the method is a strictly mathematical method, with no physical constraints. Although the method would involve extensive reprogramming, it promises worthwhile information about the flux curves, and should be tried.

## APPENDIX A

### Demonstration of Zero Diffusion Current at the Magnetic Equator for Half-Integer Bessel Function Solution

To demonstrate zero diffusion current, one must show that

$$\lim_{z \rightarrow 0} D_{zz} \mathcal{Y}'_n(z) = 0$$

for the  $\sigma = 0$  case. We know that from (31):

$$J_{-1/2}(z) = \sqrt{2/(\pi z)} \cos(z)$$

and from (16):

$$D_{zz} = D_{zz_0}$$

and from (18):

$$\begin{aligned} \mathcal{Y}_n(z) &= \frac{\sqrt{2/z_0}}{J'(\kappa_n)} \sqrt{z/z_0} \sqrt{\frac{2}{\pi(2n+1)(\pi/2)(z/z_0)}} \cos\left((2n+1) \frac{\pi}{2} \frac{z}{z_0}\right) \\ &= \left[ \frac{\sqrt{2/z_0} \sqrt{4/(\pi^2(2n+1))}}{J'(\kappa_n)} \right] \cos\left((2n+1) \frac{\pi}{2} \frac{z}{z_0}\right). \end{aligned}$$

Hence, the derivative of the eigenfunction:

$$\mathcal{Y}'_n(z) = - \left[ \frac{\sqrt{2/z_0} \sqrt{4/(\pi^2(2n+1))}}{J'(\kappa_n)} \right] \left[ (2n+1) \frac{\pi}{2z_0} \right] \sin\left((2n+1) \frac{\pi}{2} \frac{z}{z_0}\right).$$

Finally, the quantity which must go to zero is:

$$D_{zz} \mathcal{Y}'_n = - \left[ \frac{D_{zz_0} \sqrt{2/z_0} \sqrt{4/(\pi^2(2n+1))} ((2n+1) \pi/(2z_0))}{J'(\kappa_n)} \right] \sin\left((2n+1) \frac{\pi}{2} \frac{z}{z_0}\right)$$

The term in square brackets is a finite constant for any  $n$ , and clearly the sine goes to zero as  $z$  goes to zero. Hence, the limit is zero.

## APPENDIX B

### Derivation of Eigenfunction Derivatives $f'_{\infty}$ and $f'_n$

To find the derivative of the steady state function,  $f_{\infty}$ , one starts with (21):

$$f_{\infty} = \sum_{n=0}^{\infty} \frac{g_n}{\lambda_n} \int_0^{z_c} S(z') g_n(z') dz'$$

If the  $\lambda_n$  are assumed (from (19)) independent of  $z$ , then the series can simply be differentiated term-by-term, since the definite integral is simply a constant for each value of  $n$ .

$$\begin{aligned} f'_{\infty}(z) &= \frac{d}{dz} \left[ \sum_{n=0}^{\infty} \frac{g_n(z)}{\lambda_n} \int_0^{z_c} S g_n(z') dz' \right] \\ &= \sum_{n=0}^{\infty} \frac{g'_n(z)}{\lambda_n} \int_0^{z_c} S g_n(z') dz'. \end{aligned}$$

To find the derivative of the eigenfunction  $g_n$ , one starts with (18):

$$g_n(z) = \frac{\sqrt{(2-\sigma)/z_c} \left(\frac{z}{z_c}\right)^{(1-\sigma)/2} J_{\nu} \left( \kappa_{\nu n} \left(\frac{z}{z_c}\right)^{(1-\sigma/2)} \right)}{J'_{\nu}(\kappa_{\nu n})}$$

Using the product rule for differentiation:

$$\begin{aligned} g'_n &= \frac{d}{dz} (g_n(z)) \\ &= \left[ \frac{\sqrt{(2-\sigma)/z_c}}{J'_{\nu}(\kappa_{\nu n})} \right] \left\{ \left( \frac{1-\sigma}{2} \right) \left( \frac{1}{z_c} \right) \left( \frac{z}{z_c} \right)^{-(\sigma+1)/2} J_{\nu} \left( \kappa_{\nu n} \left( \frac{z}{z_c} \right)^{(1-\sigma/2)} \right) \right. \\ &\quad \left. + \left( \frac{z}{z_c} \right)^{(1-\sigma)/2} J'_{\nu} \left( \kappa_{\nu n} \left( \frac{z}{z_c} \right)^{(1-\sigma/2)} \right) \left[ \frac{\kappa_{\nu n}}{z_c} \left( 1 - \frac{\sigma}{2} \right) \left( \frac{z}{z_c} \right)^{-\sigma/2} \right] \right\} \end{aligned}$$

## APPENDIX C

### The Specific Solution of the Integral-Energy Omnidirectional Flux Equation for the Half-Integer Bessel Function Solution

The integral-energy omnidirectional flux Equation (43), which is the energy-integrated form of Equation (37), is represented as the steady state term,  $f_{\infty}$ , plus the sum of exponentially decaying eigenmodes  $f_0$  through  $f_3$ :

$$J_{>E}(y = \sqrt{B_0/B}) = f_{\infty} + f_0 + f_1 + f_2 + f_3$$

In this appendix, each term is shown, as derived from Equations (37) and (43). Note that the eigenmode sum should be infinite, but only the fundamental mode and three higher modes are shown.

