ABSTRACT

Advanced commercial and military gas turbine engines may operate at combustor outlet temperatures in excess of 1920K (3000°F). At these temperatures combustor liners experience extreme convective and radiative heat fluxes. The ability of a plasma sprayed ceramic coating to reduce liner metal temperature has been recognized. However, the brittleness of the ceramic layer and the difference in thermal expansion with the metal substrate has caused cracking, spalling and some separation of the ceramic coating. Research directed at turbine tip seals (or shrouds) has shown the advantage of applying the ceramic to a compliant metal pad. This paper discusses recent studies of applying ceramics to combustor liners in which yttria stabilized zirconia plasma sprayed on compliant metal substrates which were exposed to near stoichiometric combustion, presents performance and durability results, and describes a conceptual design for an advanced, small gas turbine combustor. Test specimens were convectively cooled or convective-tipspiration cooled and were evaluated in a 10 cm square flame tube combustor at inlet air temperatures of 533K (800°F) and at a pressure of 0.5 MPa (75 psia). The ceramics were exposed to flame temperatures in excess of 2100 K (3700°F). Results appear very promising with all thirty specimens surviving a screening test and one of two specimens surviving a cyclic durability test.

INTRODUCTION

The current trend in advanced military and commercial transport engines is to fuel efficient, durable, and environmentally acceptable engines of ever increasing pressure ratio and turbine inlet temperature. This trend has produced a more severe environment in which the entire hot section, and in particular the combustor liner, must operate.

Ceramic materials offer distinct advantages in combustors by reducing the required quantity of air used for liner cooling. The practical limit for most metal liners is near 1100K and requires substantial quantities (near 50%) of the total combustor airflow for cooling. Ceramics can withstand bulk temperatures near 1920K and thus require significantly less air for cooling.

Small gas turbine combustors, and in particular, small reverse flow annular combustors, exhibit the highest cooled surface area to combustor volume ratio. These combustion systems therefore require some of the highest cooling air flows for their survival. An engine cycle temperature approach 1920 K for these engines, it has become extremely difficult to design a satisfactory high temperature reverse flow annular combustor. The felt-ceramic concept, though by no means fully developed, offers the high temperature performance of a ceramic, plus the potential damage tolerance of a ductile metallic substrate. The introduction of these materials, if feasible, into this engine size may begin to open a new plateau of performance and efficiency.

The control and management of the air freed by the use of advanced technology liners has been a very successful approach to controlling emissions and improving combustor durability (refs. 1 & 2). Also, the hotter liner walls obtainable with ceramics will reduce the unburned hydrocarbon and carbon monoxide emissions that arise from liner thermal quenching of the combustor reactions during part power operation (ref. 3). It may now be possible to take advantage of these benefits of ceramics by the introduction of a compliant, low density sintered metal layer between a thick ceramic and a solid metallic substrate. This technique reduces the thermal stresses in the ceramic and allows the pressure stresses to be absorbed by the metallic substrate. This property may avoid ceramic spallation during thermal cycling of the liner.

Although relatively little work has been done to investigate the use of ceramic materials as combustor liners, significant research has been conducted in the application of ceramics to turbine gas path seal systems. Systems based on hot-pressed silicon carbide (SiC) and Si-SiC composites (ref. 4), ceramic honeycomb (ref. 5), sintered silicium dioxide (SiO2) (ref. 6), and plasma sprayed SiO2 (ref. 7) have been...
assessed for use as seal systems. Of these, the greatest activity is in perfecting systems utilizing plasma sprayed yttria stabilized ZrO₂ for resistance to cracking and spalling caused by thermal induced stresses; and oxidation caused by prolonged exposure to high temperatures. There are two methods known for reducing or eliminating the thermal stress generated in a plasma sprayed ZrO₂ seal system. These methods are shown in figure 1. One is to grade the material properties in a stepwise or continuous manner by grading the material composition from fully metallic adjacent to the substrate to fully ceramic adjacent to the gas path. This method is summarized in reference 7. The other method is to incorporate a low density, sintered metal pad or compliant layer between the ceramic layer and the metallic substrate, as described by Briemken (ref. 8). This strain isolator will elastically absorb the stresses generated during thermal cycling by the mismatch in the coefficients of thermal expansion of the ceramic and metal and by the difference in temperature of the ceramic and metal components. Applying a thin NICALON bond coat developed by Stoeckers (ref. 9) to the system with the low modulus pad gave this system particularly good resistance to thermal shock failure (ref. 10). The work of Bill (ref. 11) compares both of these methods under similar test conditions. He concluded that the low modulus substrate approach proved to be more effective for reducing thermal stresses in the ceramic layer and preventing spalling than the sprayed, graded composition approaches. To minimize the temperature at the interface between the ceramic layer and the low density sintered metal layer and therefore hopefully increase the specimens life, a transpiration cooled version of the low modulus substrate design was also investigated.

