ABSTRACT

This paper surveys a number of efficient randomized algorithms for selection and sorting which we derive from inefficient deterministic specifications. Along with these derivations, we simultaneously derive bounds on the probability distribution of the sequential and parallel time cost of these algorithms.

There are several potential benefits of this work. We develop, for the first time, general techniques for deriving randomized algorithms from deterministic specifications. Previous derivations only considered deterministic algorithms. Furthermore, our derivations encompass many known sequential and parallel randomized algorithms for selection and sorting which required separate proofs and probabilistic analysis.

Also, we present a new randomized comparison sorting algorithm that takes $O(\log\log n)$ time and uses $n^{1+\epsilon}$ processors to sort $n$ keys.
1. INTRODUCTION

1.1 Meaning of Derivation

A growing body of computer science literature is concerned with deriving efficient algorithms for given mathematical specifications which would be inefficient to execute as such. For example, [Scherlis 80] derives a family of parsing algorithms and [Reif and Scherlis 84] derive a family of efficient depth first search algorithms for various connectivity problems of graphs and digraphs. The process of deriving algorithms from given specifications could be thought of as restating the specifications in steps, using general algorithm design techniques and problem specific knowledge, such that the specification at any step of derivation reflects an improvement in the efficiency of its execution over the one in the previous step. The advantage of this derivation process is manyfold. These derivations serve as constructive proofs for the correctness of a family of algorithms. Also, they enable us to understand existing efficient (and possibly complicated) algorithms for the problem at hand better, than merely reading the proofs of their correctness. In this paper we derive randomized algorithms for selection and sorting.

1.2 Randomized Algorithms

A randomized algorithm $A$ defines a mapping from an input domain $D$ to a set of probability density functions over some output domain $D'$. For each input $x \in D$, $A(x) : D \rightarrow [0,1]$ is a probability density function, where $A(x)(y) \in [0,1]$ is the probability of outputting $y$ given input $x$. In order for $A(x)$ to represent a probability mass function, we require

$$\sum_{y \in D'} A(x)(y) = 1, \text{ for each } x \in D.$$

A mathematical semantics for randomized algorithms is given in [Kozen 80].
Two different types of randomized algorithms can be found in the literature: 1) those algorithms which always output the correct answer but whose run time is a random variable with a specified mean, and 2) those which output the correct answer with some probability (the probability space being the set of all possible inputs). For example, the randomized sorting algorithm of [Reischuk 81] is of the first type and the primality testing algorithm of [Rabin 76] is of the second type. In general, the use of probabilistic choice in algorithms to randomize them has often lead to great improvements in their efficiency. The randomized algorithms we derive in this paper will be of the first type.

1.3 Deriving Randomised Algorithms

No previous paper has given derivations of randomized algorithms (for any problem). We begin with the mathematical specifications of selection and sorting problems. We’ll encode these specifications into canonical algorithms. Various algorithms found in the literature for these problems will then be derived as special cases of these canonical algorithms. The former algorithms result from specializing and/or modifying one or more of the steps in the canonical algorithms.

To start with, we derive and analyze a random sampling algorithm for approximating the rank of a key (in a set). This random sampling technique will serve as a building block for the selection and sorting algorithms we derive. We analyze the run time for both the sequential and parallel execution of the derived algorithms.

1.4 An $O(\log \log n)$ Time Sorting Algorithm

Many optimal parallel comparison sorting algorithms are available in the literature. These algorithms are optimal in the sense that the product of time and processor bounds for these algorithms equals the lower bound of the run time for
sequential comparison sorting. These processors run in time $O(\log n)$. Some of these algorithms are 1) Reischuk's [Reischuk 81] randomized algorithm, 2) AKS deterministic algorithm [AKS83], 3) Column Sorting algorithm [Leighton 83], 4) FLASH SORT algorithm [Reif and Valiant 83]. The first three algorithms run on the PRAM model whereas the fourth algorithm runs on the fixed connection model.

We give a new (non optimal) sorting algorithm that runs in time $O(\log \log n)$ time and which uses $O(n^{1+\epsilon})$ processors, for any $\epsilon > 0$.