The constants in each term are defined as follows (Ref. 39:55):

$$y_0 = \sqrt{1/(L^3 \sqrt{4 - (3/L)})}$$

$$T_0 = 1 + \left\{ \left( \ln[2 + \sqrt{3}] \right) / (2\sqrt{3}) \right\} \approx 1.3801730$$

$$T_1 = (\pi\sqrt{2})/6 \approx 0.7404805$$

$$K = (4/11)[T_0 - T_1] \approx 0.2328155$$

$$Z_0 = T_0(1 - y_0^2) - K(1 - y_0^{11/4})$$

The "fitting constants" are defined as in Equation (43) or in Appendix D:

$$S = \int_E^{\infty} p^2 f_{\infty_1}(E) dE$$

$$a_n = \int_E^{\infty} p^2 a_n(E) dE$$

$$f_{\infty} = 2\pi S \int_{y=y_0}^{y=\sqrt{B_0/B}} \frac{\left[ (4/Z_0)(\pi/Z_0) \left[ \sqrt{1 - y^2(B/B_0)} \right] [T_0 - (T_0 - T_1)y^{3/4}] y \right]}{(\pi/2Z_0)^2}$$

$$\left\{ \frac{\left( \frac{\sin[(\pi/2Z_0)((1 - y^2)T_0)/2 - K(1 - y^{11/4})]}{1} \right)}{\frac{\sin[(3\pi/2Z_0)((1 - y^2)T_0)/2 - K(1 - y^{11/4})]}{9}} \right.$$

$$\left. + \frac{\left( \frac{\sin[(5\pi/2Z_0)((1 - y^2)T_0)/2 - K(1 - y^{11/4})]}{25} \right)}{25} \right\}$$

$$\frac{(\sin[(7\pi/2Z_c)((1-y^2)T_0)/2 - K(1-y^{1/4})])}{49} dy$$

$$f_0 = -2\pi a_0 e^{-(t/\tau_0)} \int_{y=y_0}^{y=\sqrt{R_0/B}} \left[ \sqrt{2/Z_c} (\pi/Z_c) \left[ \sqrt{1-y^2(B/B_0)} \right] \left[ T_0 - (T_0 - T_1)y^{3/4} \right] y \right] \left( \sin \left[ (\pi/(2Z_c)) \left( ((1-y^2)T_0)/2 - K(1-y^{1/4}) \right) \right] \right) dy$$

$$f_1 = +2\pi a_1 e^{-(t/\tau_1)} \int_{y=y_0}^{y=\sqrt{R_0/B}} \left[ \sqrt{2/Z_c} (3\pi/Z_c) \left[ \sqrt{1-y^2(B/B_0)} \right] \left[ T_0 - (T_0 - T_1)y^{3/4} \right] y \right] \left( \sin \left[ (3\pi/(2Z_c)) \left( ((1-y^2)T_0)/2 - K(1-y^{1/4}) \right) \right] \right) dy$$

$$f_2 = -2\pi a_2 e^{-(t/\tau_2)} \int_{y=y_0}^{y=\sqrt{B_0/B}} \left[ \sqrt{2/Z_c} (5\pi/Z_c) \left[ \sqrt{1-y^2(B/B_0)} \right] \left[ T_0 - (T_0 - T_1)y^{3/4} \right] y \right] \left( \sin \left[ (5\pi/(2Z_c)) \left( ((1-y^2)T_0)/2 - K(1-y^{1/4}) \right) \right] \right) dy$$

$$f_3 = +2\pi a_3 e^{-(t/\tau_3)} \int_{y=y_0}^{y=\sqrt{B_0/B}} \left[ \sqrt{2/Z_c} (7\pi/Z_c) \left[ \sqrt{1-y^2(B/B_0)} \right] \left[ T_0 - (T_0 - T_1)y^{3/4} \right] y \right] \left( \sin \left[ (7\pi/(2Z_c)) \left( ((1-y^2)T_0)/2 - K(1-y^{1/4}) \right) \right] \right) dy$$

These fitting constants are really functions of energy and  $L$ -shell.

