$()^0$	Zero superscript denotes a middle surface value
$[]_s$	Denotes a ply orientation that is symmetric with respect to the middle surface

Abstract

An analytical study was conducted to determine the influence of moisture, temperature, and curvature on the bifurcation load of cylindrical, composite panels subjected to a simple shear loading. Two laminate ply orientations, $[0/45/-45/90]_S$ and $[45/-45]_{2S}$, were analyzed for six radii, four temperatures, and two initial moisture conditions. The eight-ply composite panels were assumed to be manufactured from a graphite/epoxy, AS/3501-5. To evaluate the influence of moisture and temperature, the transverse modulus, E_2 , and shear modulus, G_{12} , were degraded based on experimental test data for the AS/3501-5 system. Each ply orientation, for a 12 in. panel radius, was evaluated at 20 time/temperature conditions that ranged from 80 to 300°F, and moisture concentrations ranging from a zero moisture content to an equilibrium moisture distribution. The investigation of curvature was conducted only for the $[45/-45]_{2S}$ laminate and at a limited number of time/temperature conditions.

The bifurcation loads were determined using the STAGS-C1 finite elements shell analysis program. This analysis used the prebuckled linear displacement option to calculate the bifurcation loads. An increase in temperature and moisture absorption was found to cause a reduction in the panels bifurcation load ranging from a maximum of 25.6 percent for the $[0/45/-45/90]_S$ laminate to 34.5 percent for the $[45/-45]_{2S}$ laminate for the panels with a 12 in. radius. This reduction

in the bifurcation load is significantly influenced by the change in curvature at elevated temperatures and moisture content. The maximum reduction in the bifurcation load varied from 34.5 percent for a 12 in. panel radius to 11.9 percent for a 10,000 in. panel radius a decrease of 22.6 percent for the $[45/-45]_2$ laminate.

THE BUCKLING OF COMPOSITE
CYLINDRICAL PANELS CONSIDERING
ENVIRONMENTAL EFFECTS

I. Introduction

Background

Composite materials' high strength to weight ratio makes it particularly well suited for aircraft structural use. The desire to improve the efficiency of the structural design through the application of composites in order to tailor the component's strength and stiffness to match the load and stiffness requirements results in components with unique structural responses. The USAF's forward swept aircraft design is an excellent example of the materials' advantage in that, through proper composite "tailoring", the problem of aeroelastic divergence can be practically avoided without the enormous weight gain associated with conventional metals. One difficulty in such applications of composites is the inability to use conventional, classical structural design practices to predict the structural response of composite laminates. The fact that their stiffness can be oriented to preferred directions make them complex structures to analyze.

In a semimonocoque design, thin skin panels along with fuselage frames and longerons or wing skins with spars and ribs are used to

achieve an efficient structure. In such a design, the accurate determination of the buckling load of curved skin panels is necessary to prevent premature structural failure. It is stated in Ref. [1] that, "Numerous papers concerning the instability of laminated, anisotropic plates and shells can be found in the open literature. Buckling of curved panels has, however, received little attention." This is especially the case for shear buckling of curved panels. Some recent work has been carried out on curved panels in order to evaluate their buckling characteristics under compression loads [2-5]. From the standpoint of shear instability of cylindrical composite panels, Harper looked at shear buckling of circular cylindrical shells [6] and Whitney examined shear buckling of symmetric and unsymmetric angle-ply, graphite/epoxy curved plates[1].

Another aspect related to composite material research is the consideration of moisture and temperature effects on the overall structural characteristics. Snead and Palazotto examined the effects of moisture and temperature on the instability of cylindrical composite panels loaded in axial compression [7]. These influences, sometimes referred to as hygrothermal effects, fall in the general category of environmental influences. Hygrothermal effects have been found to significantly degrade the mechanical properties of most organic matrix compounds [7-21].

Purpose

The purpose of this thesis is to analytically evaluate the

instability of composite cylindrical panels subject to simple shear loading, using the STAGS-C1 finite element shell analysis program. The influence of moisture, temperature, and curvature on the panel's bifurcation load will be investigated using this finite element program.

Scope

The cylindrical panels evaluated in this thesis are 12 in. by 12 in., eight-ply laminates made of graphite/epoxy. The panel's thickness, width, and height are held constant while the radius, ply orientation, laminate temperature, and initial surface moisture conditions are varied. Six radii, two ply orientations, and a simple support boundary condition are investigated. During the investigation of the environmental influences, four temperatures and two surface moisture conditions, at five time values, are evaluated.

II. Theory

Classical Laminated Plate Theory

The analysis of any composite structure requires an understanding of classical laminate plate theory (CLPT). A brief overview of the basic principles will be presented here. For a more detailed analysis of CLPT one should refer to any introductory text on composite materials [22-23]. For a single orthotropic layer, the fiber oriented reference system is shown in Figure 2.1. It will be the standard used in this thesis.

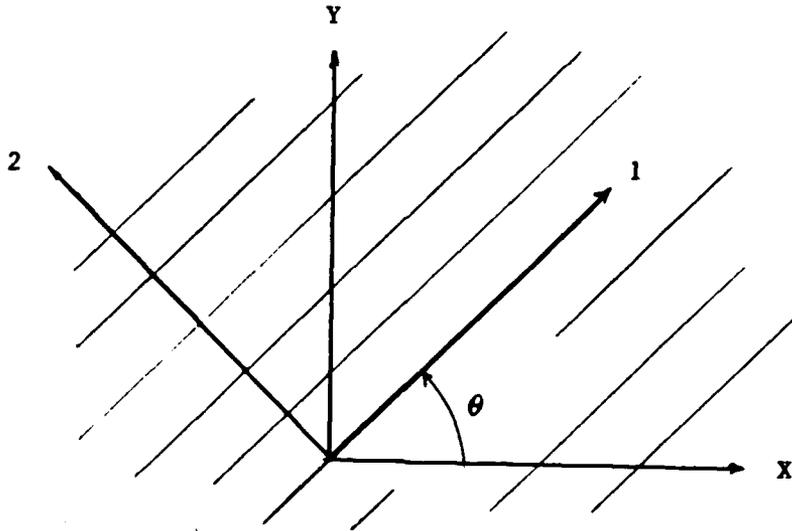

Figure 2.1 Definition of Coordinate System

The plane stress constitutive relations for an orthotropic lamina can be written as:

$$\begin{Bmatrix} \sigma_1 \\ \sigma_2 \\ \tau_{12} \end{Bmatrix} = \begin{bmatrix} Q_{11} & Q_{12} & 0 \\ Q_{12} & Q_{22} & 0 \\ 0 & 0 & Q_{66} \end{bmatrix} \begin{Bmatrix} \epsilon_1 \\ \epsilon_2 \\ \gamma_{12} \end{Bmatrix} \quad (1)$$

Where the Q_{ij} 's are the reduced stiffnesses and are defined in terms of the engineering constants as:

$$\begin{aligned} Q_{11} &= E_1 / (1 - \nu_{12}\nu_{21}) \\ Q_{12} &= \nu_{12}E_2 / (1 - \nu_{12}\nu_{21}) = \nu_{21}E_1 / (1 - \nu_{12}\nu_{21}) \\ Q_{22} &= E_2 / (1 - \nu_{12}\nu_{21}) \\ Q_{66} &= G_{12} \end{aligned} \quad (2)$$

where

$$\begin{aligned} \nu_{12} &= - \frac{\epsilon_2}{\epsilon_1} \\ \nu_{21} &= - \frac{\epsilon_1}{\epsilon_2} \\ G_{12} &= - \frac{\tau_{12}}{\gamma_{12}} \end{aligned} \quad (3)$$

In any other coordinate system with the fiber axis oriented at some angle θ with respect to the structural axes, the stresses are:

$$\begin{Bmatrix} \sigma_x \\ \sigma_y \\ \tau_{xy} \end{Bmatrix} = \begin{bmatrix} \bar{Q}_{11} & \bar{Q}_{12} & \bar{Q}_{16} \\ \bar{Q}_{12} & \bar{Q}_{22} & \bar{Q}_{26} \\ \bar{Q}_{16} & \bar{Q}_{26} & \bar{Q}_{66} \end{bmatrix} \begin{Bmatrix} \epsilon_x \\ \epsilon_y \\ \gamma_{xy} \end{Bmatrix} \quad (4)$$

Where the \bar{Q}_{ij} 's are the transformed reduced stiffnesses:

$$\begin{aligned}
 \bar{Q}_{11} &= Q_{11} \cos^4 \theta + 2(Q_{12} + 2Q_{66}) \sin^2 \theta \cos^2 \theta + Q_{22} \sin^4 \theta \\
 \bar{Q}_{12} &= (Q_{11} + Q_{22} - 4Q_{66}) \sin^2 \theta \cos^2 \theta + Q_{12} (\sin^4 \theta + \cos^4 \theta) \\
 \bar{Q}_{22} &= Q_{11} \sin^4 \theta + 2(Q_{12} + 2Q_{66}) \sin^2 \theta \cos^2 \theta + Q_{22} \cos^4 \theta \\
 \bar{Q}_{16} &= (Q_{11} - Q_{12} - 2Q_{66}) \sin \theta \cos^3 \theta + (Q_{12} - Q_{22} + 2Q_{66}) \\
 &\quad \sin^3 \theta \cos \theta \\
 \bar{Q}_{26} &= (Q_{11} - Q_{12} - 2Q_{66}) \sin^3 \theta \cos \theta + (Q_{12} - Q_{22} + 2Q_{66}) \\
 &\quad \sin \theta \cos^3 \theta \\
 \bar{Q}_{66} &= (Q_{11} + Q_{22} - 2Q_{12} - 2Q_{66}) \sin^2 \theta \cos^2 \theta + Q_{66} (\sin^4 \theta + \cos^4 \theta)
 \end{aligned} \tag{5}$$

To extend the stress-strain relationship to a multilayered laminate, two assumptions must be made. First, the laminate is assumed to have perfect bonds between the lamina so that no interlamina slipping can occur. Secondly, the Kirchhoff-Love hypothesis applies. This hypothesis states that normals to the mid-surface remain plane and normal to that surface after bending. These assumptions lead to the strain-curvature relationship for a laminate.

$$\begin{pmatrix} \epsilon_x \\ \epsilon_y \\ \gamma_{xy} \end{pmatrix} = \begin{pmatrix} \epsilon_x^o \\ \epsilon_y^o \\ \gamma_{xy}^o \end{pmatrix} + Z \begin{pmatrix} \kappa_x \\ \kappa_y \\ 2\kappa_{xy} \end{pmatrix} \tag{6}$$

Where the o superscript indicates the mid-surface strains, the κ 's are mid-surface curvatures and Z (See Figure 2.2) represents a distance from the panel's mid-surface.

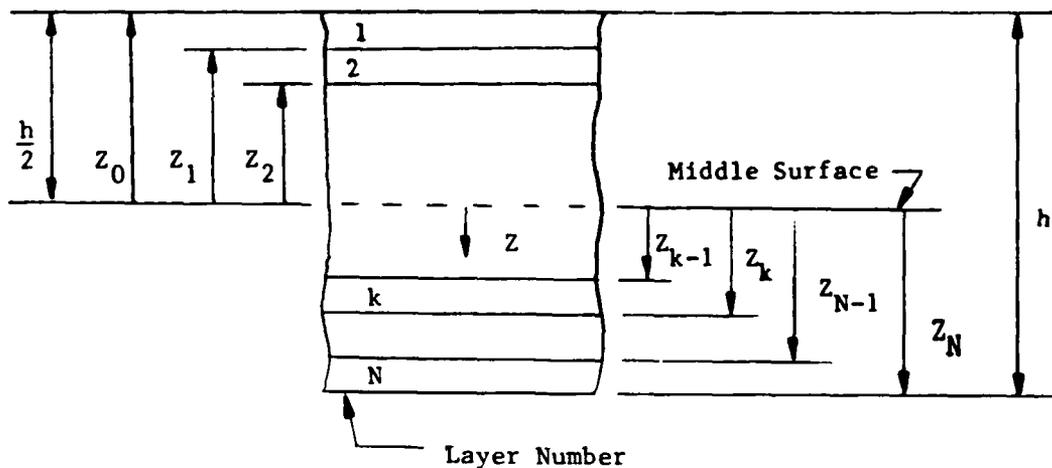

Figure 2.2 Geometry of an N-Layered Laminate

For a cylindrical panel with moderately large displacements and also moderately large rotations of tangents to its mid-surface, the above strains and curvatures are given by Sanders' kinematic relations without initial imperfections [24] as

$$\begin{aligned}
 \epsilon_x^0 &= u_{,x} + \frac{1}{2} \phi_x + \frac{1}{2} \phi^2 \\
 \epsilon_y^0 &= v_{,y} + \frac{w}{r} + \frac{1}{2} \phi_y^2 - \frac{1}{2} \phi^2 \\
 \gamma_{xy}^0 &= v_{,x} + u_{,y} + \phi_x \phi_y \\
 \kappa_x &= \phi_{x,x} \\
 \kappa_y &= \phi_{y,y} \\
 2\kappa_{xy} &= \phi_{y,x} + \phi_{x,y} + \frac{\phi}{r}
 \end{aligned} \tag{7}$$

Where u , v , and w are the axial, circumferential, and radial components of displacement, respectively, of the panel's mid-surface. The ϕ 's are

rotational components and are expressed in terms of the displacements as:

$$\begin{aligned}\phi_x &= -w_{,x} \\ \phi_y &= -w_{,y} + \frac{v}{r} \\ \phi &= \frac{1}{2}(v_{,x} - u_{,y})\end{aligned}\quad (8)$$

where r is the panel's radius of curvature.

If Eq. (6) is substituted into Eq. (4), the stresses in the k^{th} layer can be expressed in terms of the laminate mid-surface strains and curvatures as:

$$\begin{Bmatrix} \sigma_x \\ \sigma_y \\ \tau_{xy} \end{Bmatrix}_k = \begin{bmatrix} \bar{Q}_{11} & \bar{Q}_{12} & \bar{Q}_{16} \\ \bar{Q}_{12} & \bar{Q}_{22} & \bar{Q}_{26} \\ \bar{Q}_{16} & \bar{Q}_{26} & \bar{Q}_{66} \end{bmatrix}_k \left\{ \begin{Bmatrix} \epsilon_x^o \\ \epsilon_y^o \\ \gamma_{xy}^o \end{Bmatrix} + z \begin{Bmatrix} \kappa_x \\ \kappa_y \\ 2\kappa_{xy} \end{Bmatrix} \right\} \quad (9)$$

The resultant forces and moments acting on a laminate can now be found by integration of the above stresses in each lamina through the laminate thickness. Denoting the in-plane ply stress by σ_i , then

$$(N_i, M_i) = \int_{-t/2}^{t/2} \sigma_i(l, z) dz \quad (10)$$

where N_i and M_i are the force and moment per unit length (width) of the cross-section of the laminate as shown in Figure 2.3.

