**ABSTRACT (Continue on reverse side if necessary and identify by block number)**
We have measured the translational energy release for processes I and II using the Molecular Beam Time-of-Flight method.

\[ \text{C}_2\text{H}_2 \xrightarrow{193 \text{ nm}} \text{C}_2\text{H} + \text{H} \quad (I) \]

\[ \text{C}_2\text{H} \xrightarrow{193 \text{ nm}} \text{C}_2 + \text{H} \quad (II) \]

(continued on reverse)
By measuring the maximum release of translational energy for process I it has been determined that the C-H bond energy in acetylene, $D_0(C_2H-H)$ is $132 \pm 2$ kcal/mol. Since the translational energy distribution peaks well away from zero, it is quite unlikely that internal conversion of the electronically excited $C_2H_2$ is an important channel for dissociation in channel I. Because of the relatively small amount of energy appearing as product rotation, it is possible to get information on the vibrational structure of $C_2H$ radical from the translational energy distribution and it is found that the bending frequency in $C_2H$ is $550 \pm 100$ cm$^{-1}$. Our experiment is consistent with earlier work which observed $C_2(1\pi_u)$ in fluorescence.

THE PHOTODISSOCIATION OF ACETYLENE AT 193.3 nm

We have measured the translational energy release for processes I and II using the Molecular Beam Time-of-Flight method:

(I) \[ \text{C}_2\text{H}_2 \xrightarrow{193 \text{ nm}} \text{C}_2\text{H} + \text{H}_2 \]

(II) \[ \text{C}_2\text{H} \xrightarrow{193 \text{ nm}} \text{C}_2 + \text{H}_2 \]

By measuring the maximum release of translational energy for process I it has been determined that the C-H bond energy in acetylene, \( D_0(\text{C}_2\text{H}-\text{H}) \), is 132 \( \pm \) 2 Kcal/Mol. Since the translational energy distribution peaks well away from zero, it is quite unlikely that internal conversion of the electronically excited \( \text{C}_2\text{H}_2 \) is an important channel for dissociation in channel I. Because of the relatively small amount of energy appearing as product rotation, it is possible to get information on the vibrational structure of \( \text{C}_2\text{H} \) radical from the translational energy distribution and it is found that the bending frequency in \( \text{C}_2\text{H} \) is 550 \( \pm \) 100/cm. Our experiment is consistent with earlier work which observed \( \text{C}_2(1\pi_u) \) in fluorescence.
THE PHOTODISSOCIATION OF ACETYLENE AT 193.3 nm

INTRODUCTION

Acetylene is an important hydrocarbon in the area of combustion and has received a great deal of attention in the past. The ultraviolet spectrum in the 200 nm range was analyzed and found to be due to absorption to a trans-bent $^1A_u$ excited state.\textsuperscript{1,2} Electron energy loss spectroscopy was used to place the approximate energy of two low lying triplet states.\textsuperscript{3} One aspect of this molecule which is still quite uncertain, however, is the C-H bond energy, $D_o(C_2H-H)$. The lowest dissociative ionization threshold, producing $C_2H^+ + H + e^-$, was measured to be 17.365 eV by Dibeler, Walker and McCulloh\textsuperscript{4} (DWM) and more recently in a molecular beam by Ono and Ng\textsuperscript{5} (ON) to be 16.79 eV. Combining the ionization potential (IP) of $C_2H$ radical\textsuperscript{6,7} with these thresholds, $D_o(C_2H-H)$ can be derived. In an analogous way the electron affinity of $C_2H^8$ was combined in a thermochemical cycle with the acidity of $C_2H_2^9$ and the IP of H to give $D_o(C_2H-H)$. But due to the systematic deviations between experiments, the uncertainty in the determination of $D_o(C_2H-H)$ has not been smaller than 0.5 eV. Recently, ab-initio calculations have given a bond energy of 127 kcal/mol with an estimated error of 2 kcal/mole.\textsuperscript{10}

The advent and commercialization of excimer lasers (specifically ArF lasers at 193.3 nm) has allowed considerable advance in the study of the photochemistry of the $^1A_u$ absorption system. Irion and Kompa\textsuperscript{11} have used an unfocused ArF laser to dissociate acetylene in a gas cell, analyzing
the collisionally quenched, stable products with time-of-flight mass spectrometry. They concluded that C-H bond rupture is the primary, unimolecular dissociation pathway.

\[ \text{C}_2\text{H}_2 \xrightarrow{193 \text{ nm}} \text{C}_2\text{H} + \text{H} \]  

McDonald, Baranovski, and Donnelly\(^1\) and more recently Okabe, Cody, and Allen\(^1\) have used a focused ArF laser (\(3 \times 10^{26}\) photons/cm\(^2\) second) to photolyze acetylene. They observed two and three photon absorption processes to form \(\text{C}_2\) and \(\text{CH}\) in excited electronic states which were observed by dispersed fluorescence spectroscopy. Again, using a strongly focused ArF laser, emission from electronically excited C atom was observed by Miziolek, et al.\(^1\)

In order to better understand the dynamics of the primary photodissociation processes involved and in an effort to nail down \(D_0(\text{C}_2\text{H}-\text{H})\) in acetylene, we have recently performed molecular beam experiments designed to measure the translational energy release of fragments from the photolysis of acetylene at 193.3 nm under collision free conditions.