The ratios of  $\tau_0$ ,  $\tau_1$ ,  $\tau_2$ , and  $\tau_3$  should be (as computed from the eigen value ratio of the zeroes of the function):

$$\begin{array}{ll} \tau_0 \approx 9\tau_1 & \text{or alternatively} & \tau_1 = (1/9)\tau_0 \\ \tau_0 \approx 25\tau_2 & & \tau_2 = (1/25)\tau_0 \\ \tau_0 \approx 49\tau_3 & & \tau_3 = (1/49)\tau_0 \end{array}$$

## APPENDIX D

### The General Solution of the Integral-Energy Omnidirectional Flux Equation for Bessel Functions of Arbitrary Order, as a Function of Sigma

Substitution of (18), (28), and (29) into (27) completes the general expression for the differential energy omnidirectional flux,  $J$ , with Bessel functions of order

$$\nu = \frac{\sigma - 1}{2 - \sigma}$$

where  $\sigma$  is some number less than two:

$$\begin{aligned}
 J = 2\pi p^2 \left\{ \left( - \int_{y_0}^{(B_0/B)} \sum_{n=0}^{\infty} \frac{\bar{S}}{\lambda_n} \int_{z'=0}^{z'-z} \frac{\sqrt{(2-\sigma)/z_0} \left(\frac{z'}{z_0}\right)^{(1-\sigma)/2}}{J'_{\nu}(\kappa_{\nu n})} J_{\nu} \left( \kappa_{\nu n} \left(\frac{z'}{z_0}\right)^{1-(\sigma/2)} \right) dz' \right. \right. \\
 \bullet \frac{\sqrt{(2-\sigma)/z_c} \left[ \left( \frac{1-\sigma}{2z_c} \right) \left(\frac{z}{z_c}\right)^{-(\sigma+1)/2} J_{\nu} \left( \kappa_{\nu n} \left(\frac{z}{z_c}\right)^{1-(\sigma/2)} \right) \right. \\
 \left. \left. + \left(\frac{z}{z_0}\right)^{(1-\sigma)/2} J'_{\nu} \left( \kappa_{\nu n} \left(\frac{z}{z_0}\right)^{1-(\sigma/2)} \right) \right] \left( \frac{\kappa_{\nu n}}{z_c} \left(1 - \frac{\sigma}{2}\right) \left(\frac{z}{z_c}\right)^{-(\sigma/2)} \right) \right] \\
 \bullet \sqrt{1 - y^2(B/B_0)} T(y) d(y^2) \\
 - \left( \sum_{n=0}^{\infty} \Lambda_n(E, L; t) \int_{y_0}^{(B_0/B)} \frac{\sqrt{(2-\sigma)/z_c}}{J'_{\nu}(\kappa_{\nu n})} \right. \\
 \bullet \left[ \left( \frac{1-\sigma}{2z_c} \right) \left(\frac{z}{z_c}\right)^{-(\sigma+1)/2} J_{\nu} \left( \kappa_{\nu n} \left(\frac{z}{z_c}\right)^{1-(\sigma/2)} \right) \right. \\
 \left. \left. + \left(\frac{z}{z_0}\right)^{(1-\sigma)/2} J'_{\nu} \left( \kappa_{\nu n} \left(\frac{z}{z_0}\right)^{1-(\sigma/2)} \right) \right] \left( \frac{\kappa_{\nu n}}{z_c} \left(1 - \frac{\sigma}{2}\right) \left(\frac{z}{z_c}\right)^{-(\sigma/2)} \right) \right] \\
 \bullet \sqrt{1 - y^2(B/B_0)} T(y) d(y^2) \left. \right\}
 \end{aligned}$$

The analogy between the above equation and Equation (43) is seen if:

$$\left[ \int_E^{\infty} p^2 \bar{J}_{\infty_1}(E) dE \right]_L = \int_E^{\infty} p^2 \bar{S} / \bar{D}_{zz} dE$$

and if:

$$\begin{aligned}
 \left[ \int_E^{\infty} p^2 a_n(E) \right]_L (c - t/(\tau_n))_L &= \int_E^{\infty} p^2 dE \Lambda_{nL}(E) \\
 &= \int_E^{\infty} p^2 a_n(E) e^{-t/(\tau_n(E))} dE
 \end{aligned}$$

Hence, (43) is simply the energy-integrated form of (37).

# APPENDIX E

Flow Chart for Program Electrofit

## VITA

Roger Scott Dewey was born on August 15, 1947 in Akron, Ohio. He graduated from Tallmadge High School, Tallmadge, Ohio, in 1965 and attended Brown University, from which he received the Degree of Bachelor of Science in Chemistry in January 1970. Upon graduation, he received a commission in the USN through the NROTC program. He completed flight training and received his wings in April 1971. He has served as an SH-3 pilot and flight instructor in Helicopter Antisubmarine Squadrons at Naval Air Stations Quonset Point, Rhode Island and Jacksonville, Florida. He served as Assistant Air Operations Officer and UH-1N pilot aboard the USS Guadalcanal, LPH-7, out of Norfolk, Virginia, until entering the School of Engineering, Air Force Institute of Technology in August 1981.