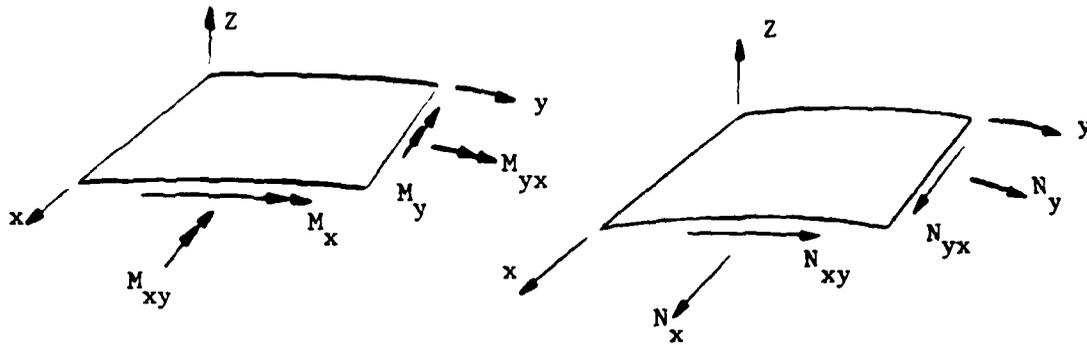

Figure 2.3 Forces and Moments on a Laminate

The forces and moments shown in Figure 2.3 can be written as:

$$\begin{Bmatrix} N_x \\ N_y \\ N_{xy} \end{Bmatrix} = \int_{-h/2}^{h/2} \begin{Bmatrix} \sigma_x \\ \sigma_y \\ \tau_{xy} \end{Bmatrix}_k dZ = \sum_{n=1}^N \int_{Z_{k-1}}^{Z_k} \begin{Bmatrix} \sigma_x \\ \sigma_y \\ \tau_{xy} \end{Bmatrix}_k dZ \quad (11)$$

and

$$\begin{Bmatrix} M_x \\ M_y \\ M_{xy} \end{Bmatrix} = \int_{-h/2}^{h/2} Z \begin{Bmatrix} \sigma_x \\ \sigma_y \\ \tau_{xy} \end{Bmatrix}_k dZ = \sum_{n=1}^N \int_{Z_{k-1}}^{Z_k} Z \begin{Bmatrix} \sigma_x \\ \sigma_y \\ \tau_{xy} \end{Bmatrix}_k dZ \quad (12)$$

where N is the total number of laminae, and Z_k and Z_{k-1} are defined in Figure 2.2.

The integration indicated by Eq's. (11) and (12) can be rearranged to take advantage of the fact that the stiffness matrix, $[\bar{Q}_{ij}]$, for each lamina is constant within that layer. Therefore, the stiffness

matrix can be removed from behind the integration but remains within the summation sign. Also note that mid-plane strains and curvatures are independent of Z and can also be removed from the integration and summation. Thus, the force and moment resultants can be written as:

$$\begin{Bmatrix} N_x \\ N_y \\ N_{xy} \end{Bmatrix} = \begin{bmatrix} A_{11} & A_{12} & A_{16} \\ A_{12} & A_{22} & A_{26} \\ A_{16} & A_{26} & A_{66} \end{bmatrix} \begin{Bmatrix} \epsilon_x^o \\ \epsilon_y^o \\ \gamma_{xy}^o \end{Bmatrix} + \begin{bmatrix} B_{11} & B_{12} & B_{16} \\ B_{12} & B_{22} & B_{26} \\ B_{16} & B_{26} & B_{66} \end{bmatrix} \begin{Bmatrix} \kappa_x \\ \kappa_y \\ \kappa_{xy} \end{Bmatrix} \quad (13)$$

$$\begin{Bmatrix} M_x \\ M_y \\ M_{xy} \end{Bmatrix} = \begin{bmatrix} B_{11} & B_{12} & B_{16} \\ B_{12} & B_{22} & B_{26} \\ B_{16} & B_{26} & B_{66} \end{bmatrix} \begin{Bmatrix} \epsilon_x^o \\ \epsilon_y^o \\ \gamma_{xy}^o \end{Bmatrix} + \begin{bmatrix} D_{11} & D_{12} & D_{16} \\ D_{12} & D_{22} & D_{26} \\ D_{16} & D_{26} & D_{66} \end{bmatrix} \begin{Bmatrix} \kappa_x \\ \kappa_y \\ \kappa_{xy} \end{Bmatrix} \quad (14)$$

where:

$$\begin{aligned} A_{ij} &= \sum_{k=1}^N (\bar{Q}_{ij})_k (z_k - z_{k-1}) \\ B_{ij} &= \frac{1}{2} \sum_{k=1}^N (\bar{Q}_{ij})_k (z_k^2 - z_{k-1}^2) \\ D_{ij} &= \frac{1}{3} \sum_{k=1}^N (\bar{Q}_{ij})_k (z_k^3 - z_{k-1}^3) \end{aligned} \quad (15)$$

The A_{ij} 's are called extensional stiffnesses, the B_{ij} 's are called bending-extensional coupling stiffnesses, and the D_{ij} 's are called bending stiffness. For a linear analysis the mid-surface strains and curvatures can be expressed in terms of the displacements by substituting Eq. (8) into Eq. (7) to yield

$$\begin{pmatrix} \epsilon_x^0 \\ \epsilon_y^0 \\ \gamma_{xy}^0 \\ K_x \\ K_y \\ 2K_{xy} \end{pmatrix} = \begin{pmatrix} u_{,x} \\ v_{,y} + \frac{w}{r} \\ v_{,x} + u_{,y} - w_{,x} \frac{v}{r} \\ -w_{,xx} \\ -w_{,yy} + \frac{v_{,y}}{r} \\ -w_{,yx} + \frac{v_{,x}}{r} - w_{xy} + \frac{1}{2}(v_{,x} - u_{,y})/r \end{pmatrix} \quad (16)$$

where the non-linear terms have been left-off.

STAGS-C1 Theory

The Structural Analysis of General Shells (STAGS-C1) is a computer code developed by the Lockheed Palo Alto Research Laboratory to analyze general shells under various static, thermal, and mechanical loading [25-26]. The approach used by STAGS-C1 to solve these problems is an energy-based finite element analysis. According to the energy method, a system's total potential energy is used to derive its equilibrium equations from which stability can be determined by the solution to an eigenvalue problem.

A shell's total potential energy, V , is equal to its internal strain energy minus the product of the external forces and their respective deflections. This can be written as [27]:

$$V = \frac{1}{2} \langle d \rangle^T [K] \langle d \rangle - d^T \langle R \rangle \quad (17)$$

where $\{d\}$ is the vector of nodal degrees of freedom of the structure, $[K]$ is the structural stiffness matrix, and $\{Rl\}$ is the structural applied load vector.

An element's strain energy, U , is given by [24]:

$$U = \frac{1}{2} \int_{\text{area}} \{\epsilon\}_0^T \begin{bmatrix} [A] & [B] \\ [B] & [D] \end{bmatrix} \{\epsilon\}_0 dA \quad (18)$$

where $\{\epsilon\}_0$ is the mid-plane strain and curvature vector given by Eq. (7) and $[A]$, $[B]$, $[D]$ are the 3 x 3 stiffness matrices given by Eq's. (13) and (14).

In general, the strain vector $\{\epsilon\}_0$ is a function of the mid-surface displacements (u , v , and w), the first order partial derivatives of u , v , and w with respect to x and y , and the second order partial derivatives of w with respect to x and y . Bauld [24] carried out the integration of Eq. (18) using the terms from Eq. (7) for $\{\epsilon\}_0$ and found that the expression for strain energy is comprised of three distinct parts. The first part is quadratic, the second part is cubic, and the third part is quartic in displacements. This result can be written in terms of the appropriate element shape functions and nodal degrees of freedom.

By using a similar finite element analysis on the element's external forces the element's external potential energy can be obtained. This combined with the strain energy gives the total system potential energy Eq. (17) and can be written in the form given by Bauld [24] as:

$$V = (1/2H_{rs} + 1/6N1_{rs} + 1/12N2_{rs})d_r d_s - R_s d_s \quad (19)$$

where the structural nodal degrees of freedom are replaced by the displacement vector, d . H_{rs} is the system's linear stiffness matrix with no dependence on the displacement vector, d . $N1_{rs}$ and $N2_{rs}$ are matrices with linear and quadratic dependence, respectively, on displacement. R_s is the surface force vector.

The principle of total potential energy states that the equilibrium configuration of a conservative mechanical system corresponds to a stationary value of the total potential energy of the system [27]. Therefore, taking the first variation of Eq. (19) and setting it equal to zero, one obtains a set of nonlinear, algebraic equations of the form:

$$(H_{rs} + 1/2N1_{rs} + 1/3N2_{rs})d_s - R_r = 0 \quad (20)$$

The loss of stability (collapse), results when the second variation of the system's total potential energy ceases to be positive definite, or:

$$\text{DET}(H_{rs} + N1_{rs} + N2_{rs}) = 0 \quad (21)$$

Equation (21) is used by STAGS-C1 to solve the eigenvalue problem of the form [28]:

$$[H] + \lambda[I] + \lambda^2[J] = 0 \quad (22)$$

Where $[I]$ and $[J]$ represent nonlinear stiffness matrices in unknown displacements and products of displacements, respectively. For a linear analysis, λ , is the proportionality constant of a convenient load level used in the equilibrium Eq's. (20) to solve for the unknown displacements. Also the J matrix, which arises from the prebuckling rotations, is omitted. The quantities H , I , J , or equivalently, H_{rs} , $N1_{rs}$, and $N2_{rs}$ are calculated once based on the equilibrium displacements. Finally, the load proportionality parameter, λ , is incremented until a sign change on the left side of Eq. (21) occurs, signifying bifurcation.

III. Finite Element Modeling

This thesis will evaluate the stability of cylindrical composite panels that are subjected to a simple shear load. Such a panel would be representative of an aircraft fuselage skin panel. The STAGS-C1 requires the user to input the type of shell surface geometry. To model the cylindrical panels and to allow for different radii of curvature, the STAGS-C1 cylindrical shell geometry was selected. (See Figure 3.1). In Figure 3.1 U, V, and W represent the displacements in the X, Y, and Z directions, respectively and RU, RV, and RW represent the rotations about the X, Y, and Z coordinate axes, respectively.

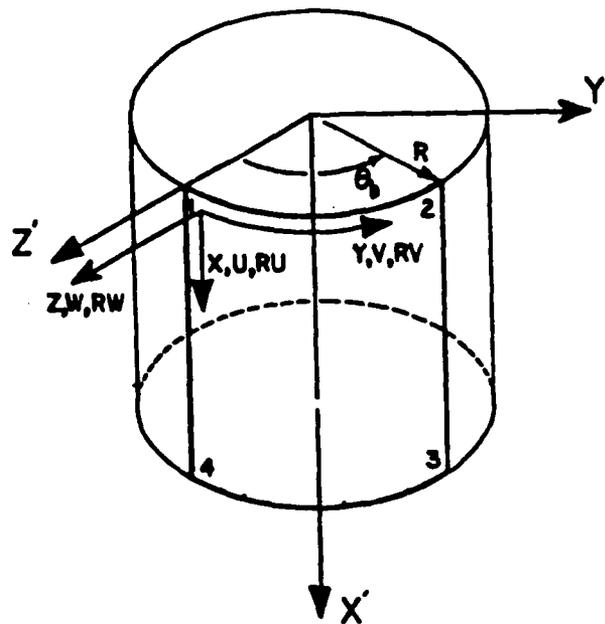

Figure 3.1 STAGS-C1 Cylindrical Shell Geometry

This study also required the equivalent of a flat plate. To model this, using the cylindrical shell geometry model, a study was run to determine what value of R would correspond to ∞ . For a symmetric laminate, a radius of 10,000 in. gave values within 0.02 percent of STAGS-C1 flat plate geometry.

Boundary Conditions and Loading

The boundary conditions used in the bifurcation analysis were selected to represent simple shear in a flat plate. The boundary conditions (See Figure 3.1) assumed that the structure's ring frames and stringers were effective in restraining out-of-plane deflections (W), also the top and bottom frames restrained the rotational movement about the X-axis (RU) and the two sides stringers restrained the rotational movement about the Y-axis (RV). The boundary conditions are summarized in Table 1, where 0 represents a fixed displacement and 1 represents a free displacement along the panel's edges. These values were used for both the pre- and post-buckle boundary conditions.

Table 2.1

Panel Boundary Conditions						
	U	V	W	RU	RV	RW
Top	1	1	0	0	1	1
Right Side	1	1	0	1	0	1
Bottom	0	0	0	0	1	1
Left Side	1	1	0	1	0	1

To input a simple shear load into the panel, line loads (N_{xy} and N_{yx}) were applied to all four edges (See Figure 3.2). They were assumed to act uniformly along all sides of the panel which in a flat plate would represent a simple shear loading.