1.5 Organization of this Paper

In section 2 we define the selection and sorting problems and our parallel comparison tree machine model. In section 3 we give and analyze an algorithm for computing the rank of a key approximately. We also state, in this section, an important result from sampling theory which will be used throughout the rest of the paper. Finally, in sections 4 and 5 we derive and analyze various randomized algorithms for selection and sorting. In section 5 we also give a new comparison sorting algorithm that runs in time $O(\log \log n)$ time.

2. COMPARISON PROBLEMS AND PARALLEL MACHINE MODELS

2.1 Comparison Problems

Let $X$ be a set of $N$ distinct keys. Let $<$ be a total ordering over $X$. For each key $x \in X$ define

$$\text{rank}(x, X) = | \{ x' \in X \mid x' < x \} | + 1.$$ 

For each index $i$, $1 \leq i \leq N$, we define $\text{select}(i, X)$ to be that key $x \in X$ such that $i = \text{rank}(x, X)$. Also define
\[
\text{sort}(X) = (x_1, x_2, \ldots, x_N)
\]

where \( x_i = \text{select}(i, X) \), for \( i=1, \ldots, N \). As defined, these functions are expensive to compute. For example, the sort definition requires \( N^2 \) comparisons.

### 2.2 Parallel Comparison Models

In the *sequential comparison tree* model of [Knuth 73] a single step at a node of the tree consists of a comparison of two keys. The outcome of this comparison takes the execution to a child of this node. The leaves of the tree provide output values. The run time in this model is the number of nodes visited on a given execution. A distinct tree is allowed for each input. In a randomized comparison tree model execution from any node branches to a random child depending on the outcome of a coin tossing.

[Valiant 75] describes a *parallel comparison tree* machine model which is similar to the sequential tree models, except that multiple comparisons between keys are allowed on each step. Thus a comparison tree machine with \( p \) processors is allowed a maximum of \( p \) comparisons at each node, which are executed simultaneously. We allow our parallel comparison tree machines to be randomized, with random choice nodes as described above.

### 2.3 Parallel RAM Models

More refined machine models of computation also take into account storage and arithmetic steps. The sequential random access machine (RAM) described in [Aho, Hopcroft, and Ullman 76] allows a finite number of register cells and also infinite global storage. A single step of the machine consists of an arithmetic operation, a comparison of two keys, reading off the contents of a global cell into a register, or writing the contents of a register into a global memory cell.
The parallel version of RAM proposed by [Fortune and Wylie 78] allows multiple RAMs to be generated from a single original RAM by execution of a *fork* operation. This model, known as PRAM, allows multiple concurrent reads but prohibits concurrent writes. WRAM model, which is a variation of PRAM, permits concurrent reads and concurrent writes. There are three variations of WRAM depending on how the write conflicts are resolved.

The models we employ, in this paper, for various algorithms will be the ones used by the corresponding authors.
3. RANDOM SAMPLING

3.1 An Algorithm for Computing Rank

Let \( X \) be a set of \( N \) keys with a total ordering \(<\) defined on it. Our first goal is to derive an efficient algorithm to approximate \( \text{rank}(z,X) \), for any key \( z \in X \). We require that the output of our randomized algorithm have expectation \( \text{rank}(z,X) \).

The idea will be to sample a subset of size \( s \) from \( X \), to compute the rank of \( x \) in this sample, and then to infer its rank in \( X \). The actual algorithm is given below.

Algorithm samplerank\(_s\)(\( z,X \));

begin

Let \( S \) be a random subset of \( X \) of size \( s \);

return \( \left\lfloor \frac{N}{s+1} \right\rfloor \text{rank}(x,S \cup \{z\}) \)

end;