Sukolowski (ref. 12) has shown that the current trend in advanced combustor liner designs is to a segmented shingle approach. For this reason the low modulus substrate concept was configured into a test specimen of appropriate size for a turbofan engine combustor liner segments as shown in figure 2.

This report will discuss combustor evaluations of thirtty combustor liner specimens fabricated by plasma spraying yttria stabilized zirconia on compliant low modulus substrates. Specimens were evaluated for thermal performance and durability. A conceptual design for an advanced, small gas turbine combustor is presented along with a description of critical areas for future research.

MATERIALS

The substrate material chosen for the plasma sprayed yttria stabilized zirconia and two yttria stabilized zirconias, Nicro 202 (98% Y₂O₃-ZrO₂) and Nicro's 98 Y₂O₃-ZrO₂. Ceramic powders were plasma sprayed to thicknesses of 0.19 and 0.35 mm. The lower limit was determined by successful turbine shroud seal designs and the upper limit by the desire to investigate thick ceramics as set by the maximum limit capability of the plasma spray process used.

The backing for all specimens was a 0.06 cm thick Inconel Alloy 718 sheet. All backing sheets had sixteen 0.10 cm diameter holes Electric Discharge Machined (EDM) along the front and back edges to cool the attachment areas.

All felt pads were brazed to Inconel 718 backing plates after EDM completion using a high temperature nickel base brazing metal compatible with both the felt and backing as described in reference 13. After brazing, the specimens were inspected and cleaned by alumina grit blasting immediately prior to application of a bondcoat. All specimens were plasma sprayed with a 0.008 to 0.013 cm thick Ni-15.2 Cr-5.5 Al-0.67 bondcoat. Specimens were then plasma spray coated with the selected ceramic in a continuous spray to the desired thickness as tabulated in table 1. Transpiration cooled specimens were fabricated in the same manner as the respective cooled specimens described above and are shown in figure 3. These specimens contained 3 arrays totaling 44 counter flow cooling passages 0.13 cm wide and 1.9 cm long and 0.11 cm deep.

APPARATUS AND PROCEDURE

The gas turbine combustor test rig used for this evaluation is shown in figure 4. The test rig was designed and fabricated by General Electric Science Laboratory (GE) of West Lynn, New York. The experimental evaluation of the thirty test specimens was also conducted at GEAL and is described in greater detail in reference 14. The test rig was designed as a segment of a large annular combustor and produces a premixed propane-air flame stabilized by a perforated plate flameholder. The hot section is 10 cm x 10 cm with film cooled liners as the top and bottom sections and ceramic coated water cooled sides.

The combustor section is shown schematically in figure 5. This figure illustrates the placement of the felt ceramic test panels and the variable flow film cooling slots upstream of the felt ceramic panels. This cooling slot was designed to admit from 0% to 30% of the total combustor airflow to film cool the test panels. The panels were mounted 7 cm downstream of the flameholder exit plane.

All test specimens were instrumented from three to nine thermocouples. Thermocouples were placed on the back surface of the Inco 718 sheet, at the felt-brazing interface, and at the ceramic-felt interface. All thermocouples were installed after completion of the plasma spray process used for specimen fabrication. Interface thermocouples were closed end couples inserted into a hole drilled to the desired
interface depth. Backsurface thermocouples were open ball type spot welded to the backing. Figure 6 depicts the location of thermocouples whose temperature data is presented later in this report.