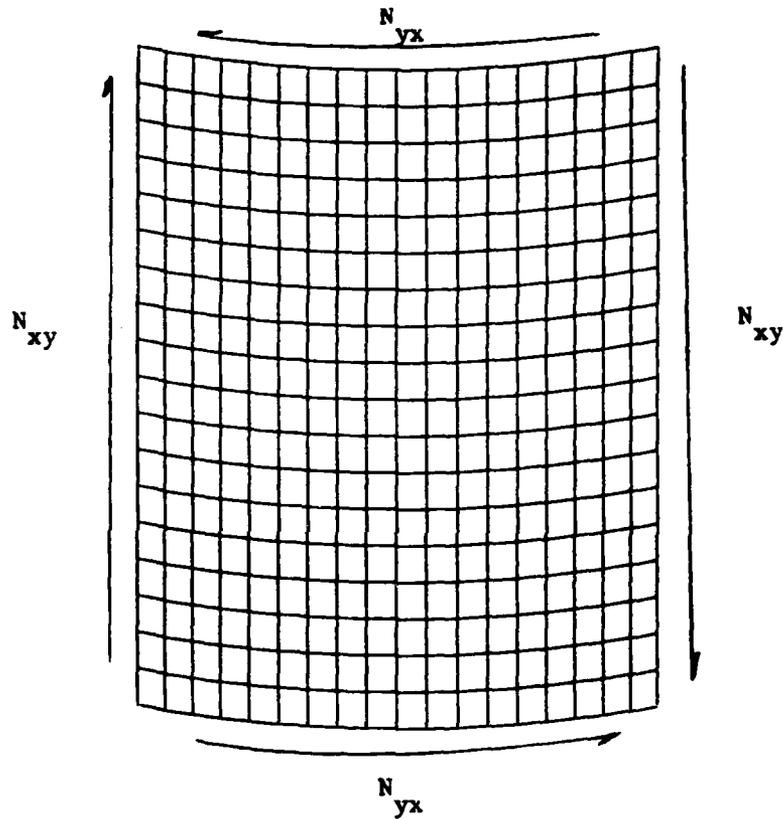

Figure 3.2 Finite Element Grid

Grid Size

The determination of a finite element grid size is a trade-off between cost and accuracy. Nelson [29] found that to obtain accurate results, there should be at least five node points per each half sine

wave of the buckled pattern in the circumferential direction. Several papers [2, 3, and 7] indicate that for the panel used in this analysis a grid of 0.5 x 0.5 in. elements represent a good trade-off between accuracy and computer economics. For the 12.0 x 12.0 in. panel, used in this analysis, a 0.5 x 0.5 in. element would correlate to a mesh of 24 x 24 elements or a total of 576 elements and 625 nodes. Due to the large number of computer runs needed to complete this analysis, it was decided to increase the element size to 2/3 x 2/3 in. which correlates to a mesh of 18 x 18 elements or a total of 324 elements and 361 nodes. (See Figure 3.2) Computer runs showed that this still gave five nodes per each half sine wave and reduced the cost per run by 2.3 times. To verify that this reduction would still yield valid results, a convergence study was run which showed that the difference between the bifurcation loads for the 324 elements and 576 elements is approximately 0.24 percent which was well within engineering accuracy.

Finite Element Selection

The STAGS-C1 finite elements program, as used in this analysis, uses flat elements to model curved surfaces. Figure 3.3 illustrates how a cylindrical surface can be modeled with flat elements. The use of flat elements presents conformity problems which are important when dealing with nonlinear and stability problems. Compatibility problems develop for both the rotational and displacement degrees of freedom at the nodes.

The rotational problem is dealt with by assuming that the angle of intersection α is small, and, as a consequence, the normal rotation β_z

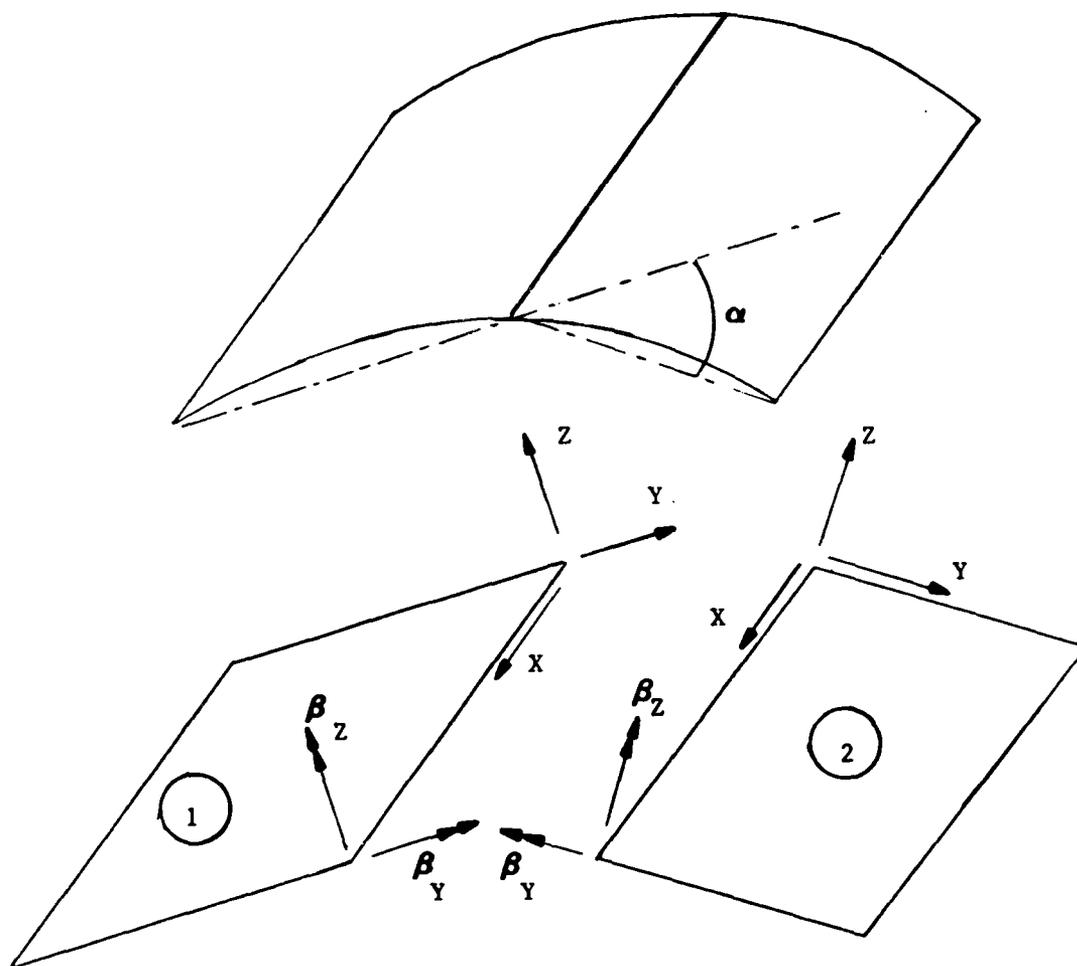

Figure 3.3 Modeling of Cylindrical Shell with Flat Plates

is ignored while the conformity constraint is satisfied by letting $\beta_y^{(1)} = \beta_y^{(2)}$.

Complete displacement compatibility along the common boundary requires that:

$$\begin{aligned} (v^{(1)} - v^{(2)}) \cos (\alpha/2) - (w^{(1)} + w^{(2)}) \sin (\alpha/2) &= 0 \\ (w^{(1)} - w^{(2)}) \cos (\alpha/2) + (v^{(1)} + v^{(2)}) \sin (\alpha/2) &= 0 \end{aligned} \quad (23)$$

Where v and w are the displacements in the y and z directions, respectively. These conditions will not be met if v and w are not represented by polynomials of the same order. To satisfy this requirement, additional degrees of freedom are added to the element to raise the order of the polynomials representing the inplane deformation. Since w is represented by a cubic polynomial, because the strain energy expression includes second order derivatives of the transverse displacement w , it is necessary that u and v also be represented by cubic polynomials. This is achieved by the use of two rotations at each corner node, $-v_{,x}$ and $u_{,y}$, and tangential displacements at mid-side nodes. The difference between these two rotations yields a shear strain at each corner node, which is introduced as an additional degree of freedom. Thus, each element has a total of 32 degrees of freedom. In STAGS-C1 this element is referred to as the SH411. (See Figure 3.4)

A somewhat simpler version of the SH411 element, the SH410 element, is also included for thin shell analysis. This element excludes the

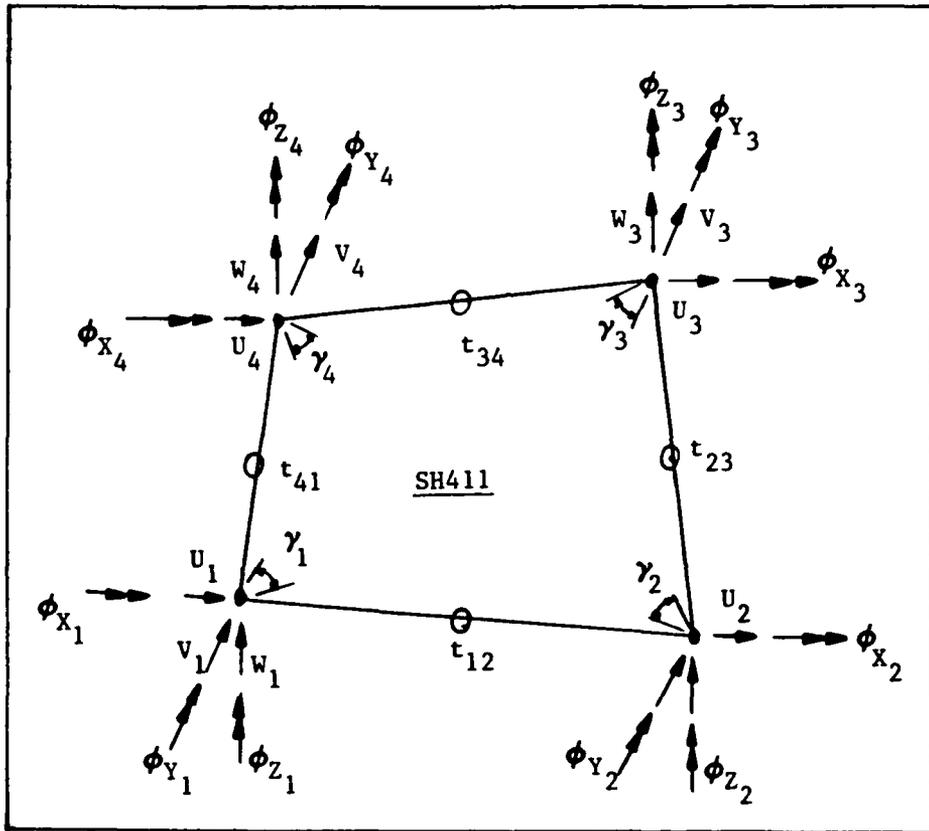

Figure 3.4 SH411 Element

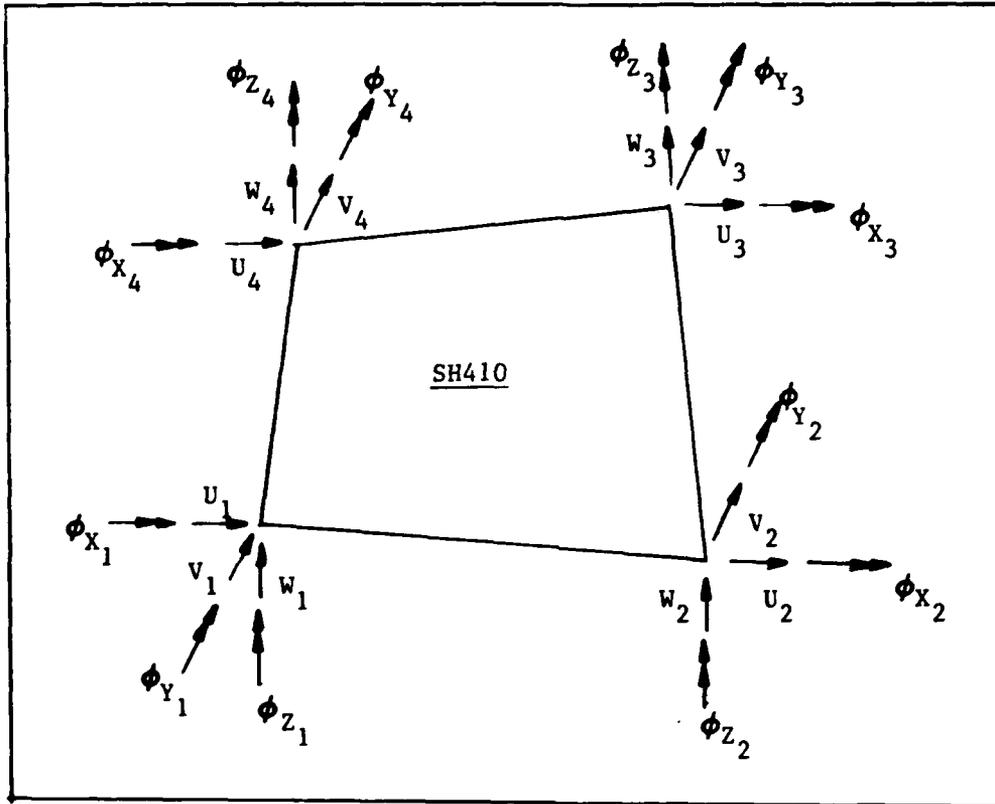

Figure 3.5 SH410 Element

mid-side tangential displacements and uses only an average normal rotation at each of the corner nodes. This restricts u to a linear function in the x -direction and v to a linear function in the y -direction. Also the shear strain is suppressed at the corner nodes. (See Figure 3.5) Because of this the SH410 element is an incompatible element, but it still yields valid results for some problems. For a more thorough explanation of these elements development, the reader should refer to Reference [30] and [31].

To help assist in the decision of which element to use, a small convergence study was conducted for both elements (See Figure 3.6 and 3.7). The geometric radius was selected to be 24 in. for the 12 in. x 12 in. panel. Figure 3.6 shows the differences between the eigenvalues for the SH411 and SH410 elements verses the number of elements in the grid. The SH410 converges to a slightly higher value (about 1.6 percent higher at 324 elements) than the SH411. The reason for this is that the SH410 produces a stiffer element than the SH411 due to it's incompatibility. Figure 3.7 shows a 8.2 percent difference in the bifurcation load, \bar{N}_{xy} , at 324 elements. The values for \bar{N}_{xy} were calculated by multiplying the eigenvalues by the internal resulting force N_{xy} . This force was calculated by STAGS based on the applied load and the element selected. For this analysis a unit line load N_{xy} was applied to the boundaries. Therefore, the difference between the SH410 and SH411 values in Figure 3.7 was due to the differences in the elements and how STAGS distributed the load through the panel. Since the SH410 suppresses the shear strain at the nodes, it requires a higher shear load to produce bifurcation.