**EXPERIMENTAL**

The experiments were performed on a new molecular beam apparatus designed specifically for crossed laser, molecular beam photodissociation studies. Some of the features of this machine are shown in Fig. 1. The instrument consists of three parts: a rotating molecular beam source, a fixed, ultra-high vacuum, mass–spectrometric detector, and a "main" interaction chamber.
A continuous molecular beam was formed by passing 250 torr of a 15 percent mixture of acetylene in neon through a dry ice ethanol trap to remove acetone and expanding it through a 0.125 mm nozzle into the source region. The source region is pumped by two 6" diffusion pumps which do not move with the rotating source and maintain a pressure of 10^{-4} torr when the beam is on. The beam is skimmed and a region of differential pumping intervenes between the source region and the main chamber. The differential region is normally at 10^{-5} torr and is pumped by a 350 liter/sec turbomolecular pump which rotates with the source. A pulsed laser beam, which propagates along the rotation axis of the beam source, crosses the molecular beam creating a pulse of dissociation products.

A small angular fraction of this pulse of products will travel through two regions of differential pumping, spreading as it goes due to the velocity distribution of the nascent products. The pulse of dissociation products is then ionized in a liquid nitrogen cooled chamber (typically 10^{-10} torr), by a Brink-type, electron-impact ionizer. Ions produced are directed through a quadrupole mass filter then to a Daly-type ion counter, made up of an ion target, a scintillator and a photomultiplier tube. The transient pulse or time-of-flight (TOF) spectrum is recorded on a 255 channel scaler operating as a pulse counter with a minimum channel width of 1 \mu sec which is triggered by the laser pulse. For high TOF resolution using a 1 \mu sec channel width, a digital delay was introduced on the trigger of the multi-channel scaler so that the transient pulse would be recorded in as many of the 255 channels as possible. The data acquisition is overseen and directed by a macro program running on a DEC LSI-11 lab computer.
Typically, data produced by one million laser pulses are collected at a repetition rate of 150 Hz for each TOF spectrum.

The holes in the detector walls between 3 and 7 in fig. 1 are precision machined and define the "viewing window" of the detector. These are placed so that the detector "sees" all parts of the 3mm x 3mm x 1mm interaction volume (at 3) for all angles to which the beam source can rotate. One might think that the background in the detector that is created by the operation of the molecular beam could be calculated from the conductance of the defining slits and the pumping speeds of the pumps on each region of differential pumping according to the following equation.

\[ P_{Detector} = P_{Main \ Chamber} \left( \frac{C_1}{S_1} \right) \left( \frac{C_2}{S_2} \right) \left( \frac{C_3}{S_3} \right) \]

Where

- \( P_{Detector} \) = partial pressure in the detector
- \( P_{Main \ Chamber} \) = partial pressure in the main chamber
- \( C_i \) = Conductance of each differential pumping aperture
- \( S_i \) = Pumping speed of each pump on each differential pumping region

But for those molecules that travel straight through all of the differential pumping apertures, the above equation will not apply. This so-called "direct-through background" cannot be decreased by any number of differential pumping regions. When this is the limiting source of background in the detector, the above equation will always calculate a background level much lower than that which is experimentally observed. Since the pressure in the main chamber is \( 2 \times 10^{-7} \) torr, the mean free path
is much larger than the dimensions of the chamber itself. For this reason "direct through background" cannot come from collisions with other molecules within the viewing window of the detector. It can only be formed by first bouncing off of surfaces that are within the viewing window of the detector. Consequently a closed cycle refrigerator was used to cool a copper collimation slit to 300K at 2 in fig. 1. This lowers the background, originating from the main chamber, by a factor of ten. In addition to this, liquid nitrogen is supplied to the main chamber and cools large copper panels which serve as cryopumps. Undissociated acetylene strikes one of these panels. This is an effective beam catcher for condensible gases.