The transpiration cooled specimens were calibrated in an atmospheric stand to determine the flow characteristics of the coolant passages for various pressure drops. During these measurements conducted both before and after hot testing, the edge cooling holes located along the front and back of the backing were sealed.

The felt-ceramic specimens were tested at an inlet pressure of 0.5 MPa, an inlet air temperature of 538°C, a primary zone equivalence ratio of 0.63 with a resultant adiabatic flame temperature of 2170°C. The differential pressure drop across the panel was 0.0163 MPa or 1% of the inlet air pressure. The combustor reference velocity was 25 m/sec. All specimens were convectively cooled on their back surfaces by bypass air at 493 K with a velocity of 13.6 m/s. The specimens were film cooled by 16 of the total entrance airflow of 0.83 kg/sec. The variable cooling air slot was incorporated to thermal protect the specimens in the event it was needed. A complete listing of all test conditions is presented in Table 2. For the transpiration cooled panels, the primary zone equivalence ratio was established as 0.68 ± 0.01. All other conditions were the same as Table 2 values.

Combustion testing was divided into screening tests and endurance tests. In the screening tests the conditions of Table 2 were maintained for 3 minutes followed by a shutdown. The shutdown procedure involved an abrupt fuel shut-off to provide the greatest possible thermal shock, followed by a gradual cessation of air flow. This sequence was repeated four times.

Endurance testing was similar to screening tests except that the test conditions of Table 2 were maintained for 2 minutes, followed by a shutdown. This shutdown was followed by abrupt fuel shut-off followed by a gradual cessation of air flow. This sequence was repeated 30 times. The 30-cycle sequence was run as 5 multiples of 6 cycles. Each multiple of 6 cycles was run at 24 hour intervals. This down time was required to reheat the noninitiating pebble bed preheater used for these tests.

RESULTS AND DISCUSSION

Screening Tests

The operating conditions for the screening tests, discussed earlier, are given in Table 2. After conduct of the screening test on all 30 specimens, none of the panels showed any visible evidence of deterioration or failure except for the discoloration of the ceramic and back surfaces. There were no multidepth cracks, felt-ceramic separations, or felt-backing separations on any of the panels. The ceramic surfaces of all the panels, after the screening tests, are shown in Figure 7. The black-gray material on the ceramic surfaces of panels 8, 9, and 10 is a slag deposition from a flameholder burnout which occurred during an aborted screening test of these panels. The combustor rig was then repaired and these panels retested. They also displayed no visible signs of distress after testing.

It was expected that some of the specimens would have displayed varying degrees of distress after conduct of the screening tests, and that their physical condition would be the basis for their performance ranking. However, all post test inspections showed the specimens in excellent condition with no visible performance discriminators between them. Therefore, a combination of theory and experiment was employed to rank the performance of the various panel designs.

There are two areas critical to the performance of this low modulus substrate concept. First, the temperature at the felt-ceramic interface must be below approximately 1240 K to reduce or eliminate the growth of NiO oxidation modules at this interface. The growth of these nodules results in oxidation induced cracks with subsequent ceramic spallation. Secondly, the ceramic layer itself must operate in a range where structurally and thermally induced stresses are not beyond the ceramic's capability.

Figure 8 depicts the measured thermocouple data for all 22 convectively cooled test specimens. The solid curves are theoretical heat transfer calculations based on ceramic and felt material properties published in references 10, 13, and 15. The thermal analysis was based on reference 14 for the overall characterization of the radiative and convective heat transfer. The data from references 17 and 18 for the effects of the film cooling slot on the hot side convective heat flux.