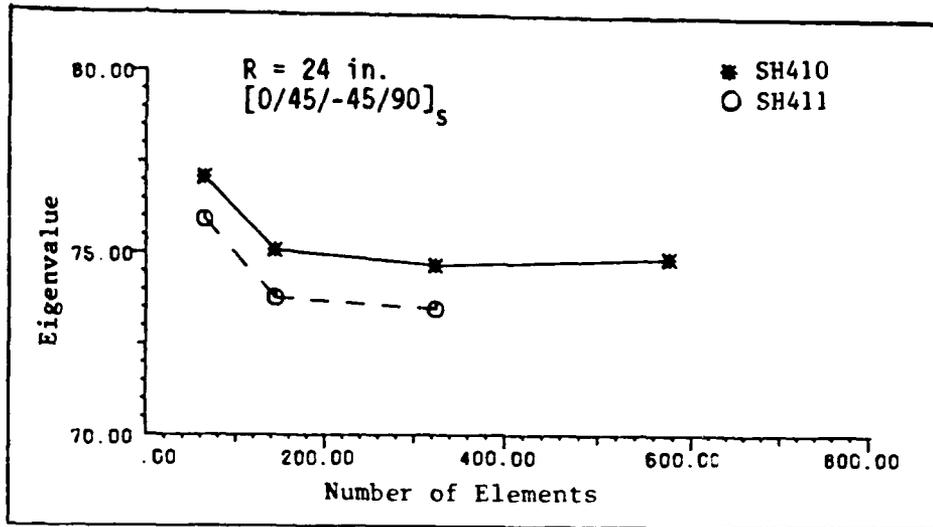

Figure 3.6 Convergence Comparison for the Eigenvalue

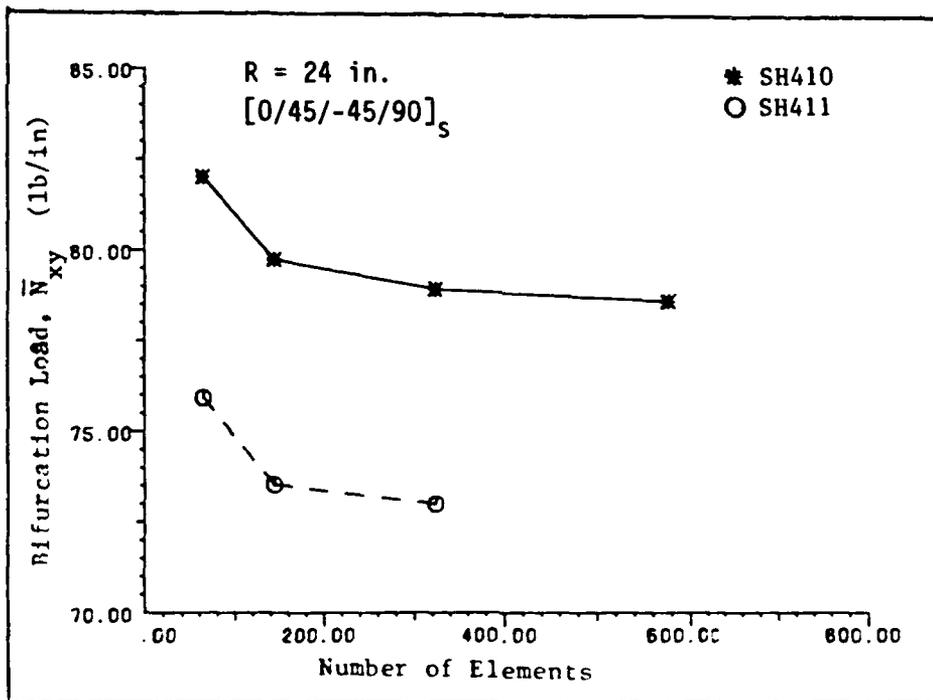

Figure 3.7 Convergence Comparison for the Bifurcation Load, \bar{N}_{xy}

Even though the SH410 element does not perform as well as the SH411, it was selected for use in this analysis when evaluating the influence of hygrothermal and curvature effects. Part of this reason is cost. The SH411 cost between 2 and 2.5 times that of SH410 run. The other reason is that this analysis is interested in the trends, so when the bifurcation load is normalized with respect to the room temperature and zero moisture values, the differences in the bifurcation load reduces to a ratio of the eigenvalues and the error divides out.

Bifurcation Analysis Method

STAGS-C1 has two buckling analysis modes. One uses a linear, pre-buckling displacements state and is referred to in the STAGS-C1 manual as the bifurcation analysis with a linear stress state. The second method uses a geometric pre-buckling, nonlinear displacement calculation and is referred to as the bifurcation analysis with a non-linear displacement state. For this study the bifurcation analysis with a linear stress state will be used. This method will calculate the pre-buckling displacements and rotations, stress resultants, strains, and stresses as desired. It also predicts the bifurcation eigenvalue and the shape of the eigenvector. It does not yield any post-buckling information.

Validation of Model

To check the boundary conditions, loading, and how well STAGS predicts buckling with bending-extensional coupling, the finite element

model was compared to a Galerkin solution obtained by Whitney [1]. In his paper, he presented an analytical solution for the buckling of anisotropic cylindrical plates under arbitrary combinations of axial load, internal pressure, and in-plane shear load. He used the Donnell equations, as they are applied to laminated cylindrical shallow panels, in conjunction with the Galerkin method to determine the critical buckling loads. Two of his solutions were selected to check the finite element model. One related to the effects of bending-twisting coupling and the second related to the effects of bending-extensional coupling.

This comparison considered two 12-layer angle-ply laminates with the stacking geometries $[+45_3/-45_3]_s$ and $[+45_6/-45_6]$ under pure in-plane shear loading. The panels were 18 x 18 in. square with a thickness of $h = 0.06$ in. In order to keep the same number of elements, the grid spacing was increased to 1 in. x 1 in., which still gave five nodes per half sine wave. The buckling boundary conditions also had to be changed in STAGS to the simple support boundary conditions referred to as BC-1 to correlate to Whitney's work. These boundary conditions are:

At $x = 0, 18$ in.

$$N_n = M_n = V = W = 0 \quad (24)$$

and at $y = 0, 18$ in.

$$N_n = M_n = U = W = 0$$

The Galerkin method satisfies the natural boundary conditions. Whitney also used the following ply properties for his laminates:

$$E_1/E_2 = 14.0, \quad G_{12}/E_2 = 0.5, \quad \nu_{12} = 0.25 \quad (25)$$

which are typical properties of current graphite/epoxy composite materials. These values had to be modified somewhat for input into the STAGS program to give:

$$\begin{aligned} E_1 &= 14 \times 10^6 \text{ psi} \\ E_2 &= 1 \times 10^6 \text{ psi} \\ G_{12} &= 0.5 \times 10^6 \text{ psi} \\ \nu_{12} &= 0.25 \end{aligned} \quad (26)$$

which yields Whitney's ratios.

Figure 3.8 shows the comparison for the model studying the effects of bending-twisting coupling. The two sets of curves correspond to a + or - shear load. The symmetric lay-up $[+45_3/-45_3]_s$ eliminates all B_{1j} 's from Eqn's (13) and (14) along with A_{16} and A_{26} , but leaves in the bending-twisting coupling terms D_{16} and D_{26} . Since Whitney used the Donnell equations as shown

$$\begin{pmatrix} \epsilon_x^o \\ \epsilon_y^o \\ \gamma_{xy}^o \\ K_x \\ K_y \\ 2K_{xy} \end{pmatrix} = \begin{pmatrix} u_{,x} \\ v_{,y} + w/R \\ v_{,x} + u_{,y} \\ -w_{,xx} \\ -w_{,yy} \\ -2w_{,xy} \end{pmatrix} \quad (27)$$

He had to restrain the radius parameter in order to keep the assumptions used by the Donnell equations valid. The smallest radius

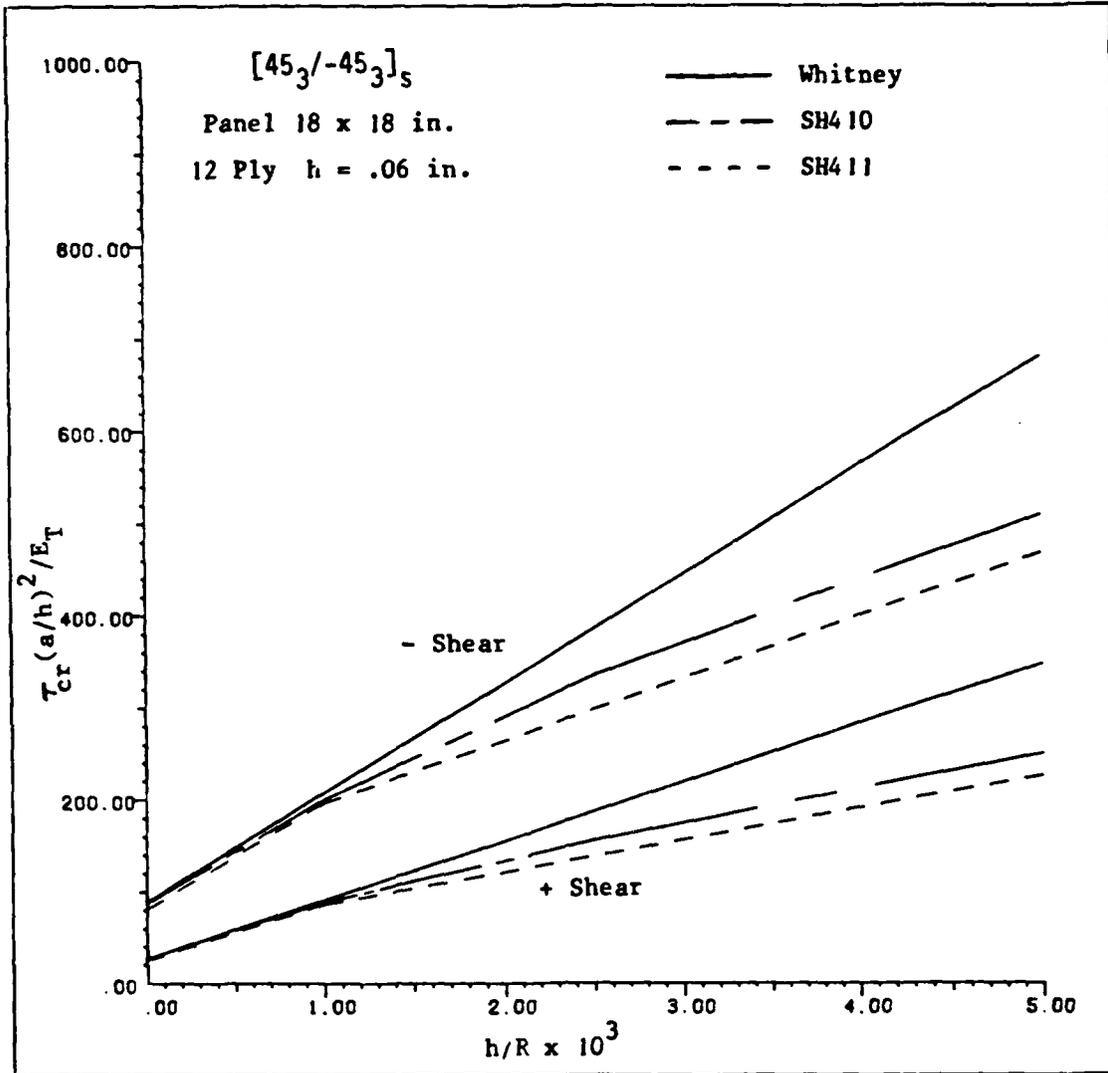

Figure 3.8 STAGS-C1 Finite Element vs Whitney's Galerkin, $[45_3/-45_3]_S$

he investigated was for an $R = 60$ in., which correlates to a $h/R \times 10^3$ of 1.0. Whitney's work was extrapolated linearly down to a radius of 12 in. for comparison purposes. This is possible because Donnell's equations are linear in R . Both STAGS elements SH410 and SH411 correlate to what Whitney found in the range from $R = 60$ to ∞ . What differences were found came about because Whitney was able to input a pure shear load, N_{xy} , into his equations and zero out all remaining resultant forces and moments. With STAGS the input of a pure shear load also generates some additional resultant forces and moments which contribute to reduce the bifurcation load. The deviation between the extrapolated Whitney and STAGS solutions is primarily due to the use in STAGS of the general shell equations:

$$\begin{pmatrix} \epsilon_x^0 \\ \epsilon_y^0 \\ \gamma_{xy}^0 \\ K_x \\ K_y \\ 2K_{xy} \end{pmatrix} = \begin{pmatrix} u_{,x} \\ v_{,y} + w/R \\ v_{,x} + u_{,y} - \underline{w_{,x} v/R} \\ -w_{,xx} \\ -w_{,yy} - \underline{w_{,y}/R} \\ -2w_{,xy} + \underline{v_{,x}/2R + (v_{,x} - u_{,y})/2R} \end{pmatrix} \quad (16)$$

The underlined terms are functions of the radius which are not found in Donnell's equation and come into play as the radius decreases. The use of the Donnell equation for a radius of 12 in. would introduce an error from 34 - 39 percent if compared to the SH410 element and from 45 - 54 percent if compared to the SH411 element.

Figures 3.9, 3.10, 3.11 show the comparison for the model studying the effects of bending-extensional coupling with Figure 3.11 being a combination of Figures 3.9 and 3.10. The unsymmetric lay-up $[+45_6/-45_6]$ eliminates A_{16} , A_{26} , D_{16} , and D_{26} along with all the B_{1j} 's except B_{16} and B_{26} , the bending-extensional coupling terms, from Eqn's (13) and (14). One can see that similar conclusions can be reached from these curves. The main difference is that the prebuckle displacements, forces, and moments play a much more important role in this lay-up no matter what the curvature since they can not be removed from the STAGS runs. Again, using the Donnell equation for a radius of 12 in. would introduce an error of around 59 percent if compared to the SH410 element and around 79 percent if compared to the SH411 element. Again, if the correct value for the bifurcation load is needed the SH411 should be used as found in the bending-twisting components and the convergence test.

The influence of hygrothermal effects can develop bending - extensional coupling in symmetric lay-ups. This analysis indicates that the model selected for this thesis should give a good indication of the influence of hygrothermal and curvature effects on cylindrical composite panels loaded in shear if the curvature is greater than $R = 60$ in. Also since the bifurcation load, \bar{N}_{xy} , will be normalized in this thesis for analysis of the effects of hygrothermal and curvature, the use of the SH410 instead of the SH411 will not influence the outcome of the analysis when comparing a curvature down to $R = 12$ in.

IV. Evaluation of Moisture and Temperature Conditions

Due to their excellent performance characteristics, advanced composite materials have been gaining wide use in aerospace structures. However, it is recognized that absorption of moisture and exposure to thermal environments can have undesirable effects on the mechanical properties of such materials [7-21]. Shirrell, Halpin, and Browning [19] reported that, unless these effects are accounted for in designing a system, the service life and reliability of a polymeric matrix composite may be compromised. Moisture absorption affects the composite in several different ways. Firstly, the resin swells causing a change in the residual stresses of the composite and possibly micro-crack formation. Secondly, the resin may be plasticized thus causing an increase in the elongation of the resin near failure. This also has an effect on the damping of the material. This plasticization is the result of the lowering of the glass transition temperature T_g . The glass transition temperature is actually a temperature range below which the resin is essentially brittle and above which it behaves rubbery. Thirdly, the interface between fiber and resin may be affected thus influencing the composites' strength and toughness. The fibers are not affected by either moisture absorption or moderate thermal environments which might be encountered during a normal aircraft service life. These changes in the resin have been found to result in a decrease in the tensile properties [13] and a reduction in the transverse and shear moduli [12 and 15] of the composite material. Also a slight increase in the longitudinal elastic modulus was reported in Reference [12].