The correctness of the above algorithm is stated in the following

**Lemma 3.1** The expected value of \( \text{samplerank}_s(z,X) \) is \( \text{rank}(z,X) \).

**Proof** Let the number of elements \( \leq z \) in \( X \) be \( k \) (i.e., \( \text{rank}(z,X) = k \)). Then, for a random \( y \in X \), \( \text{Prob.}[y \leq z] = \frac{k}{N} \). Therefore, out of \( s \) elements chosen randomly from \( X \), \( \text{Prob.}[\text{exactly } l \text{ of them are } \leq z] \leq B\left(l; s+1, \frac{k}{N}\right) \) (where \( B \) is a binomial distribution). Mean of this binomial distribution is \((s+1)\frac{k}{N}\). Therefore,

\[
\text{Mean} \left[ \frac{N}{s+1} \text{rank}(x,S \cup \{z\}) \right] = k = \text{rank}(z,X)
\]

i.e., \( \text{Mean} [\text{samplerank}_s(z,X)] = \text{rank}(z,X) \) □

Another way of proving the correctness of our algorithm is to use some well-known results from Sampling Theory. We address ourselves to the following
problem: "Given a set $X$ and a random $x \in X$. Also, $S$ is a random subset (or sampling) of $X$. If the number of elements $\leq x$ in $S$ is $l$, how many elements in $X$ are $\leq x$?" Let $r_i = \text{rank(select}(i, S), X)$. In the next subsection we'll obtain the distribution of $r_i$ and show that $\text{Mean}(r_i) = \frac{i-N}{s+1}$.

3.2 Distribution of $r_i$

Let $Y_1, Y_2, \ldots, Y_s$ be a random sample from a continuous distribution with density function $f(y)$. If $Y_1 \leq Y_2 \leq \cdots \leq Y_s$ is the sorted order of the sample, then $Y_i$ is called the $i$th order statistics of the sample $Y_1, \ldots, Y_s$. If $f(y) = 1$ in $[0,1]$ and 0 elsewhere, then the density function of the $i$th order statistics [Wilks 76] is given by

$$f_i(y_i) = \frac{s!}{(i-1)! (s-i)!} y_i^{i-1} (1-y_i)^{s-i}$$

which is a Beta distribution with parameters $(i, s-i+1)$. Therefore, asymptotically, $\frac{r_i}{N}$ has a Beta distribution with parameters $(i, s-i+1)$, immediately implying that

$$\text{Mean}(r_i) = \frac{i}{s+1} \quad \text{and} \quad \text{Var}(r_i) = \frac{i(s-i+1)}{(s+1)^2} \frac{N^2}{2}.$$ 

From this Beta distribution we can also obtain the following confidence interval on $r_i$.

**Lemma 3.2** For every $\alpha$, Prob. $\left| r_i - \frac{i-N}{s+1} \right| > c \alpha \frac{N}{\sqrt{s}} \sqrt{\log N} < N^{-\alpha}$ for some constant $c$.

**Proof** We'll assume $\log N = o(s)$ in the following proof. Also, this proof is given in two cases on the parameters of the Beta distribution.
Case 1 Both \(i\) and \(s-i+1\) are \(>\sqrt{s}/\log N\).

Let \(Z\) be a random variable with probability density function \(f(z)\), mean \(\mu\), and variance \(\sigma^2\). It is a known fact from statistics that if the skewness of \(Z\) is 0, then \(\frac{Z-\mu}{\sigma}\) can be approximated by the normal variate \(N(0,1)\). The skewness of a Beta distribution with parameters \((\alpha, \beta)\) is 0 when either \(\alpha = \beta\) or both \(\alpha\) and \(\beta\) are \(\infty\). Therefore, when both \(i\) and \(s-i+1\) are \(>\sqrt{s}/\log N\), asymptotically, the skewness of \(r_i\) tends to 0, making the approximation of \(\frac{r_i-\mu}{\sigma}\) by the standard normal variate meaningful. And hence,

\[
\text{Prob.} \left\{ \left| \frac{r_i-\mu}{\sigma} \right| > t \right\} = 2 \int_t^\infty \exp(-u^2/2) du
\]

\[
\leq 2 \frac{1}{\sqrt{2\pi}} \frac{\exp(-t^2/2)}{t}
\]

\[
\leq b \exp(-dt^2) \leq b N^{-\alpha}, \text{ for constants } b \text{ and } d
\]

and \(t=\sqrt{\frac{\log s}{d}}\).

Notice that \(\text{Var}(r_i) \leq \frac{N^2}{2s}\). Now, substituting \(\text{Mean}(r_i) = \frac{i}{s+1} N\) and \(\text{Var}(r_i) \leq \frac{N^2}{2s}\), we get the desired result.