Data analysis consists of finding the center-of-mass frame translational energy distribution function, P(E_T), from the observed laboratory frame time-of-flight spectra. For the analysis of primary dissociation processes we use the "forward convolution" method. This means that we guess at a trial P(E_T) and calculate what our data should look like, taking into consideration several instrumental averaging factors including: beam velocity and angular dispersion, ionizer length, detector angular resolution and multichannel scaler channel width. We then alter the P(E_T) until the calculated TOF fits the data. For secondary dissociation (i.e. in the case where primary photolysis products are themselves photolyzed) we use a similar program which performs much more averaging. In a sense looking at secondary dissociation is like looking at a primary process with a very poorly defined molecular beam. In this forward convolution program, the entire primary dissociation flux map in the three dimensional laboratory frame is calculated. This flux map is converted to number density and used
to characterize the angular and velocity distributions of the "molecular beam" to which the primary process gives rise.

Experiments were done at two nozzle temperatures to observe the influence of unrelaxed bending vibrations in acetylene and also a neat beam of acetylene was used for low laser power experiments. Table I gives the beam characteristics.

The laser was a Lambda-Physik EMG 103 MSC Excimer laser and was run with ArF. Typically, 100 mJ/pulse at 150 Hz were obtained and focused to a 1 mm x 3 mm rectangular spot.

RESULTS AND ANALYSIS

Laser photolysis gives signal at mass-to-charge ratios (m/e) of 25, 24, 13, and 12 amu. From the comparison of TOF spectra we know that the signal at m/e=13 and 12 comes from electron-impact induced dissociative ionization of neutral products of masses 25 and 24. The TOF spectra at 20° for ion masses 25 and 24 are shown in Fig. 2. The m/e=25 signal can only come from C₂H radical produced in the photolysis process. C₂H⁺ ion formed in the ionizer can easily fragment to C₂⁺ and gives rise to some of the signal at m/e=24. If C₂H were the only neutral product the m/e=25 and 24 spectra would be identical, apart from a very small difference in the flight time of the ions. The m/e=24 spectrum shows a substantial amount of signal arriving at significantly shorter arrival times (higher translational energies) than the C₂H product and hence we conclude that C₂ is also formed in the collisionless photolysis. As will be shown in the next section from the laser power dependence of the dissociation signal,
processes I and II which involve sequential photolysis of $\text{C}_2\text{H}$ are responsible for the observed data.

\[
\text{C}_2\text{H}_2 \xrightarrow{193 \text{ nm}} \text{C}_2\text{H} + \text{H} \quad \text{(I)}
\]

\[
\text{C}_2\text{H} \xrightarrow{193 \text{ nm}} \text{C}_2 + \text{H} \quad \text{(II)}
\]

The determination of $D_0(\text{C}_2\text{H-H})$ in acetylene relies on the principle of conservation of energy. When acetylene absorbs a photon at 193.3 nm it has 148 kcal/mol of energy at its disposal. We assume that the $\text{C}_2\text{H}$ radical appearing with maximum translational energy corresponds to the ground state fragment. The validity of this assumption will be discussed later. The difference between the photon energy and the maximum translational energy release is $D_0(\text{C}_2\text{H-H})$. Although we can neglect any rotational energy of the parent acetylene which is well relaxed during the supersonic expansion, we cannot ignore unrelaxed vibrational energy in the two, doubly degenerate bending modes which can contribute to the translational energy of the products. The frequencies of these two vibrations are 611 cm\(^{-1}\) and 729 cm\(^{-1}\) which correspond to about 3kT at room temperature. These will not be cooled efficiently in the supersonic expansion. In principle, one could remove these "hot bands" by cooling the nozzle, but in practice it is necessary to avoid cluster formation at low temperatures by heating the nozzle and identifying the contribution from the bending modes by observing a temperature dependent increase in the fastest products.
A.) Time-of-Flight Spectra of \( \text{C}_2\text{H} \) at 300°K Nozzle Temperature

Figure 3 shows the Newton diagram of the photolysis experiment for the 15 percent acetylene seeded in neon beam maintaining the nozzle temperature at 300°K. The purpose of a Newton diagram is to clarify the relationship between the lab frame of reference and the center-of-mass frame of reference. The bold arrow represents the molecular beam velocity in the lab frame. The center-of-mass of the system travels inertially along this vector. Vectorially adding the beam velocity vector to any center-of-mass frame vector yields the corresponding laboratory frame vector. The circles which are drawn centered on the tip of the beam vector indicate various recoil speeds in the center-of-mass frame of reference for the \( \text{C}_2\text{H} \) fragment, that is, all lab velocities observed on a given circle are from the same center-of-mass recoil speed of the dissociating fragment. Figure 3 indicates the relative translational energy release to which these \( \text{C}_2\text{H} \) fragment speeds correspond for process I. One can see that molecules with a large amount of internal excitation and hence low center-of-mass translational energies will not be scattered far from the beam. It is therefore necessary to look as close as 6° to the beam to see the most internally excited products. A more subtle, experimental consideration comes from the fact that the resolution of the measurement of the laboratory velocity is limited by the ratio of the length of the ionizer to the total flight length, according to the following relationships.
of degrees of freedom and the excellent signal/noise in our data, 16.25 ± 2 kcal/mole is an accurate determination of the maximum release in translational energy and hence, the bond energy in acetylene is found to be 132 ± 2 kcal/mole.