Advanced resinous composites can absorb water through the following mechanisms:

1. the fiber - matrix interface (capillary);
2. cracks and voids in the composite; and,
3. the resin (diffusion).

Of these three, the primary mechanism of water penetration in large well-fabricated composite structures is a rapid surface absorption followed by diffusion of the water through the resin [19].

Prediction of Moisture Absorption

The testing of composite materials to determine their mechanical properties is usually done at known temperatures and moisture concentrations. Since the primary mechanism for absorption of moisture is through diffusion, Fick's second law of diffusion [32] which, under certain circumstances has been shown to correlate with test data [12], will be used as the model for diffusion in this analysis. Fick developed this equation in 1855 by drawing an analogy between heat conduction in a solid and diffusion through a solid. Fick's second law is:

$$\frac{\partial c}{\partial t} = K \frac{\partial^2 c}{\partial z^2} \quad (28)$$

where C is the concentration of the diffusing substance through the thickness of the laminate as a function of time and distance through

the thickness, Z is the space coordinate measured normal to the surface, K is the diffusion constant, and t is time.

The solution of this partial differential equation, with boundary and initial conditions pertinent to the problem of diffusion, is shown below. This is the same solution used by Snead and Palazotto [7] and is slightly different from that form found in Section 4.3.3 of Reference [32].

$$C(Z,t) = C_1 + (C_2 - C_1) \frac{Z}{h} + \frac{2}{\pi} \sum_{n=1}^{\infty} \frac{C_2 \cos(n\pi - C_1)}{n} \sin\left(\frac{n\pi Z}{h}\right) \star$$

$$\exp\left[-\frac{Kt}{h^2} n^2 \pi^2\right] + \frac{4C_0}{\pi} \sum_{m=0}^{\infty} \frac{1}{2m+1} \sin \frac{(2m+1)\pi Z}{h} \star \quad (29)$$

$$\exp\left[-\frac{Kt}{h^2} (2m+1)^2 \pi^2\right]$$

Where C is as previously defined, C_0 is the initial, uniform moisture concentration through the thickness of the laminate, C_1 and C_2 are the initial moisture concentration conditions at the inside ($-z$) and outside ($+z$) surface of the laminate, respectively, and h is the thickness of the laminate.

The moisture concentration distribution through the thickness can be determined by using this series solution with a known diffusion constant and prescribed initial conditions. Then the reduced mechanical properties of each ply can be obtained from appropriate test data by assuming that the effective moisture concentration of each ply can be

approximated by the calculated moisture concentration at the middle of that ply.

This series solution is a combination of a steady state moisture distribution (the first two terms) and a transient moisture distribution (the last two terms) which decreases with increasing time. Therefore, the accuracy of this series approximation is dependent upon the number of terms used during the two summations. Snead [7] wrote a computer program which was used in this analysis to calculate the solution to the series approximation. To insure an accurate solution, the program carries out the summation until there is no change from the previous answer. For the CDC computer, this is equivalent to 14 significant digits of accuracy. A version of Snead's computer program is shown in Appendix A.

The use of Fick's equation has certain limitations which must be considered. The series solution of Fick's equation was derived assuming a constant moisture diffusion coefficient K . In reality the diffusion coefficient is a function of the laminate's temperature and moisture concentration. The diffusion of moisture into a composite can be assumed to take place at a constant temperature in simple cases since the process is relatively slow, requiring many months or years before the laminate achieves a state of equilibrium moisture concentration.

The accuracy of Fick's equation to model moisture diffusion in composites is also affected by rapid temperature changes. The rapid thermal heating of the laminate to temperature near the material's T_g

has been found to increase the rate of moisture weight gain above that which is predicted by Fick's equation [11, 12, 14, and 17]. This increase is believed to be due to the development of surface crazing and cracking brought about by the rapid heating and resin swelling [12].

Fick's equation has been generally accepted as a good initial approximation of the moisture concentration distribution through a composite laminate, for simple cases, when the restrictions of no rapid heating, surface crazing or cracking, and assuming that a constant K are observed [12, 16, 18, and 19]. These are the assumptions being made for this analysis.

AS/3501-5 Mechanical Properties

The material properties required by STAGS-C1 as input parameters are the composite's longitudinal modulus E_1 , transverse modulus E_2 , shear modulus G_{12} , and Poisson's ratio ν_{21} . Poisson's ratio ν_{12} relates the strain in the 2 direction to the strain in the 1 direction when stressed in the 1 direction. Snead and Palazotto [7] used the experimentally - measured data for the graphite/epoxy system, AS/3501-5, found in Figure 8.18 of Reference 22 to determine the elastic moduli as a function of temperature and moisture concentration. The values of E_2 and G_{12} used in his work from which intermediate values are linearly interpolated, are shown in Table 4.1. For a better perspective, Figure 4.1 shows this data in graphical form. The material properties as calculated by Snead and Palazotto will be used in this work in order to correlate the findings.

TABLE 4.1

Values of Transverse and Shear Moduli
for AS/3501-5 [15]

Transverse Modulus, E_2 (psi)

Moisture Concentration (percent)	Temperature			
	80°F	200°F	250°F	300°F
0.0	1.41375E06	1.09475E06	1.015E06	1.015E06
0.050	1.305E06	0.9135E06	0.6235E06	0.522E06
1.050	1.2615E06	0.841E06	0.4785E06	0.290E06

Shear Modulus, G_{12} (psi)

0.0	0.8555E06	0.7830E06	0.6815E06	0.6525E06
1.050	0.8555E06	0.6597E06	0.3915E06	0.1522E06

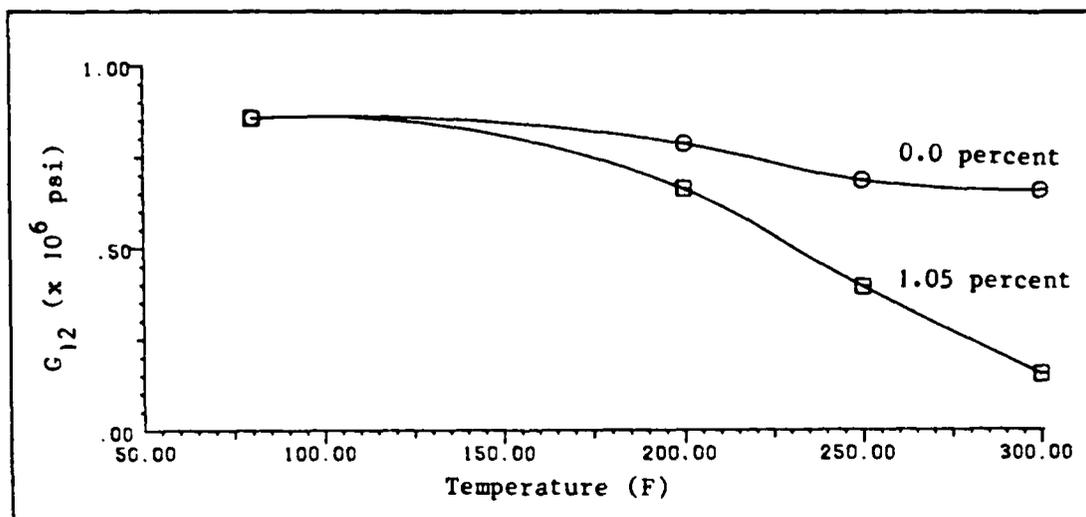

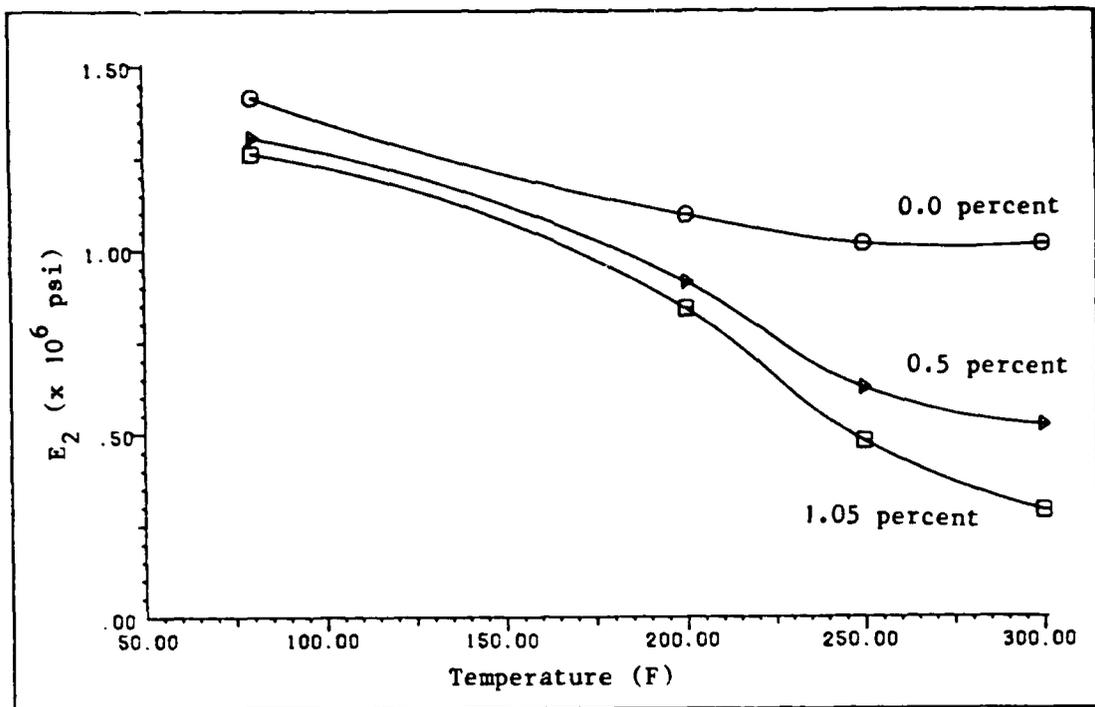

Figure 4.1 E_2 and G_{12} Degradation vs Temperature at Constant Values of Moisture Concentration

The moisture and temperature influences on the transverse and shear moduli are clearly evident in the experimental data for AS/3501-5 shown in Table 4.1 and Figure 4.1. The transverse modulus E_2 shows degradation both at room temperature and elevated temperatures while the shear modulus G_{12} only shows degradation at elevated temperatures. Also visible is the change in the T_g caused by the absorbed moisture. The resulting plasticization of the resin is shown by the increased degradation in the moduli with increasing moisture concentration at each elevated temperature. The longitudinal modulus E_1 is dominated by the fiber stiffnesses and hence is not significantly influenced by changes in moisture and temperature as are the matrix dominated E_2 and G_{12} moduli. Therefore, E_1 is assumed to be constant and has a value of 18.85×10^6 psi for AS/3501-5. Also for this work the value of ν_{12} was assumed to be a constant, $\nu_{12} = 0.3$.

Moisture Conditions

The series solution, Eq. (28), to the Fick's equation requires three moisture concentration coefficients C_0 , C_1 , and C_2 to determine the moisture concentration through the laminate's thickness as a function of time. These moisture concentrations, measured as a percentage of the weight gained by the composite, correspond to the initial moisture concentration in the laminate, the moisture concentration at the interior (-Z) surface, and the moisture concentration at the exterior (+Z) surface, respectively, for the cylindrical panel. Table 4.2 lists the three moisture concentration conditions considered by Sneed and Palazotto [7].

Table 4.2

Snead and Palazotto's Moisture Conditions

Cond. No.	C_0	C_1	C_2
1	0.00	0.00	0.0105
2	0.00	0.0105	0.00
3	0.00	0.0105	0.0105

They used a surface moisture concentration of 0.0105 to correspond to the material test data, Table 4.1, that was available for a saturation moisture concentration of 1.05 percent. (Note: The concentration of 1.05 percent relates to an environment which has a 75 percent relative humidity.) Conditions 1 and 2, in Table 4.2, result in an unsymmetric degradation of the E_2 and G_{12} moduli resulting in an unsymmetric laminate, which will introduce bending-extension coupling. Condition 3, in Table 4.2, is symmetric and will not produce any bending-extension coupling. Snead and Palazotto found that conditions 1 and 2 produced similar results to each other, therefore, only one unsymmetric condition was examined in this thesis along with one symmetric condition. Table 4.3 shows these moisture conditions.

Table 4.3

Moisture Conditions

Cond. No.	C_0	C_1	C_2
1	0.00	0.00	0.0105
2	0.00	0.0105	0.0105

Along with the coefficients C_0 , C_1 , and C_2 , in Eq. (29), it is standard to use a dimensionless time t^* , where $t^* = K (\text{in}^2/\text{sec}) \times t(\text{sec})/h^2(\text{in})^2$. This eliminates the need to pick a specific diffusion coefficient, K and time. The dimensionless times used in this analysis are 0.0, 0.001, 0.01, 0.1, and 0.5. These values represent from zero moisture absorption to a steady-state distribution, respectively. Table 4.4 shows how t^* corresponds to real time given a specific K and laminate thickness h .

Table 4.4

Relation Between Real and Dimensionless Time

Real Time (sec)	Real Time (days)	Dimensionless Time t^*
0.0	0.0	0.0
3.045E04	0.35	0.001
3.045E05	3.52	0.01
3.045E06	35.24	0.1
1.527E07	176.24	0.5

Note: These times were calculated using $K = 0.52537\text{E-}10$ (in^2/sec) for an 8-ply, 0.04 thick, AS/3501-5 laminate.