Case 2 Either \(i\) or \(s-i+1\) is \(\leq \sqrt{s}/\log N\).

The case \(i \leq \sqrt{s}/\log N\) is identical to the case \((s-i+1) \leq \sqrt{s}/\log N\). So, we'll consider only the case \(i \leq \sqrt{s}/\log N\).

If \(k_1, k_2, \ldots, k_s\) are the elements of the random sampling set \(S\) in sorted order, then these elements divide the set \(X\) into \((s+1)\) subsets \(X_1, X_2, \ldots, X_{s+1}\) where \(X_1 = \{x \in X / x \leq k_1\}\), \(X_i = \{x \in X / k_{i-1} < x \leq k_i\}\), for \(i=2, \ldots, s\) and \(X_{s+1} = \{x \in X / x > k_s\}\). In terms of the cardinalities of these subsets, \(r_i\) can be expressed as \(\sum_{j=1}^{i} |X_j|\) for \(i=1, \ldots, s\). It can be shown that (see lemma 3.3 below) the

\[\text{g}\]
maximum cardinality of any subset $X_i$ is $\leq \frac{N}{s} \log N$, with probability greater than $1 - O(N^{-\alpha})$ (for any $\alpha$). This result immediately implies that $r_i \leq \frac{N}{s} \log N$ with probability $> 1 - O(N^{-\alpha})$ thus proving our claim.

**Lemma 3.3** A random $S \subseteq X$ of size $s$ divides $X$ into $s+1$ subsets as explained above. The maximum cardinality of any of the resulting subsets is $\leq \frac{a}{2} \log_e N$ with probability greater than $1 - N^{-\alpha}$. ($|X|=N$).

**Proof**

First we'll compute the probability that at least one subset is of size at least $v$. Realize that the selection of a random subset $S$ of $X$ results in a random $(s+1)$-partition of $X$. Total number of $(s+1)$ partitions of $X$ is $\left(\begin{array}{c}N-1 \\ s \end{array}\right)$. Number of partitions of $X$ that have at least one part of size $\geq v$ is $\left(\begin{array}{c}N-v-1 \\ s \end{array}\right)$.

Therefore, the probability that there is at least one part which is of size at least $v$ is

$$P = \frac{\left(\begin{array}{c}N-v-1 \\ s \end{array}\right)}{\left(\begin{array}{c}N-1 \\ s \end{array}\right)}.$$  

Using Stirling's approximation,

$$P \approx \frac{(N-v-1)^{N-v-1} (N-s-1)^{N-s-1}}{(N-s-v-1)^{N-s-v-1} (N-1)^{N-1}} \left(1 - \frac{v+1}{N}\right)^{N-v-1} \left(1 - \frac{s+1}{N}\right)^{N-s-1}$$

$$\approx \frac{\frac{1}{1-\frac{v+1}{N}}^{N-v-1} \frac{1}{1-\frac{s+1}{N}}^{N-s-1}}{1-\frac{v+1}{N}}^{N-v-1} \frac{1}{1}$$

$\cdot$
Using the fact \( \left( 1 - \frac{1}{\epsilon} \right)^N < \frac{1}{\epsilon} \),

\[
P \leq \exp \left( \frac{-2\alpha}{N} \right)
\]

If \( \alpha = \frac{\alpha N}{2} \log N \), then \( P \leq N^{-\alpha} \).

i.e., the probability that none of the resulting subsets is of size greater than \( \frac{\alpha N}{2} \log N \) is \( > 1 - N^{-\alpha} \), which is our claim.

This completes our proof of Lemmas 3.3 and 3.2. These Lemmas will be used repeatedly hereafter.