If Frank-Condon considerations prevent the formation of any C₂H in the vibrationless ground state, the value 132 kcal/mole would be an upper limit to the bond energy. Recently, very accurate ab-initio calculations have been performed by Melius et al.¹⁰. These have given a value of 127 kcal/mole for the bond energy. Single reference configuration calculations of this type suffer from spin contamination due to the many low lying quartet states in this C₂H. Therefore, the error in this calculation is higher than in other molecules. In the isoelectronic case of HCN, which also has the spin contamination problem, the calculated value was slightly lower than the experimental value. This leads us to believe that 127 kcal/mol is a lower limit to D₀(C₂H-H).

Janousek et al.⁸ have come up with a value for D₀(C₂H-H) of 132±5 kcal/mol by combining processes VIII, IX and X in a thermochemical cycle. This result is in good agreement with the present work although the uncertainty is still fairly large.

\[ \text{C}_2\text{H}^- \rightarrow \text{C}_2\text{H} + \text{e}^- \quad \text{(VIII)} \]
\[ \text{C}_2\text{H}_2 \rightarrow \text{C}_2\text{H}^- + \text{H}^+ \quad \text{(IX)} \]
\[ \text{H}^+ + \text{e}^- \rightarrow \text{H} \quad \text{(X)} \]
The IP of $C_2H$ was measured directly by Wyatt and Stafford\textsuperscript{20} (WS) using electron impact threshold ionization and they obtain a value of $11.6 \pm 0.5$ eV. In two much more precise experiments, Okabe and Dibeler\textsuperscript{6} (OD) and Miller and Berkowitz\textsuperscript{7} (MB) have obtained $11.96 \pm 0.05$ eV and $11.51 \pm 0.05$ eV respectively. Their experiments are conceptually shown in Fig. 19 and 20 where the numbers with asterisks are the measured values and the underlined values are well known. Table III shows all possible values of the C–H bond energy obtained by combining in all possible ways the various experiments.

As can be seen, this work substantiates the values reported by DWM and MB. All the values calculated using the results of ON are far too low (by about the electron affinity of H). This suggests that ON may be looking at the threshold for the ion pair production channel. It is quite possible that in the dissociative ionization of $C_2HCN$ there is a barrier to dissociation. This would give OD a value for the IP of $C_2H$ which is too high and consequently a $D_0(C_2H-H)$ which is too low.

As mentioned previously, our $D_0(C_2H-H)$ determination rests upon the assumption that it is possible for all available energy to appear as translation in some of the products, in other words, some of the products should be in the ground state. There are less than twenty non-rotational internal states energetically accessible in the $C_2H$ product, even though the bending vibration is excited, it is not likely that it would be so highly inverted that no ground state is formed. One reason for this is the light mass of the H atom. The H atom cannot impart a large impulse to the partner $C_2H$ fragment and hence, it cannot act to excite it vibrationally with any degree of efficiency. We believe that because of the small number
$2^2A^m$ and are both considerably bent. If one or both of these states is responsible for the secondary absorption that we are observing in C$_2$H, we do expect that the absorption cross-section would increase for C$_2$H molecules that are more highly excited in the bending degree-of-freedom since the Frank-Condon factors would be higher. This is, in fact what we have observed in the power dependence experiment.

In fluorescence emission work, the C$_2$ Phillips band has been observed. This is a result of the $^1\pi_u$ state which is formed with 25 kcal/mole excess energy. In the $P(E_T)$ shown in Fig. 16 it is easy to see a sharp peak at around 10 kcal/mole, which we attribute to $^1\pi_u$ of C$_2$. This sharp peak has underlying it a broad hump originating from one or both of two low lying electronic states of C$_2$ ($^1\Sigma_g^+$ or $^3\pi_u$ or both).

D. The C-H Bond Energy in Acetylene

In previous experiments, the C-H bond energy was determined indirectly by measuring the dissociative ionization threshold for acetylene and the IP for the C$_2$H radical, that is processes VI and VII respectively.

\[ \begin{align*}
\text{C}_2\text{H}_2 & \rightarrow \text{C}_2\text{H}^+ + \text{H} + e^- & E_{VI} \quad (VI) \\
\text{C}_2\text{H} & \rightarrow \text{C}_2\text{H}^+ + e^- & E_{VII} \quad (VII)
\end{align*} \]