The parametric equation used to determine the value of $K = 0.52537\text{E-}10$ (in^2/sec) in Table 4.4 was

$$K(\text{in}^2/\text{sec}) = 6.51 \exp(-5722/T) (0.03937)^2 \quad (30)$$

where T is the laminate temperature in degrees Kelvin. This equation was taken from Reference [22]. Figure 4.2 shows the moisture

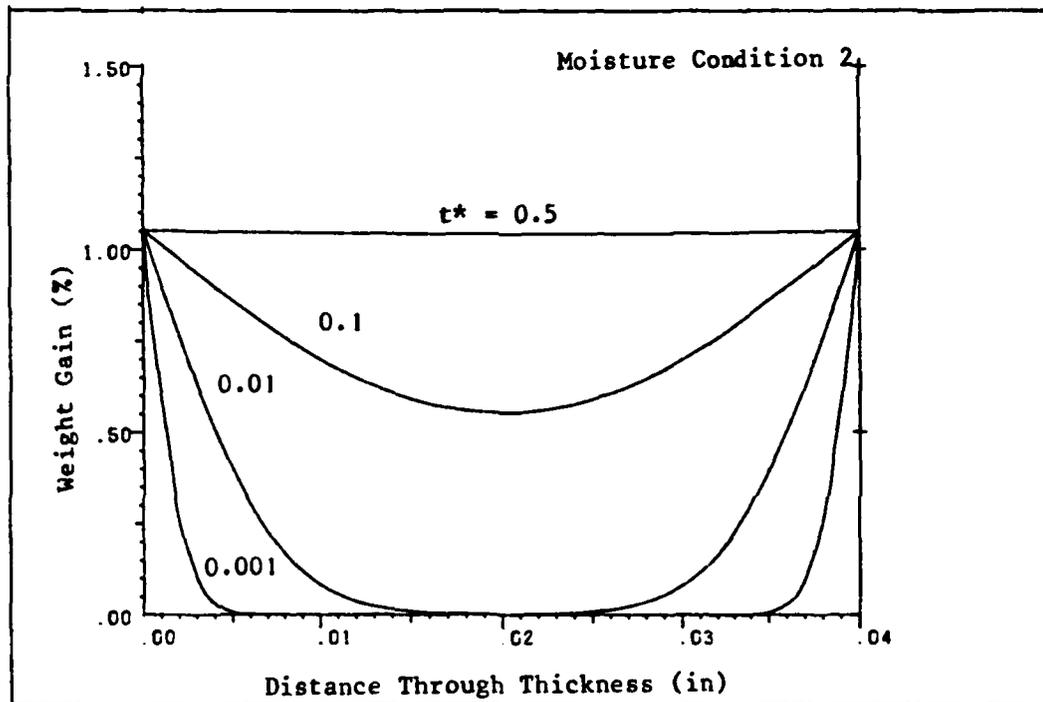

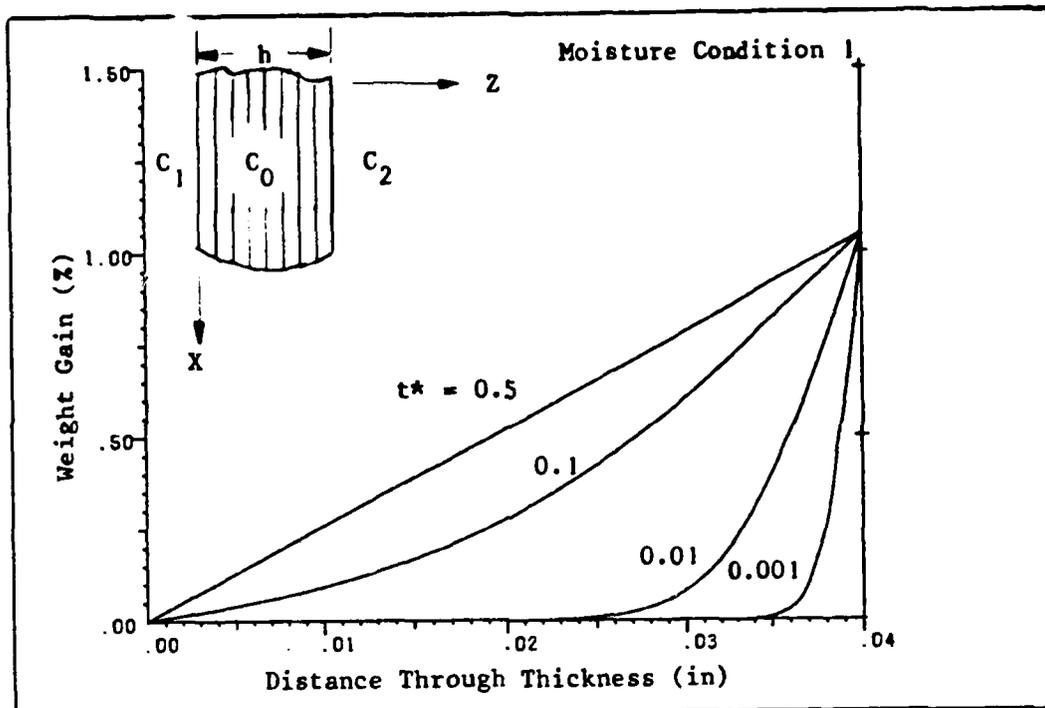

Figure 4.2 Moisture Concentration Distribution for Moisture Condition 1 and 2

distribution through the thickness for the five time values and moisture conditions 1 and 2. This figure shows that the panel will absorb moisture nonsymmetrically, for moisture condition 1. This means that, as time increases, the panel will reach a steady state condition, $t^* = 0.5$, where each lamina has a different moisture content. The symmetric nature of moisture condition 2 is also shown, and as time increases, the panel will reach a steady state condition, $t^* = 0.5$, where each lamina has the same moisture content. The moisture distribution is shown as a continuous function in Figure 4.2, however, as mentioned previously, the moisture concentration is calculated at the center of each ply and then assumed to be constant through the ply thickness in this analysis.

Temperature Conditions

For this analysis the laminate was assumed to be at a constant temperature. This is possible since the moisture diffusion process is much slower than that of thermal diffusion. Crank [32] indicated a factor of 10^6 for the time difference. Four different temperatures; 80, 200, 250 and 300°F; were used in this analysis to evaluate the influence of a wide range of temperatures on a composite panel. This range varies from room temperature to the operational service limit. The service limit for graphite/epoxy is approximately 300°F. These temperatures were selected because the material test data, Figure 4.1, was taken at these four temperatures.

Laminate Ply Orientations

Two eight-ply laminates will be evaluated. The two ply orientations chosen are the $[0/45/-45/90]_8$ and the $[45/-45]_{28}$, which correspond to two of the three orientations investigated by Snead and Palazotto [7].

V. Results and Discussion

For the hygrothermal investigation carried out within this study, a combination of moisture conditions, temperatures, and times generates a matrix of 40 cases for each given laminate per radius. These 40 cases are broken into two sets of 20 cases; 20 cases for each moisture condition. Because of the large number of cases to be evaluated, all 40 cases were run for only the radius of 12 in. for both laminates. In the analysis of curvature, the radii 36, 48, 96, and 10,000 in. were run for only the $[45/-45]_{2s}$ laminate, with a limited number of temperature and time steps. This reduced the number of cases, but still provided adequate information to analyze the effects of curvature on the bifurcation load. In this last mentioned analysis, moisture condition 1 was evaluated at 300°F and time steps 0.00 and 0.5, while moisture condition 2 was evaluated at 80, 200, and 300°F for all five time steps. A matrix of the case numbers and corresponding conditions is shown in Table 5.1 and a list of the bifurcation loads, \bar{N}_{xy} , for these cases can be found in Appendix B.

The computation of the moisture concentration distribution and the reduction in the transverse and shear moduli is done by the computer program listed in Appendix A. This computer program also generated the input deck for the STAGS-C1 program, and is a modification of the computer program written by Snead [7]. It was modified to allow for shear loading and changes in curvature.

Table 5.1

Moisture, Temperature, and Radius Conditions Evaluated

Case No.	Moisture Condition	Temperature	Radius (in.)	Laminate
1-20	1	a,b,c,d	12	[0/45/-45/90] _s
21-40	1	a,b,c,d	12	[45/-45] _{2s}
41-60	2	a,b,c,d	12	[0/45/-45/90] _s
61-80	2	a,b,c,d	12	[45/-45] _{2s}
81-91	2	a,b,c,d	24	[45/-45] _{2s}
92-93	1	d	24	[45/-45] _{2s}
300-305	2	a,d	36	[45/-45] _{2s}
100-110	2	a,b,d	48	[45/-45] _{2s}
111-112	1	d	48	[45/-45] _{2s}
121-128	2	a,b,d	96	[45/-45] _{2s}
131-132	1	d	96	[45/-45] _{2s}
141-147	2	a,b,d	10,000	[45/-45] _{2s}

Note: The cases with a R = 12 in. were run for all five times and four temperatures, however, the remaining cases were run at a mixture of time steps and temperatures depending on the moisture condition and radius.

Notation:

Moisture Condition	Temperature (°F)
1 — $C_0 = C_1 = 0.00$ $C_2 = 0.0105$	a — 80.0
	b — 200.0
2 — $C_0 = 0.0$ $C_1 = C_2 = 0.0105$	c — 250.0
	d — 300.0

Reduction in Bifurcation Load

The evaluation of the data for a panel loaded in shear indicates that the degradation of the E_2 and G_{12} moduli due to moisture and temperature effects results in a reduction of the panel's bifurcation load, \bar{N}_{xy} . Figures 5.1 and 5.3 show the results of the STAGS-C1 runs for the two 12 in. by 12 in. panels, with a radius of 12 in., while Figures 5.2 and 5.4 show the results found by Snead and Palazotto [7] for a similar panel acting under compressive loads. In these plots $\bar{N}_{xy\text{orig}}$ and $\bar{N}_{x\text{orig}}$ represents the bifurcation loads for a panel at 80°F, and a dimensionless time of $t^* = 0.00$ when loaded in shear and axial compression, respectively. These values are unaffected by either temperature or moisture degradations. The actual shear buckling values are shown in tabular form along with individual plots for each time and temperature series in Appendix B.

As was expected, the panel's bifurcation load decreased with increasing temperature and absorbed moisture. Comparing Figure 5.1 to Figure 5.2 shows a similarity in the trends for the reduced bifurcation loads for the $[0/45/-45/90]_S$ laminate considering shear and compression. A point should be made that even though the percent reductions are similar the actual values for the bifurcation loads, Table 5.2, differ considerably, i.e., for room temperature, zero moisture $\bar{N}_x = 514.8$ lb/in compared to $\bar{N}_{xy} = 123.4$ lb/in for the $[0/45/-45/90]_S$ laminate. The difference in Figures 5.1 and 5.2 is that the curves for the shear loading are shifted down below those for axial

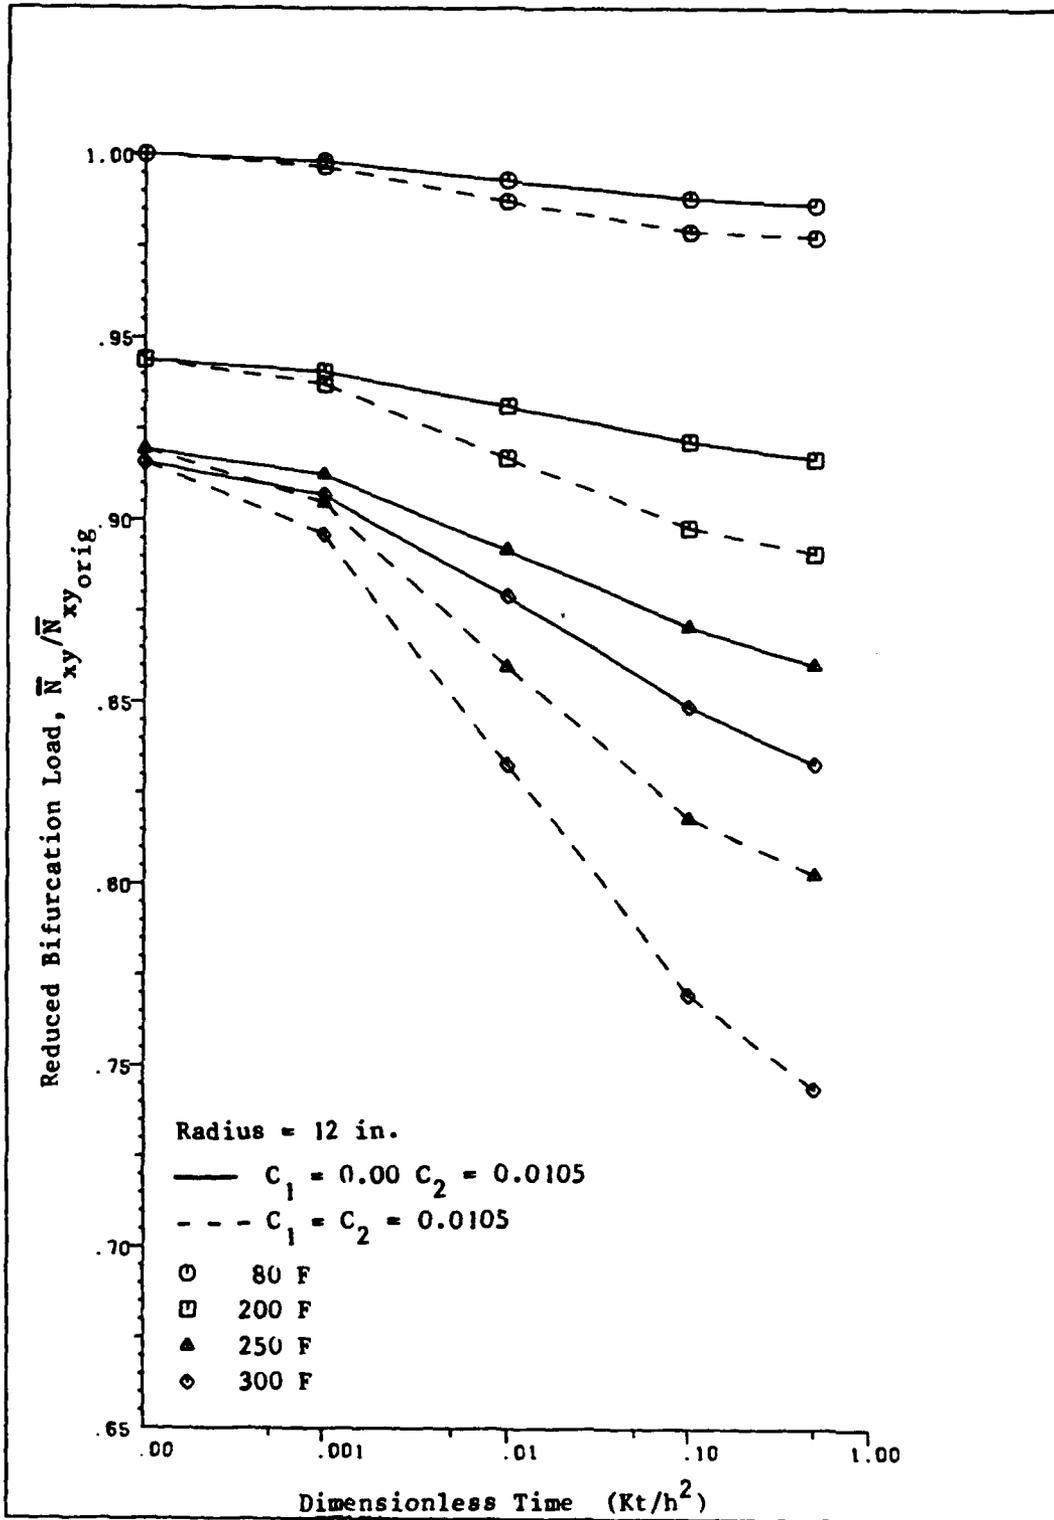

Figure 5.1 Degradation in \bar{N}_{xy} for the $[0/45/-45/90]_s$ Laminate

Table 5.2

Comparison of Bifurcation Loads (lb/in)
 at 80°F, $t^* = 0.00$, and $R = 12$ in.