4. DERIVATION OF RANDOMIZED SELECT ALGORITHMS

4.1 A Summary of Select Algorithms

Let \( X \) be a set of \( N \) keys. We wish to derive efficient algorithms for \( \text{select}(i, X) \) where \( 1 \leq i \leq N \). Recall we wish to get the correct answer always but the run time may be a random variable. We display a canonical algorithm for this problem and then show how select algorithms in the literature follow as special cases of this canonical algorithm.

```
algorithm canselect;
begin
  select a bracket (i.e., a subset) \( B \) in \( X \) such that \( \text{select}(i, X) \) lies in this bracket with very high probability;
  Let \( i_1 \) be the number of keys in \( X \) less than the smallest element in \( B \);
  return canselect(\( i-i_1 \), \( B \))
end;
```

*10*
Select algorithm of [Hoare 61] chooses a random splitter key $k \in X$, and recursively considers either the low key set or the high key set based on where the $i$th element is located. And hence, $B$ for this algorithm is either $\{x \in X / z \leq k\}$ or $\{x \in X / z > k\}$ depending on which set contains the $i$th largest element of $X$. $|B|$ for this algorithm is $\frac{N}{e}$ for some constant $c$.

On the other hand, select algorithm of [Floyd and Rivest 75] chooses two random splitters $k_1$ and $k_2$ and sets $B$ to be $\{z \in X / k_1 \leq z \leq k_2\}$. $k_1$ and $k_2$ are chosen properly so as to make $|B| = O(N^a)$, $a < 1$. We'll analyze these two algorithms in more detail now.

4.2 Hoare's Algorithm

Detailed version of Hoare's select algorithm is given below.

```algorithm
Hselect(i,X);
(assert 1 \leq i \leq |X|)
begin
if $X = \{x\}$ then return $x$;
Choose a random splitter $k \in X$;
Let $B = \{z \in X / z < k\}$;
if $|B| \geq i$ then return $Hselect(i,B)$
else return $Hselect(i-|B|, X - B)$
end;
```

Let $T_p (i,N)$ be the expected parallel time of $Hselect(i,X)$ using at most $p$ simultaneous comparisons at any time. Then the recursive definition of $Hselect$ yields the following recurrence relation on $T_p (i,N)$.

$$T_p (i,N) = \frac{N}{p} + \frac{1}{N} \left[ \sum_{j=1}^{i} T_p (i-j, N-j) + \sum_{j=i+1}^{N} T_p (i,j) \right]$$

An induction argument shows

$$T_N (i,N) \leq O(\log N)$$

*11*
and

\[ T_1(i,N) \leq 2N + \min(i,N-i) + o(N). \]

To improve this Hselect algorithm, we can choose \( k \) such that \( B \) and \( X - B \) are of approximately the same cardinality. This choice of \( k \) can be made by fusing \texttt{samplerank} into \texttt{Hselect} as follows.

```plaintext
algorithm sampleselect \(_i,X\);
  (assert \( 1 \leq i < |X| \))
  begin
    if \( X = \{x\} \) then return \( x \);
    Choose a random sample set \( S \subseteq X \) of size \( s \);
    Let \( k = \text{select}(\lfloor s/2 \rfloor, S) \);
    Let \( B = \{x \in X / x < k\}; \)
    if \( |B| \geq i \) then return sampleselect \(_i,B\)
    else return sampleselect \(_i - |B|, X - B\)
  end;
```

This algorithm can easily be analyzed using Lemma 3.2.

### 4.3 Algorithm of Floyd and Rivest

As was stated earlier, this algorithm chooses two keys \( k_1 \) and \( k_2 \) from \( X \) at random to make the size of its bracket \( B=O(N^\beta) \), \( \beta<1 \). The actual algorithm is

```plaintext
algorithm FRselect \(_i,X\);
  begin
    if \( X = \{x\} \) then return \( x \);
    Choose \( k_1,k_2 \in X \) such that \( k_1 < k_2 \);
    Let \( r_1 = \text{rank}(k_1,X) \) and \( r_2 = \text{rank}(k_2,X) \);
    if \( r_1 > i \) then FRselect \(_i,\{x \in X / x < k_1\}\)
    else if \( r_2 > i \) then FRselect \(_i-r_1,\{x \in X / k_1 \leq x \leq k_2\}\)
    else FRselect \(_i-r_2,\{x \in X / x > k_2\}\)
  end;
```

Let \( T_p(i,N) \) be the expected run time of the algorithm \texttt{FRselect} \(_i,X\), allowing at most \( p \) simultaneous comparisons at any time. Notice that we must choose \( k_1 \) and \( k_2 \) such that the case \( r_1 \leq i \leq r_2 \) occurs with high likelyhood and \( r_2 - r_1 \) is
not too large. This is accomplished in FRselect as follows.