OWM measured $E_{VII}$ very carefully, looking at the temperature dependence of hotbands near threshold to get a value of 17.37 $\pm$ 0.01 eV. Recently, ON have disputed this value on the basis of a very sensitive molecular beam photoionization threshold measurement. ON claim the threshold to be 16.79 $\pm$ 0.03 eV.
the bend. The inability to resolve all the peaks at higher translational
energy can be explained in two ways. First, the inherent resolution of the
experiment degrades as products release more and more translational energy,
which can be seen from equation 1 and is shown in figures 10-12. Second,
due to the exit impact parameter being -1 Å, the rotational widths of the
vibrational peaks can become larger than 550 cm\(^{-1}\) at translational energy
releases greater than 8 kcal/mole. This implies that even in a very high
resolution experiment, measuring the translational energy release may not
distinguish between the different vibrational states that are produced. If,
in addition to this, more than one vibrational mode in \(\text{C}_2\text{H}\) is excited by
the photolysis the situation would be more complicated. This is indeed not
unreasonable. A simple geometrical comparison of the \(^1\text{A}_u\) state of
\(\text{C}_2\text{H}_2\) to the \(^2\Sigma\) state of \(\text{C}_2\text{H}\) would predict bending and C-C stretching to be
excited. The bend is excited because it is going from a bent to a linear
state and the C-C stretch is excited because the C-C bond order increases
upon going from \(^1\text{A}_u\) \(\text{C}_2\text{H}_2\) to \(^2\Sigma\) \(\text{C}_2\text{H}\). Nevertheless, it very much appears that
the bending frequency of \(\text{C}_2\text{H}\) is 550 \(\pm\) 100 cm\(^{-1}\) and that the nascent
\(\text{C}_2\text{H}\) is produced with a large amount of energy in this degree of freedom.

\[
\text{C.}) \quad P(E_T) \quad \text{for} \quad \text{C}_2\text{H} \quad \text{193 nm} \quad \text{C}_2 + \text{H}
\]

According to theoretical calculations there are two excited states of
\(\text{C}_2\text{H}\) in the energy range of a 6.4 eV photon that are of doublet spin
multiplicity.\(^{15}\) These are the two lowest doublet states above the \(\text{A}\) state
and are electric dipole coupled to the ground state. They are \(3^2\text{A}'\) and
contrast to acetylene, it is not likely that internal conversion to $X^1A'$ is an important decay channel in our experiment.

The underlying broad structure between zero and six kcal/mol is tentatively assigned to $C_2H(A^2\pi)$. Because of the poor quality of the data at small laboratory angles, corresponding to high internal energy fragments, it is presumptuous to estimate a branching ratio, but it does appear that most of the $C_2H$ is being formed in the ground electronic state.

It is important next to consider the partitioning of energy into the vibrational degrees of freedom. If one assumes that our experiment resolves all the vibrational quantum states populated by the photolysis, then the widths of the peaks are due solely to rotational excitation. One would be tempted to make the assignment of peaks 1, 2, 3 and 5 to the $v_3$ bending vibration of $C_2H$ with a frequency of about 1100 cm$^{-1}$. Peak 4 could then easily be assigned to $v=1$ of the C-H stretch observed in a matrix at 3612 cm$^{-1}$.

However, $v_2 = 1100$ cm$^{-1}$ is quite different than $C_2H_2$ bends of 600-700 cm$^{-1}$. In fact, there is no spectroscopic determination of the bending frequency in $C_2H$. Carrick et al.$^{16}$ estimate it from 1-type doubling measurements to be between 390 and 475 cm$^{-1}$ adding the caveat that vibronic coupling to the $A^2\pi$ state might increase the uncertainty of this estimate. Without further spectroscopic evidence and because peaks I and II are the least well determined features of the P$(E_T)$ (see "RESULTS AND ANALYSIS" section A), we would not recommend this assignment.

A more likely explanation of the P$(E_T)$ would label the most closely spaced peaks, which are also the most accurately determined in the experiment, and are separated by about 550 cm$^{-1}$ as sequential quanta of
Fig. 18 has been constructed with the previous considerations taken into account and is meant as a qualitative picture of the dissociation process. Using fig. 18 as a guide we see that after acetylene is initially pumped to the $1^1A''$ it's total energy, which is 6.4 eV, may well be less than the barrier height in the exit channel of this surface. Since the vibrational energy initially deposited in the molecule is mainly in the bending degree-of-freedom, even if the photon energy is slightly above the barrier height, the barrier will act as a bottleneck to $C_2H(A^2\pi)$ formation. We expect that the barrier will at least slow down the production of $C_2H(A^2\pi)$ enough that vibronic coupling from $1^1A''$ to $2^1A'$ will become a competing dissociation pathway. Because of the repulsive nature of the $2^1A'$ surface and the consequent large H atom velocity, the curve hopping to the $X^1A'$ surface will be very efficient. It is therefore not unreasonable that both electronic states of $C_2H$ are being formed in our experiment and that they should be formed with a significant release of translational energy, as observed.