<u>Laminate</u>	<u>Axial Compression [7]</u>	<u>Shear</u>
[0/45/-45/90] _s	514.8	123.4
[45/-45] _{2s}	428.9	160.9

loading. For example at a temperature of 300°F and moisture condition 2, the reduction in shear was 26 percent while for axial compression it was 21 percent, a difference of 5 percent. A similar analogue can be drawn from Figures 5.3 and 5.4 for the [45/-45]_s laminate, except that the curves for the shear loadings are shifted up above those for an axial load. For example at a $T = 300^\circ\text{F}$ and moisture condition 2, the reduction for shear was 35 percent while for axial compression it was 43 percent a difference of 8 percent. To illustrate this better, Figures 5.5 thru 5.8 show these comparisons for each moisture condition and laminate. Figures 5.5 thru 5.8 also show that the laminates perform as designed. That is, the rate of reduction for the [45/-45]_{2s} laminate loaded in shear was less than that for the [0/45/-45/90]_s laminate loaded in shear while the rate of reduction for the [0/45/-45/90]_s laminate loaded in compression was less than that for the [45/-45]_{2s} laminate loaded in compression for a given temperature and moisture conditions.

As with Snead and Palazotto's [7] work, the reductions in the

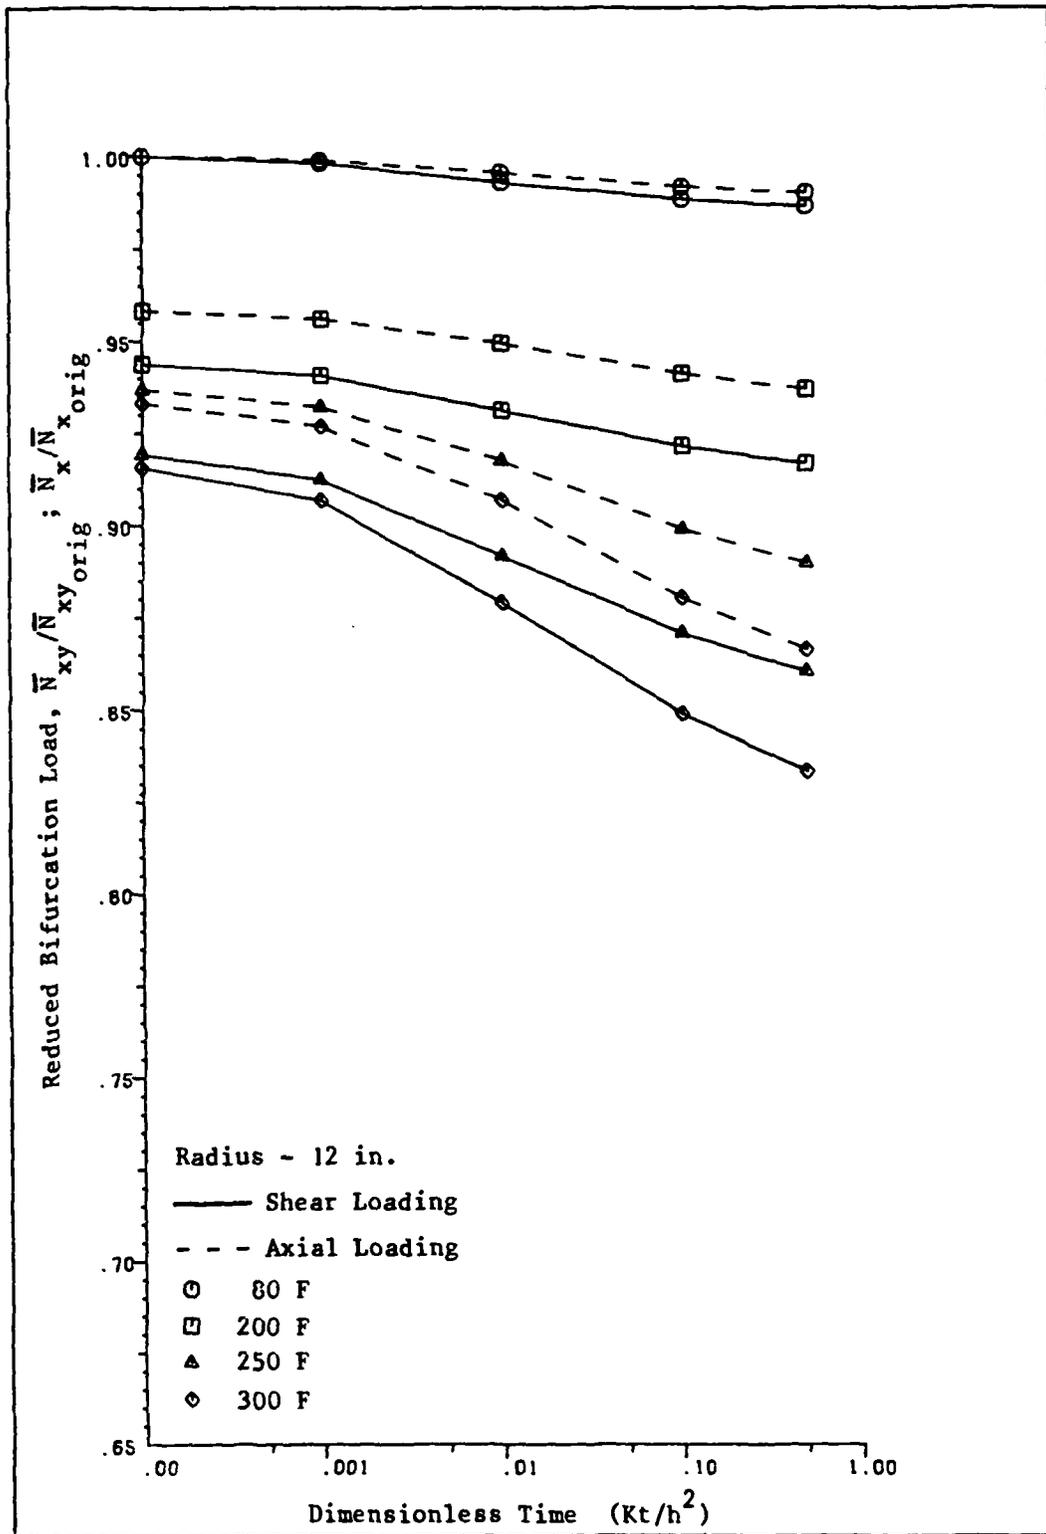

Figure 5.5 Axial vs Shear Loading for Moisture Condition 1, [0/45/-45/90]_s

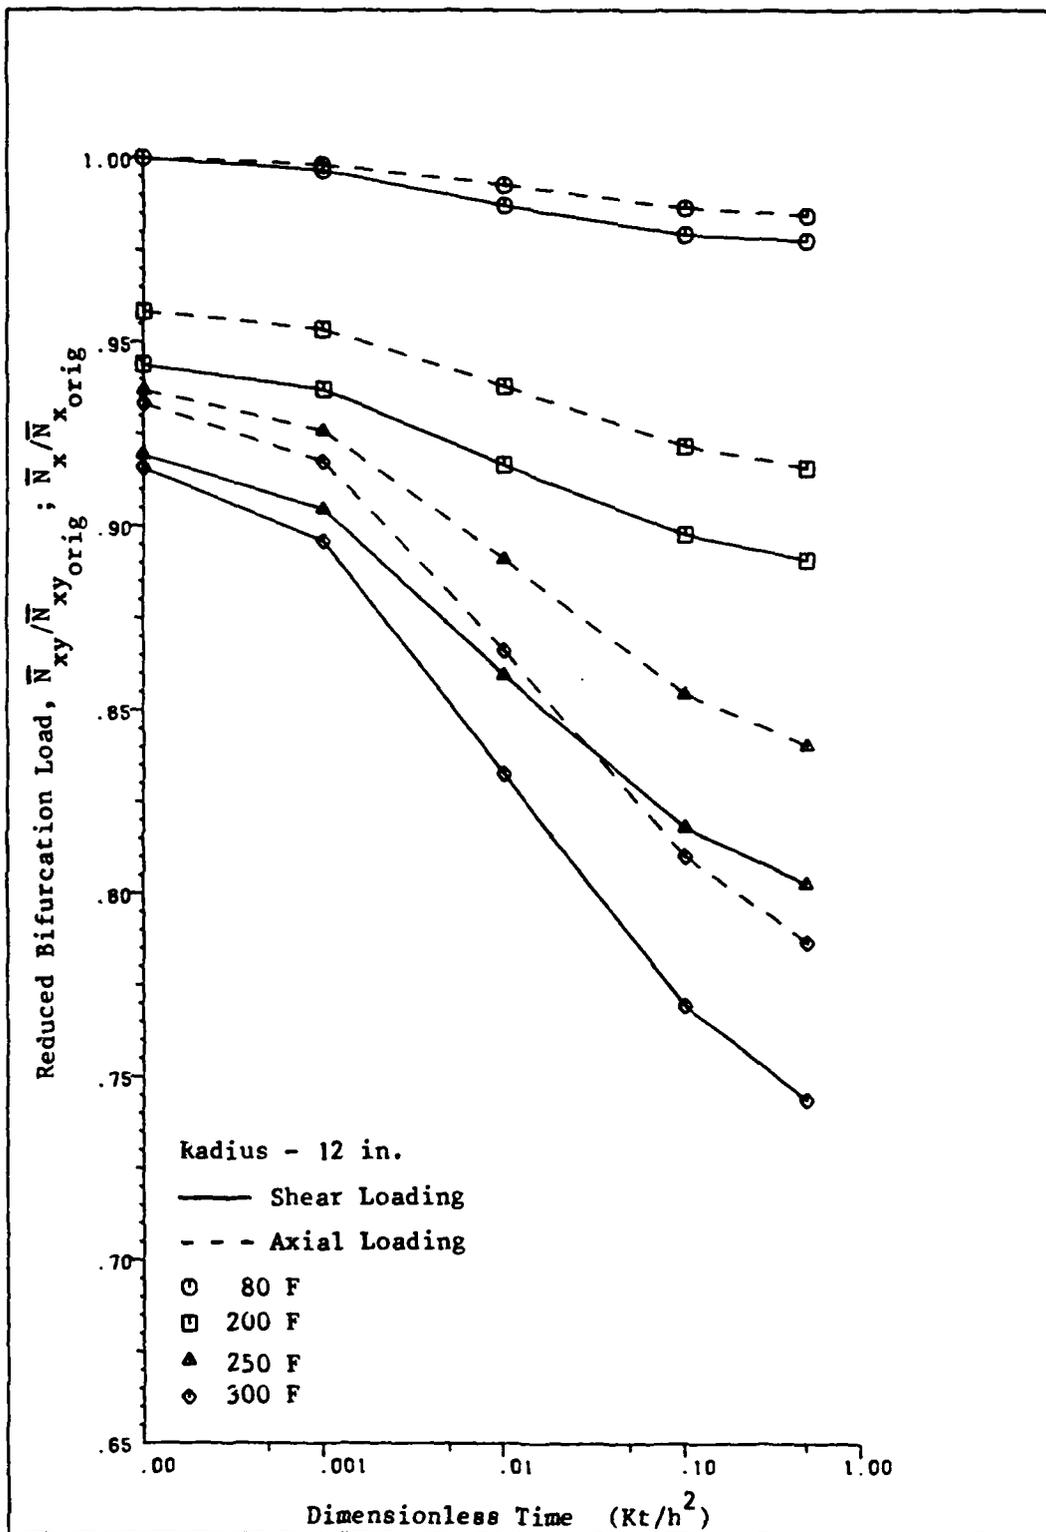

Figure 5.6 Axial vs Shear Loading for Moisture Condition 2, [0/45/-45/90]_S

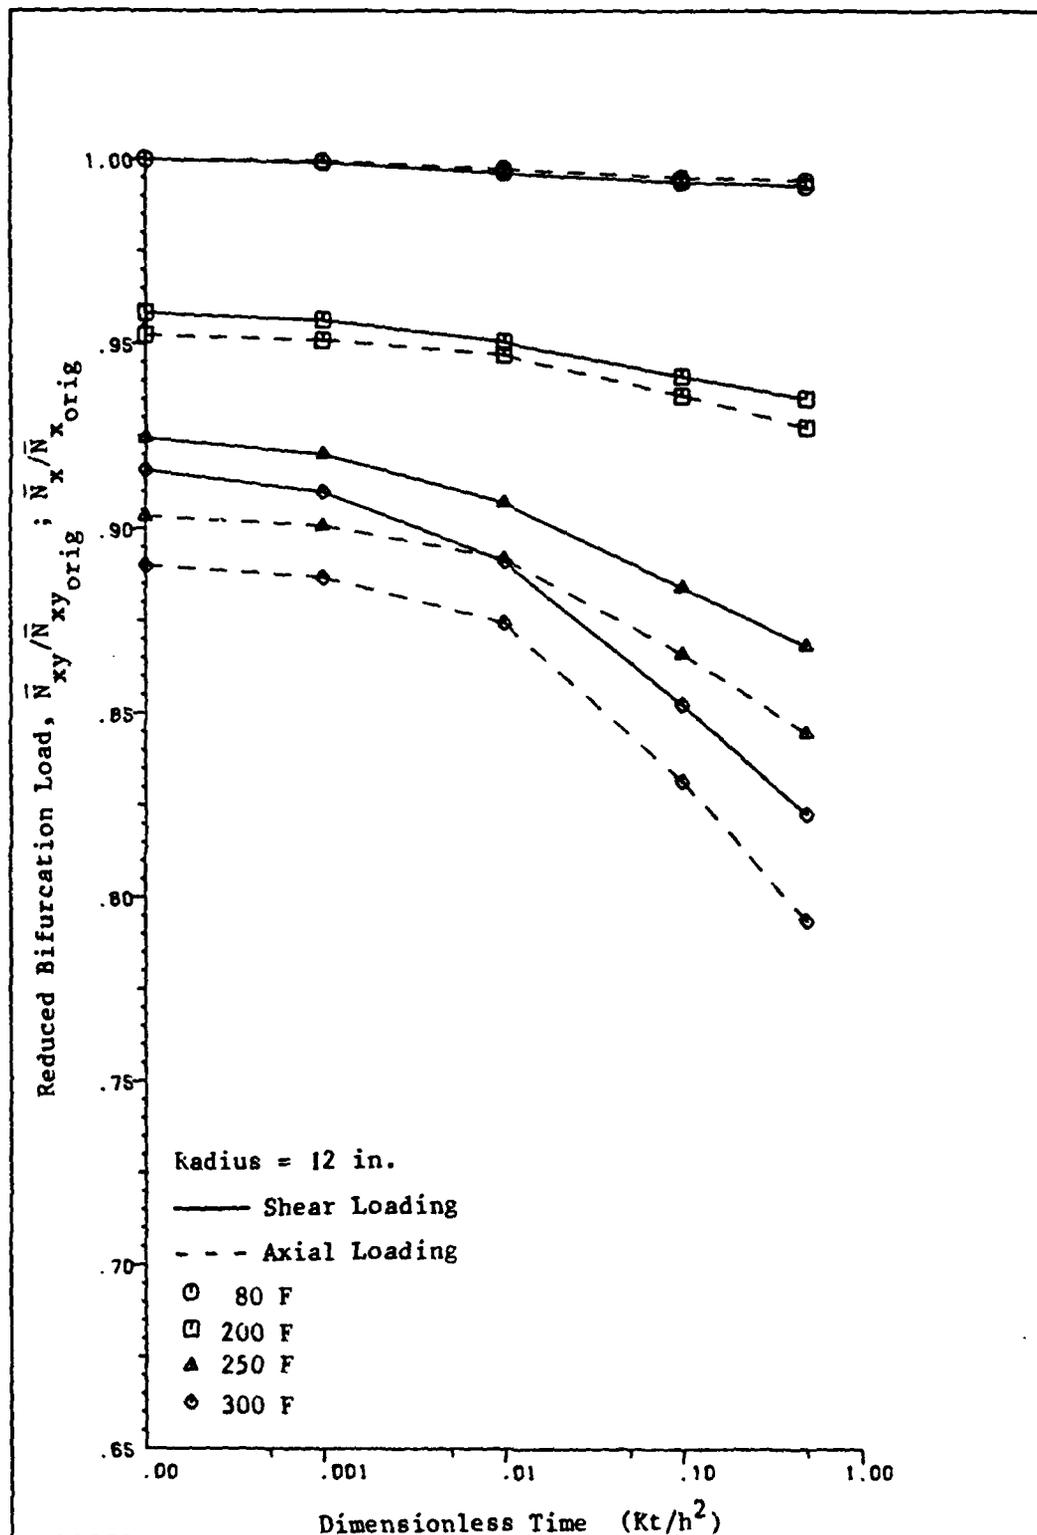

Figure 5.7 Axial vs Shear Loading for Moisture Condition 1, $[45/-45]_2s$

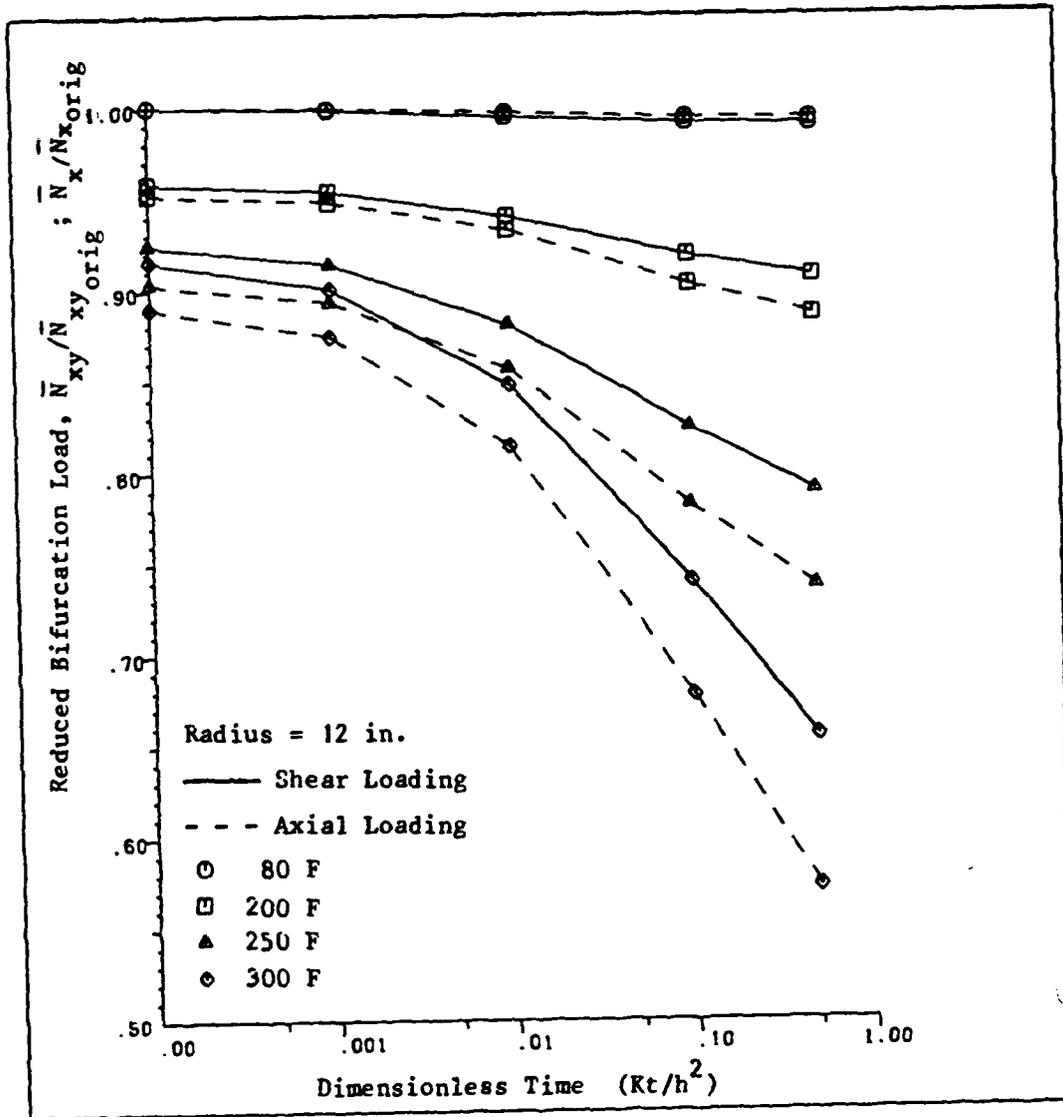

Figure 5.8 Axial vs Shear Loading for Moisture Condition 2, [45/-45]_{2s}

bifurcation loads are significant considering that dimensional changes due to resin swelling were not included. The maximum reduction in \bar{N}_{xy} for each laminate and moisture condition is summarized in Table 5.3 for the radius of 12 in.

Table 5.3

Percent Reduction in Bifurcation Load, \bar{N}_{xy}
at 300°F, $t^* = 0.5$, and $R = 12$ in.

<u>Laminate</u>	<u>Moisture Condition</u>	
	1	2
$[0/45/-45/90]_s$	16.7	25.6
$[+45/-45]_{2s}$	17.8	34.5

Another similarity to Snead and Palazotto's [7] work is that for moisture condition 1 the reduction in the bifurcation load, \bar{N}_{xy} , was not as great as it was for moisture condition 2 even though moisture condition 1 causes the initially symmetric laminate to become unsymmetric, which introduces bending - extension coupling. The symmetric moisture condition 2 has a much greater influence on both laminates. This is due to an over all general reduction in the material properties as moisture is absorbed into the panel symmetrically.