The data of figure 8 displays extreme scatter in both the backing felt and felt-ceramic interface temperature data. Most measured interface temperatures appear well below the theoretical level. Although this scatter could be generated by non-uniform crossstream temperature and velocity profiles it is most likely caused by the partial failure of the metal to ceramic interface thermocouples. Previous attempts to measure the interface temperatures were done by welding thermocouples to the felt during the manufacturing process prior to plasma spraying the bond coat and the ceramic. Although this method provided accurate placement and measurement of the temperature, cyclic testing of these specimens resulted in failures at the thermocouple locations. For this reason closed ball thermocouples were installed after complete specimen fabrication. The thermocouple ball was held against the interface by the spring pressure of a HICAILT ribbon spot welded to the back of the specimen. It is felt that during thermal cycling of the specimen, this pressure was relaxed or removed resulting in loss of contact between the thermocouple and the interface. This phenomena would result in low measured temperatures. For this reason, a qualitative theoretical method was used for the selection of the two specimens for durability testing.
Referring to figure 3 one can see that the axial edge of a the ceramic layer are constrained by a compressible fiberfax layer against the combustor side walls. Consequently, specimen thermal expansion of the ceramic will produce only low compressive stresses. Since the compressive strength of the ceramic is high, ceramic adherence is not likely to cause ceramic 57 failure. The front and back edges of the ceramic, on the other hand, are free to move.

The temperature of the felt-ceramic interface governs the potential relative thermal expansion between the felt pad and ceramic layer. the strength of both materials, the thermally induced surface stress on the ceramic, and the oxidation resistance of the felt. At the measured values of the felt-ceramic interface temperatures, typically about 900°C, the felt pad has a very low yield strength of about 7 x 10^6 N/m². Consequently, it is unlikely that the felt pad could produce a significant level of stress on the ceramic.

Full analysis of thermal stress induced failure of the ceramic panels requires detailed consideration of shutdown transient as well as steady state temperature distributions, interfacial shear stresses and normal stresses, and some ability to track changes in ceramic layer compliance as "modul" cracks develop. Such analysis requires accurate and detailed temperature dependent material properties. It is assumed that failure mechanisms are driven by tensile stresses in the ceramic-bondcoat interface, and the time dependent effects of oxidation and stress relaxation drive the failure. It is recognized that failure is not always driven by a single failure mechanism, but the assumed failure mechanism is driven by tensile stresses in the ceramic-bondcoat interface, and the time dependent effects of oxidation and stress relaxation drive the failure. It is assumed that failure mechanisms are driven by tensile stresses in the ceramic-bondcoat interface, and the time dependent effects of oxidation and stress relaxation drive the failure. It is assumed that failure mechanisms are driven by tensile stresses.

Table 3 presents the analytical temperature difference across the ceramic layer and the felt-ceramic interface temperatures for the specimen matrix of Table 1 at the mid-axis, mid-plane thermocouple locations of figure 6. This table assumes that the thermal properties of the two ceramics and the two felts tested are similar and that the thermal conductivity of the felt was dependent upon density.

This tabulation shows that increasing the ceramic thickness from 0.19 cm to 0.33 cm or 74% results in a 66% increase in the ceramic thermal gradient (ΔT) while only reducing the felt-ceramic interface temperature by approximately 3%. For 0.19 cm thick ceramic layers, increasing pad density from 35% to 45% density increases ceramic ΔT's by 10% to 15% while decreasing felt-ceramic interface temperatures by approximately 5%. The lowest ceramic ΔT's occurred for the 0.19 cm thick ceramic coupled with the 35% density pad. In this combination of materials increasing pad thickness from 0.25 cm to 0.30 cm resulted in a 9% ceramic ΔT decrease but increased the felt-ceramic interface temperature by 4% and resulted in the highest felt-ceramic interface temperature of the entire matrix. For these reasons two specimens #3, #4 from the group of 0.19 cm thick ceramic, 0.25 cm thick 35% density felt for durability testing. These two specimens were both plasma sprayed with the Y₂O₃-ZrO₂ ceramic, with 87 fabricated of N875 pad material and #28 of N534 material.

Endurance Tests

After completion of the screening tests, panels #7 and #28 were selected from among the group exhibiting lowest stress levels for further testing to evaluate their endurance characteristics. The selection criteria were low stress levels in panels with approximately the same properties but with different pad materials. These two specimens both had a 1.9 cm thick Y₂O₃-ZrO₂ ceramic over an approximately 35% dense 2.5 cm thick pad. For exact specifications refer to Table 1.