We do not believe that vibronic coupling to the $X^1A'$ state is an important dissociation pathway. When formaldehyde was pumped 1 eV above its $S_1$ origin, it was found that vibronic coupling to $S_0$ and subsequent C-H bond rupture was the dominant process\textsuperscript{18}. However, because dissociation on the $S_0$ PES involves a smooth and continuous rearrangement of the bonding electrons in formaldehyde to non-bonding, free-radical electrons in HCO and H, there is no barrier to dissociation. It is for this reason that simple bond rupture reactions that occur along the ground electronic surface so often lead to $P(E_f)$'s that peak near zero kinetic energy release. This was indeed observed in the formaldehyde experiment. Since this is in sharp
we don't expect that the surface that is analogous to the \(3^1A'\) surface in figure 1 of ref. 17 will influence the dynamics of acetylene at the energies found in our experiment.

Despite these differences, we do expect the qualitative features of Vazquez' figure 1 to apply in the case of acetylene. In particular, the avoided crossing between the \(1^1A''\) and the \(2^1A''\) curves should be present. In our experiment we pump \(C_2H_2\) to the \(1^1A''\) curve of figure 18. This state is di-radical like, with a C-C bond order of two and it is trans-bent. It resembles ethylene with two diagonally opposed H's removed. The avoided crossing is the quantum mechanical representation of the rearrangement of the electronic configuration that is necessary in going from this di-radical structure with a C-C double bond to the electronic structure of \(C_2H\ (A^2\pi)\) where the bond order is 2.5 and there is only one free radical electron.

The avoided crossing between \(X^1A'\) and \(2^1A'\) shown in figure 18 occurs only for significantly bent geometries. \(X^2\Sigma\ C_2H\) has all \(\pi\) orbitals filled and a half filled \(\sigma_{pz}\) orbital. For bent geometries the incoming H feels a net repulsion due to its interaction with the closed \(\pi\) orbitals. In contrast \(A^2\pi\ C_2H\) has a filled \(\sigma_{pz}\) orbital and a half filled \(\pi\) orbital (as well as a degenerate filled \(\pi\) orbital). For bent geometries the incoming H atom breaks the degeneracy of the \(\pi\) orbitals. There is a strong attraction to the half filled \(\pi\) orbital, while there is a strong repulsion toward the filled \(\pi\) orbital. This avoided crossing has been invoked to explain the formation of \(X^2\Sigma\) CN in the photodissociation of HCN\(^{17}\). It is likely that this avoided crossing occurs even more easily in \(C_2H\) since the separation of the \(X\) and \(A\) states is much smaller in \(C_2H\) than in CN.
C₂H product will come only from repulsive bond rupture in which the orbital angular momentum of the departing fragments will be cancelled exactly by the rotational excitation of C₂H. But the creation of this pair of antiparallel angular momenta is constrained by the small mass of the departing hydrogen atom, the limited excess energy and the impact parameter of the half-collision. One can see that information on the vibrational structure of C₂H radical is available through the P(E₁).

Because the A²Π state of C₂H is only 3692 cm⁻¹ above the X²Σ state, we must first decide which electronic states of C₂H are being formed in the photolysis at 193.3 nm. To understand this, one would like to see the electronic state correlation diagram for process I. The calculation of the potential energy surfaces (PES's) that are involved in the dissociation has not, as yet, been done. However, Vazquez has calculated the eight lowest surfaces for bent geometries of HCN, which is isoelectronic with C₂H₂. Figure 1 of their paper serves as a guide to what the surfaces for acetylene would look like. Our figure 18 is a schematic representation of the corresponding curves for excited C₂H₂ based on the calculations of Vazquez.

There are, undoubtedly, many differences between HCN and C₂H₂. For instance, the 1¹A" origin should be lower than the bond dissociation energy for acetylene. So, we expect that the avoided crossing between 1¹A" and 2¹A" will be lower in energy and occur at a longer C–H bond length than in HCN. Another difference occurs between CN and C₂H. In CN the B²Σ state is only 3.2 eV above the X²Σ state, while in C₂H the B²Σ is calculated to be 7.3 eV higher than X²Σ. For this reason,
It should be mentioned that we also did not observe CH product which is due to process V.

\[
\text{C}_2\text{H}_2 \xrightarrow{2 \times 193 \text{ nm}} 2\text{CH} \quad (V)
\]

Channel V was a minor channel observed optically in ref. 10 and 11. McDonald et al. determined that V is less than 1 percent of the two-photon process that produces C\textsubscript{2}. This would almost certainly be beyond our limit of detection. In summary, Table II lists the observed channels in this work as well as some channels that have been postulated, but not observed in this experiment.