Choose a random sample \( S \subseteq X \) of size \( s \). Set \( k_1 \) to be

\[
\text{select } \left( \frac{s+1}{N+1} - \delta, S \right)
\]

and set \( k_2 \) to be select \( \left( \frac{s+1}{N+1} + \delta, S \right) \). If the parameter \( \delta \) is fixed to be \( \lfloor \sqrt{d\alpha s \log N} \rfloor \), for some constant \( d \), then by lemma 3.2, \( \text{Prob.}[r_1 > i] < N^{-\alpha} \) and \( \text{Prob.}[r_2 < i] < N^{-\alpha} \). Let \( T_p (-,s) = \max_j T_p (j,s) \). The resulting recurrence for the expected parallel run time with \( p \) processors is

\[
T_p (i,N) \leq \frac{N}{p} + T_p (-,s) + \text{Prob.}[r_1 > i] \times T_p (i,r_1) + \text{Prob.}[i > r_2] \times T_p (i-r_1, N-r_2) + \text{Prob.}[r_1 \leq i \leq r_2] \times T_p (i-r_1, r_2-r_1) \leq \frac{N}{p} + T_p (-,s) + 2N^{-\alpha} \times N + T_p \left( i, \left\lfloor \frac{N+1}{\delta+1} \right\rfloor \right).
\]

Note that \( k_1 \) and \( k_2 \) are chosen recursively. If we fix \( d\alpha < 3 \) and let \( s = N^{2/3} \log N \), the above recurrence yields [Floyd and Rivest 75]

\[
T_1 (i,N) \leq N + \min (i,N-i) + O(s).
\]

Observe that if we have \( N^2 \) processors, we can solve the select problem in one time unit, since, all possible pairs of keys can be compared in one step. This implies that \( T_p (i,N) = 1 \) for \( p \geq N^2 \). Also, from the above recurrence relation,

\[
T_n (i,N) \leq O(1) + T_n (-,\sqrt{N}) = O(1),
\]

as is shown in [Reischuk 81].

\*13\*
5. DERIVATION OF RANDOMIZED SORTING ALGORITHMS

5.1 A Canonical Sorting Algorithm

The problem is to sort a given set \( (X) \) of \( N \) distinct keys. The idea behind the canonical algorithm is to divide and conquer by splitting the given set into (say) \( s \), disjoint subsets of almost equal cardinality, to sort each subset recursively, and finally merge the resultant lists. A detailed statement of the algorithm follows.

```algorithm
cansort(X);
    begin
        if \( |X| = 1 \) then return \( X \);
        Choose a random subset \( S \subseteq X \) of size \( s \);
        Let \( S_1 \) be sorted \( S \);
        As explained in section 3.2, \( S_1 \) divides \( X \)
        into \( s+1 \) subsets \( X_1, X_2, \ldots, X_{s+1} \);
        return cansort(\( X_1 \)) . cansort(\( X_2 \)) . . . cansort(\( X_{s+1} \));
    end;
```

Now we'll derive various sorting algorithms from the above.

5.2 Hoare's Sorting Algorithm

When \( s = 1 \) we get Hoare's algorithm. Hoare's sorting algorithm is very much similar to his select algorithm. Choose a random splitter \( k \in X \) and recursively sort the set of keys \( \{x\in X / x<k\} \) and \( \{x\in X / x>k\} \).

```algorithm quicksort(X);
    begin
        if \( |X| = 1 \) then return \( X \);
        Choose a random \( k\in X \);
        return quicksort(\( \{x\in X / x<k\} \)) . \( (k) \) . quicksort(\( \{x\in X / x>k\} \));
    end;
```

Let \( T_1(N) \) be the number of sequential steps required by \( \text{quicksort}(X) \) if \( |X| = N \).