These two specimens were then exposed to 30 thermal cycles to the conditions of Table 2 as previously described. Both panels completed the endurance test procedure without failure. Panel #7, shown in figure 16, shows some discoloration of the ceramic and back surface. A closeup view of the ceramic surface reveals modul cracks. These cracks are found over the surface and show no preferential location. The ceramic did not separate from the intermediate felt pad and there is no visible damage to the felt pad, the backing, or the felt-backing interface. The black-grey material seen on the ceramic surface 31 is the slag deposition from the flameholder burnout noted earlier. Figure 11 depicts specimen #28 after the endurance test. This panel did display failure where 5 major cracks linked up over approximately 50% of the ceramic surface. Figure 12 depicts the same specimen after removal of the loose ceramic. The spalling that did occur was not limited entirely to the felt-ceramic interface as approximately 10% of the interface area in the spalling region is still covered with ceramic. Despite the fact that 50% of the ceramic surface was not attached to the pad, when the rig was disassembled after completion of the endurance tests, this loose ceramic was found in place on the pad surface. The major loose pieces fell off as the specimen was removed from the rig and the missing piece in the center of figure 11 was damaged at this time. This failure would be indicative of critical internal ceramic stresses. The complete survival of specimen #7 may indicate the superiority of the N875 pad material when compared to specimen #28 which is otherwise similar except that the pad is of N 534 alloy. However, the success or failure of the single test does not present a satisfactory statistical basis for firm conclusions about the superiority of N875 pad material at this time.
Transpiration Coold Specimen Tests

The flow characteristics of the eight transpiration cooled panels, identified in Table 1, were measured in an atmospheric discharge test stand before and after undergoenth screening tests. The mass flow results are shown in figure 1. Regression analysis was used to yield the same mass flow rate for a given pressure drop. This design goal is essentially verified by the results and, as expected, the measured mass flow rate is proportional to the square root of the pressure drop. An average 12% decrease in the mass flow rate of all panels is observed after undergoing combustion testing. This is due to oxidation of the felt pad material which tends to reduce its porosity. This trend may have a significant effect upon the service life of the specimens if oxidation closure of the coolant passages continues at this rate.

The backface temperatures recorded for the transpiration cooled specimens are tabulated in Table 4. Using the pre-test flow calibrations of figure 9, each transpiration cooled specimen flowed 0.015 kg/s or approximately 2% of the total combustor airflow. The temperatures recorded are remarkably cool and certainly attest to the efficiency of transpiration cooling.

Since there were no interface thermocouples installed in the transpiration cooled specimens, and the analytical heat transfer model used to predict interface and ceramic surface temperatures of the convective cooled specimens could not model the transpiration cooling, no calculations are attempted on these specimens. It is expected that the transpiration cooling would have a similar effect of reducing the felt-ceramic and ceramic surface temperatures.

If the transpiration cooling scheme were to be applied to a typical axial, annular modern small gas turbine combustor, it would require approximately 12% of the total combustor airflow for liner cooling. This compares most favorably with the current requirement of approximately 50% of the total combustor airflow for liner cooling.

SUMMARY OF RESULTS

Experiments were conducted to evaluate a new felt-ceramic composite material for use as a combustor liner material. Experiments included a combustor screening test of 32 convectively cooled and 8 transpiration cooled specimens and a 30 cycle endurance test of 2 specimens to near stoichiometric combustion temperatures.

Combustor screening tests exposed all 30 test specimens to temperatures of 2170 K for 4 cycles. These tests did not experimentally discriminate between the test specimens as all 30 specimens showed no visible evidence of deterioration or failure except for dislocation of the ceramic and back surfaces. There were no mudflat cracks, felt-ceramic or backing-felt separations on any of the panels. The transpiration cooled specimens clearly documented the ability of this cooling scheme to keep the backface temperature and therefore all interface and ceramic surface temperatures extremely cool. While the convectively cooled specimens recorded backface temperatures near 900 K, the transpiration cooled specimens were typically less than 350 K. A combination of experimental data, theoretical heat transfer calculations, and fundamental stress analyses was therefore used to select 2 specimens for the durability tests.

Combustor durability tests exposed 2 selected test specimen configurations thought to have the lowest internal ceramic stresses based on low indicated temperature gradients, to temperatures of 2170 K for 90 thermal cycles. This repeated thermal cycling produced non-catastrophic mudflat cracks in the ceramic coating of one test specimen and caused partial ceramic separation from the felt pad in the other test specimen.