**B.) P(E\textsubscript{T}) for C\textsubscript{2}H\textsubscript{2} \xrightarrow{193 \text{ nm}} C\textsubscript{2}H + H**

Because of the conservation of total energy, in an experiment with infinite resolving power the P(E\textsubscript{T}) would appear as a series of discrete peaks, one corresponding to each internal quantum state of the C\textsubscript{2}H radical, since only the \textsuperscript{2}S\textsubscript{1/2} state of H atom can be populated at these energies. Although it is not practical to resolve rotational quantum states of polyatomic molecules in velocity measurements, structure due to the vibrational state distribution can be observed in a favorable situation. In this experiment, we are able to see significant structure in the P(E\textsubscript{T}) due to the internal quantum state distribution of the C\textsubscript{2}H. This is due primarily to the small amount of energy appearing as product rotation. Acetylene is rotationally cold in the beam so the rotational excitation of
The light $\text{H}_2$ products scatter in a much wider laboratory angular and velocity range than do the $\text{C}_2$ fragments. In addition, the smaller ionization cross section and shorter residence time in the ionizer for $\text{H}_2$ make it much harder to detect than heavier fragments such as $\text{C}_2\text{H}$ and $\text{C}_2$. It is also very difficult to detect $\text{H}_2$ because of the very high m/e=2 background found in our mass spectrometer. We must, therefore, confine our search to looking for $\text{C}_2$. Because of the small release of translational energy that is possible (4 kcal/mol at most), we can look at m/e=24 data at $20^\circ$ and be assured that there is no contribution from process IV. If we then use the $P(E_T)$'s derived from the $20^\circ$ data to fit the data at m/e=24 and $10^\circ$, where we would be able to see process IV if it were present, we can get an upper limit to the importance of this channel by adding in the contribution from process IV little by little until the data is no longer fit. Sensitivity to the observation of this channel depends upon the amount of translational energy released in process IV. If less translational energy is released, channel IV is easier to see. In estimating a conservative upper limit to the importance of this channel we have assumed the worst case, that all of the available 4 kcal/mole appears as translation. This "masks" channel IV in the TOF so that it could appear very inconspicuously. Taking into consideration the relative ionization efficiencies of $\text{C}_2$ and $\text{C}_2\text{H}$ to give $\text{C}_2^*$, this leads to an upper limit for process IV of 15 percent of process I. This is a very conservative estimate, since if the translational energy release is less (say 2 kcal/mole) then the branching ratio would be less than 2 percent.
sequential mechanism involving processes I and II would have no problem conforming to this constraint.

While there is no way to prove that process III is unimportant, there is compelling evidence for the existence of process II in the power dependent TOF spectrum at m/e=25 shown in Fig. 17. These spectra were taken with a neat acetylene beam for maximum signal. It has close to the same velocity as the neon seeded beam but the velocity distribution is nearly twice as broad. The upper trace shows the TOF spectrum taken at low power, 5-10 mJ/pulse, while the lower trace shows the spectrum at close to 100 mJ/pulse. If process III were dominant we would expect only the magnitude and not the shape of the TOF to change with power. If process II dominates it is not at all unlikely that certain internal states of the C2H radical would have a higher absorption cross-section at 193.3 nm than others. This would give rise to a change in the shape of the m/e=25 TOF as a function of laser power, due to differential depletion of the C2H radical, and that is exactly what has been observed in this experiment. Further evidence for the importance of process II is the calculation of Shih et al. The results of their ab-initio calculations on C2H radical show that the two lowest doublet states above the A2π state are both in the vicinity of an ArF laser photon. The symmetries of these states are such that they would both be dipole allowed transitions. One of these states (32A') correlates directly to C2 (1wu) + H as observed in fluorescence and in this work (see below).

We do not see any obvious evidence for the molecular elimination channel IV.
DISCUSSION

A.) Observed Collision Free Processes

The observation of laser induced m/e=25 signal at angles as large as 28°, and at lab velocities nearly twice that of the primary beam is conclusive evidence that C₂H radical is being photochemically produced in the collision free environment of a molecular beam. The amount of energy released as product translational motion is consistent with a single photon being absorbed. Although this is hardly a surprising finding, the presence of C₂H has always been inferred in past studies, while this is the first direct observation of the nascent C₂H radical in the gas phase.