Then,

\[
T_1(N) \leq N-1 + \frac{1}{N} \sum_{i=1}^{N} (T_1(i-1) + T_1(N-i)) \leq 2N\log N.
\]

*14*
A better choice for \( k \) will be sampleselect, \([N/2], N\). With this modification, quicksort becomes

```plaintext
algorithm samplesort, \( (X) \); begin
    if \( |X| = 1 \) then return \( X \);
    Choose a random subset \( S \subseteq X \) of size \( s \);
    Let \( k = \text{select}([s/2], S) \);
    return samplesort, \((\{x \in X / x < k\} \cup k) \) samplesort, \((\{x \in X / x > k\})\);
end;
```

By Lemma 3.2,

\[
\text{Prob.} \left[ |\text{rank}(k, X) - N/2| > \sqrt{d_0 N \log N} \right] < N^{-d}
\]

for some constant \( d \). Let \( \bar{C}(s, N) \) be the expected number of comparisons required by samplesort, \( (X) \). Since the [Floyd and Rivest 75] selection algorithm requires only \( N + o(N) \) comparisons, we have for \( s(N) = N/\log N \),

\[
\bar{C}(s(N), N) \leq \bar{C}(s(N_1), N_1) + N^{-d} \bar{C}(s(N), N) + o(N)
\]

where

\[
N_1 = N/2 + (\sqrt{d_0 N}) \log N.
\]

Solving this recurrence [Frazer and McKeller 70] show

\[
\bar{C}(s(N), N) \approx N \log_2 N,
\]

which asymptotically approaches the optimal number of comparisons required to sort \( N \) numbers on the comparison tree model.

Let \( T_p(s, N) \) be the number of steps on a parallel comparison tree model with \( p \) processors to execute samplesort, \( (X) \) where \( |X| = N \). Since only a constant number of steps are required to select the median \( k = \text{select}(N/2, X) \) using \( N \) processors, [Reischuk 81] observes for this specialized algorithm with \( s(N) = N \),

\[
T_N(N, N) \leq O(1) + T_{N/2}(N/2, N/2)
\]

*15*
5.3 Multiple Sorting

Any algorithm with $s > 1$ falls under this category. Let us call cansort as multisort when $s > 1$. As was shown in Lemma 3.3, the maximum cardinality of any subset $X_i$ is $\leq \frac{N}{s} \log N = N_1$, say with probability $> 1 - O(N^{-\alpha})$. Therefore, if $T_p(N)$ is the expected parallel comparison time for executing multisort, $X$ with $p$ processors (where $|X| = N$), then,

$$T_p(N) \leq T_{pN_1/N}(N_1) + N^{-\alpha} T_p(N) + T_p(s) + \frac{N}{p} \log(s)$$

$$\leq T_{pN_1/N}(N_1) + O(1) + \frac{N}{p} \log(s).$$

[Reischuk 82] uses the specialization $s = N^{1/2}$ which yields the following recurrence for $T_p(N)$.

$$T_N \leq T_{N_1}(N_1) + \frac{1}{2} \log N + O(1)$$

$$= O(\log N).$$

Alternatively we can set $p = N^{1+\epsilon}$ and $s = N^\epsilon$ for any $0 < \epsilon < 1$ and get an $N_1 = N^{1-\epsilon/2} \sqrt{d \log N}$ for some constant $d$. This choice of $S$ yields the recurrence

$$T_{N^{1+\epsilon}}(N) \leq T_{N^{1+\epsilon}N_1}(N_1) + O(1) + N^{-\alpha} \log N$$

$$\leq T_{N^{1+\epsilon}N_1}(N_1) + O(1)$$

$$\leq O(\log \log N)$$

5.4 FLASHSORT

[Reif and Valiant 83] give a method FLASHSORT for dividing $X$ into even more equal sized subsets. This method is useful for sorts within fixed connection

*10*
networks, where the processors can not be dynamically allocated to work on various size subsequences. The idea of [Reif and Valiant 83] is to choose a subsequence $S \subset X$ of size $N^{1/2}$, and then choose as splitters every $(\alpha \log N)$th element of $S$ in sorted order, i.e., to choose $k'_i = \text{select}(\alpha i \lfloor \log N \rfloor, S)$ for $i = 1, 2, \ldots, N^{1/2}/\log N$. Then they recursively sort each subset $X'_i = \{ z \in X \mid k'_{i-1} < z < k'_i \}$. Their algorithm runs in time $O(\log N)$ and they have shown that after $O(\log N)$ recursive stages of their algorithm, the subsets will be of size not more than a factor of $O(1)$ of each other.