The results of this program suggest the superiority of a system composed of the BRUSHWOOD (2) B-875 compliant pad at approximately 0.25 cm thickness and 354 density, coupled with a NiCrAlY bond coat and a 8% Y2O3 - 6% O2 ceramic top coat of approximately 0.15 cm thickness. Results also indicate the outstanding cooling performance of the transpiration cooling scheme and the need to further investigate this system.

FUTURE APPLICATIONS

The benefit of a felt-ceramic composite liner in a gas turbine combustor is primarily realised by operating the engine at elevated temperatures which results in improved engine cycle efficiency. However, many problems currently exist and must be resolved before a viable felt-ceramic combustor concept can be demonstrated. Composite matrix properties such as ceramic type and thickness, pad type, thickness and density, and substrate selection must be determined. These properties should be optimised by a unified design system taking into account the fundamental characteristics of the individual materials and the required isothermal performance of the combustor. Although numerous difficulties currently exist, the technology to solve these problems is within the realms of feasibility. In particular, the composite matrix properties need to be integrated into a 3-D finite element structural analysis.

Preliminary evaluation reported herein has shown that the integrity of the ceramic can be maintained even when exposed to near stoichiometric combustion temperatures with backside cooling provided by convection or by pseudo-transpiration techniques. A proposed design for a combustor applicable to a small gas turbine engine is shown in figure 12. This design takes advantage of a simple circumferentially stacked ring construction which minimizes axial stresses. In this design the thickness and density of the ceramic layer and the substrate can be varied from zone to zone to account for the differences in cooling requirements imposed by the combustion gases and the backside coolant.
flows in each zone. The stacked ring construction also has the potential for lower manufacturing costs, the elimination of the sealing problems inherent with segmented tile construction, simpler mounting to the engine casing, and elimination of flame tube annulus blockage present in a segmented tile design.

While the composite liner approach is potentially applicable to most high temperature combustors, where high cycle efficiency and low specific fuel consumption is paramount, the example selected is related to small advanced gas turbine engines. Due to the inherent geometric constraints, a small combustor has a relatively large surface-to-volume ratio as compared to large combustors. If in addition a reverse-flow design is considered the surface-to-volume ratio is even more critical. Thus, due to the large cooling requirements, the greatest potential and hence, the greatest benefit exist for composite application in the small combustor.

While a reverse-flow design is presented in figure 13, the principle is equally applicable to axial configurations. It would be expected that performance improvements would be most dramatically achieved in the smaller combustor because of the narrow annular height and the influence of wall quenching on part power efficiency. In addition, where it is located, the hightest system wall effects would be expected to be less pronounced.

ACKNOWLEDGEMENTS

The authors would like to thank Mr. Jack Brown of NASA for plasma spray fabrication of the test specimens and Mr. R. S. Venkat Raman and Dr. Gerald Hof for the conduct of the evaluation program at General Applied Science Laboratory.

Figure 13. - Felt-ceramic combustor concept for advanced small reverse flow combustor.
Advanced commercial and military gas turbine engines may operate at combustor outlet temperatures in excess of 1920 K (3000° F). At these temperatures combustor liners experience extreme convective and radiative heat fluxes. The ability of a plasma sprayed ceramic coating to reduce liner metal temperature has been recognized. However, the brittleness of the ceramic layer and the difference in thermal expansion with the metal substrate has caused cracking, spalling and some separation of the ceramic coating. Research directed at turbine tip seals (or shrouds) has shown the advantage of applying the ceramic to a compliant metal pad. This paper discusses recent studies of applying ceramics to combustor liners in which yttria stabilized zirconia plasma sprayed on compliant metal substrates which were exposed to near stoichiometric combustion, presents performance and durability results, and describes a conceptual design for an advanced, small gas turbine combustor. Test specimens were convectively cooled or convective-transpiration cooled and were evaluated in a 10 cm square flame tube combustor at inlet air temperatures of 533 K (500° F) and at a pressure of 0.5 MPa (75 psia). The ceramics were exposed to flame temperatures in excess of 2000 K (3320° F). Results appear very promising with all 30 specimens surviving a screening test and one of two specimens surviving a cyclic durability test.