There are two conceivable explanations to our m/e=24 data. A sequential photodissociation described by processes I and II or a two photon absorption creating a very highly excited C₂H₂ and subsequent decay as shown in process III.

\[ C₂H₂ → 2 \times 193 \text{ nm} \rightarrow H + C₂ + H \]  

(III)

Consideration of the P(Eₜ) for the two photon dissociation allows us to eliminate a simultaneous dissociation mechanism for process III. In a simultaneous, three particle production process, conservation of linear momentum would require the two hydrogen atoms to be emitted in exactly the same direction in order to produce C₂ at as large a laboratory-frame velocity as we are observing. Even in a cis-bent excited state it is difficult to imagine a concerted dissociation mechanism that would do this. If the two photon absorption of acetylene led to sequential loss of hydrogen atoms with time for the intermediate C₂H to rotate, it is possible that both hydrogen atoms could be emitted in the same direction. Similarly, the
well determined. The $\text{P}(E_T)$ shown has the minimum structure necessary to fit the data. Figures 10, 11 and 12 show a highly structured $\text{P}(E_T)$ and the fit it gives to the data. One can see that the data is not sensitive to these high frequency oscillations for products which are formed with high translational energy.

B.) Time-of-Flight Spectra of $\text{C}_2\text{H}$ at 530°K Nozzle Temperature

In order to determine the effect of unrelaxed bending vibrations in $\text{C}_2\text{H}_2$ on the determination of the maximum release of translational energy, the nozzle was heated to 530°K, about tripling (in comparison to the 300°K experiment) the number of parent acetylene molecules not in the ground vibrational state. The TOF at 21° is shown in Fig. 13 along with the best fit $\text{P}(E_T)$ in Fig. 14. One can see that the fast peak labeled "H" (for hot bands) has increased in intensity with respect to the other peaks by about a factor of three. We therefore conclude that the maximum release of translational energy occurs not at 18 kcal/mol but at slightly more than 16 kcal/mole, giving a $D_0(\text{C}_2\text{H}-\text{H})$ of 132 kcal/mole.

C.) Secondary Dissociation

Figures 15 and 16 show the m/e=24 ($\text{C}_2\text{H}_2^*$) TOF and the best $\text{P}(E_T)$ which fits the data after removing the contribution from $\text{C}_2\text{H}$ fragment. Although there is considerably less detail in the $\text{P}(E_T)$, the qualitative features are still apparent. The $\text{P}(E_T)$ appears to have two components. One is a sharp peak at about 10 kcal/mol and the other is a broad hump extending out to the maximum allowed translational energy. The maximum release of translational energy indicates that $\text{C}_2\text{H}$ has absorbed only one photon.
\[
\frac{\Delta V_{LAB}}{V_{LAB}} = \frac{\Delta t}{t} = \frac{\Delta L}{L} = \frac{1\text{ cm}}{37\text{ cm}} \approx 0.03
\]  \hspace{1cm} (1)

where

\begin{align*}
\Delta L & = \text{ionizer length (1 cm.)} \\
L & = \text{flight length (37 cm.)} \\
\Delta V_{LAB} & = \text{lab velocity resolution element} \\
V_{LAB} & = \text{lab velocity} \\
\Delta t & = \text{arrival time resolution element} \\
t & = \text{arrival time}
\end{align*}

from this equation one can see that at high lab velocities a certain velocity difference will be spread out in time to a lesser extent than at low lab velocities. Also, at large laboratory angles, in addition to the fact that the lab velocity for a given Newton circle is smaller, the separation between a pair of Newton circles in laboratory velocity space is larger. Therefore, it is always better to look at large angles to get better resolution of the fast products.

Figure 4-9 shows the data obtained at 28°, 20°, 17°, 10°, and 6° as well as the center-of-mass translational energy probability distribution, \( P(E_T) \) used to fit the data. In Fig. 4-8, the circles are the data and the solid lines are the fit to the data. The structure that is being partially resolved is due to the internal state population distribution of the nacent \( C_2H \) radical. The peaks in the \( P(E_T) \), Fig. 9, have been labeled with arbitrary symbols and correspond to the like labeled bumps and shoulders in the TOF spectra. Experimentally, the peaks marked 1 and 2 are the least
CONCLUSIONS

We have measured the translational energy distribution for acetylene photodissociation at 193.3 nm. The primary processes are

\[ \text{C}_2\text{H}_2 \overset{193 \text{ nm}}{\longrightarrow} \text{C}_2\text{H} + \text{H} \quad (\text{I}) \]
\[ \text{C}_2\text{H} \overset{193 \text{ nm}}{\longrightarrow} \text{C}_2 + \text{H} \quad (\text{II}) \]

Process II is important even at fluences as low as \(10^{26}\) photons/cm\(^2\) second. The translational energy distribution for I shows up to 16.25 kcal/mole translational energy release implying a \(D_0(\text{C}_2\text{H}-\text{H})\) of 132 ± 2 kcal/mole. This is the first measurement of this quantity in a single experiment. The vibrational structure of \(\text{C}_2\text{H}\) is partially resolved and we conclude that the bending frequency in \(\text{C}_2\text{H}\) is near 550 cm\(^{-1}\). The translational energy distribution for II is consistent with fluorescence work showing population of \(\text{C}_2(1\pi_u, 1\pi_g, 3\pi_u)\).