Effects of Curvature

The $[45/-45]_{2s}$ laminate was examined at six different radii (12, 24, 36, 48, 96, and 10,000 in.), considering moisture condition 2, to evaluate the effects of curvature on the bifurcation load. This laminate was selected because, in comparison to the $[0/45/-45/90]_s$

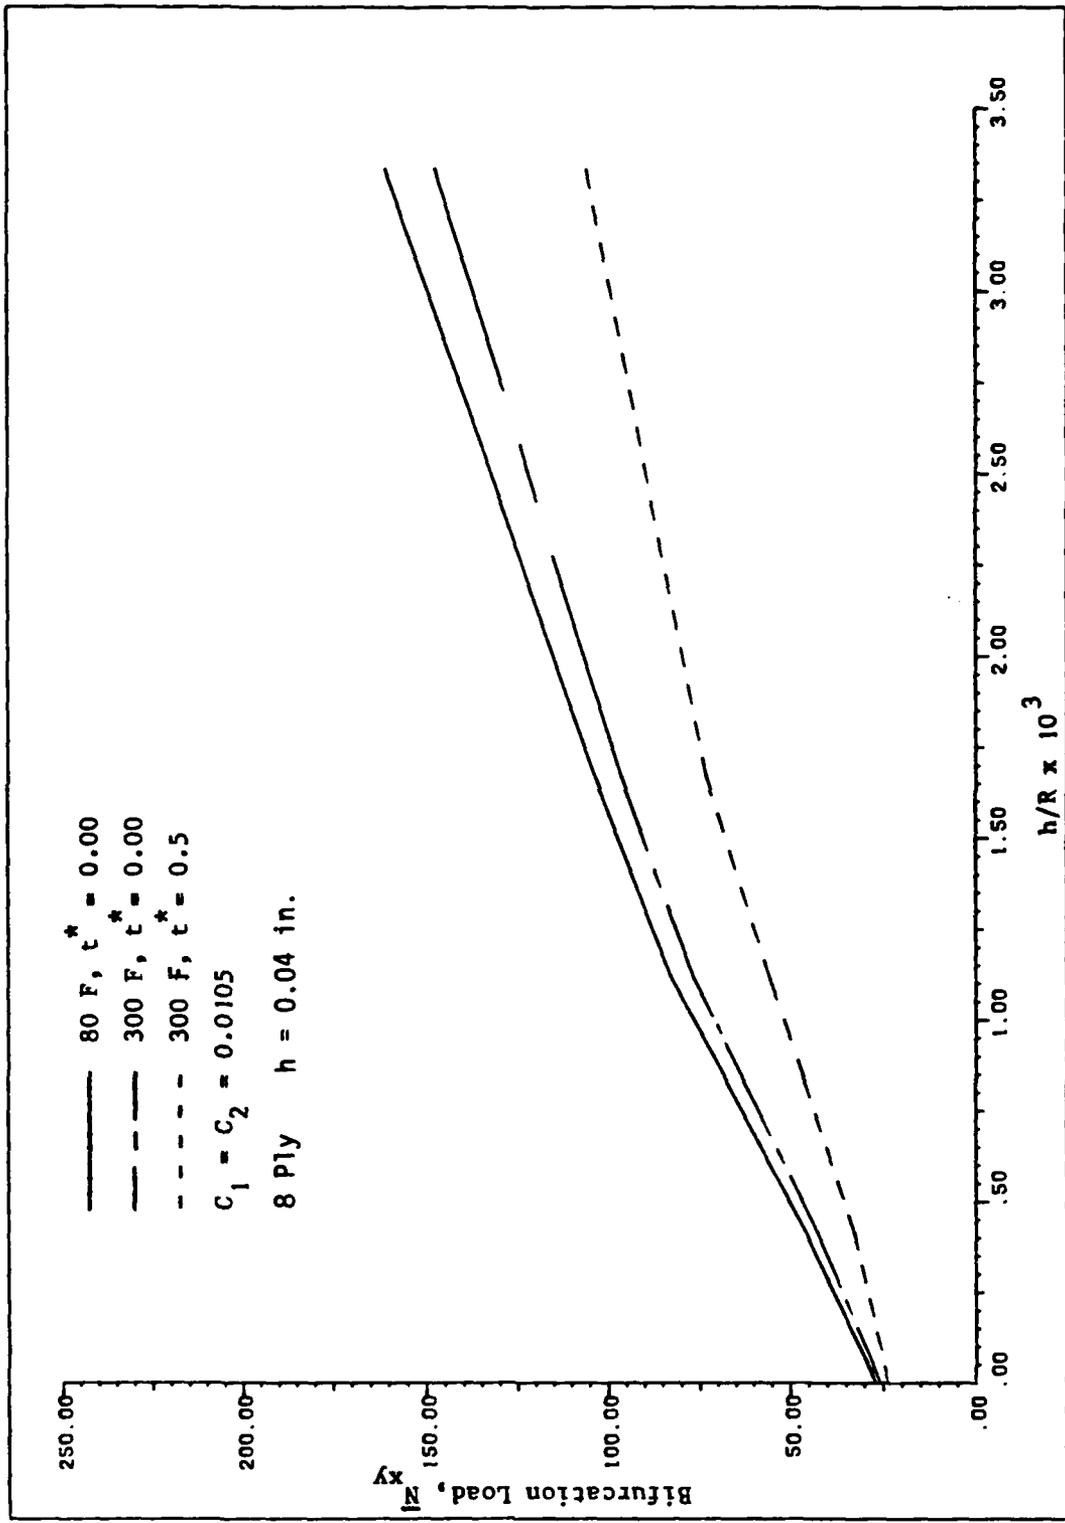

Figure 5.9 Curvature Effects on the Bifurcation Load, \bar{N}_{xy} [45/-45]_{2s} Laminate

laminates, it exhibits a greater reduction in the reduced bifurcation load for a given moisture content and temperature. Figure 5.9 shows the general overall effects of curvature on the bifurcation load. That is, as the panel's radius increases the bifurcation load, \bar{N}_{xy} decreases. Also shown in this figure are the effects of temperature and moisture absorption on the bifurcation load. Though the only temperature shown is 300°F with times absorption set at $t^* = 0.0$ and 0.5, it can be stated that for any given radius the increase in temperature and moisture content reduces the bifurcation load. A better illustration of the effects of curvature is shown in Figure 5.10. This figure shows that curvature does influence the percent reduction in the bifurcation load. This is different from Snead and Palazotto's [7] findings. They investigated three radii, 12, 24, and 48 in. and came to the conclusion that for a panel under axial loading the reduction in the panels' bifurcation load, \bar{N}_x , did not significantly vary from those for the 12 in. radius panel. They therefore concluded that the results obtained for the 12 in. radius panel should be valid for any radius. Figure 5.11 shows how this conclusion can be reached by only examining panels of radii 12, 24, and 48 in. If the radii 96 and 10,000 in. are added to their work, the effects of curvature become apparent. The overall effect of curvature is to decrease the influence of temperature and moisture on the panels bifurcation load. This means that using the reduced bifurcation load results for the 12 in. radius, or any other radius, as a valid approximation for another radius will yield invalid results. Thus in general, the effects of curvature must be accounted for. One needs to compare results for the reduced bifurcation load for

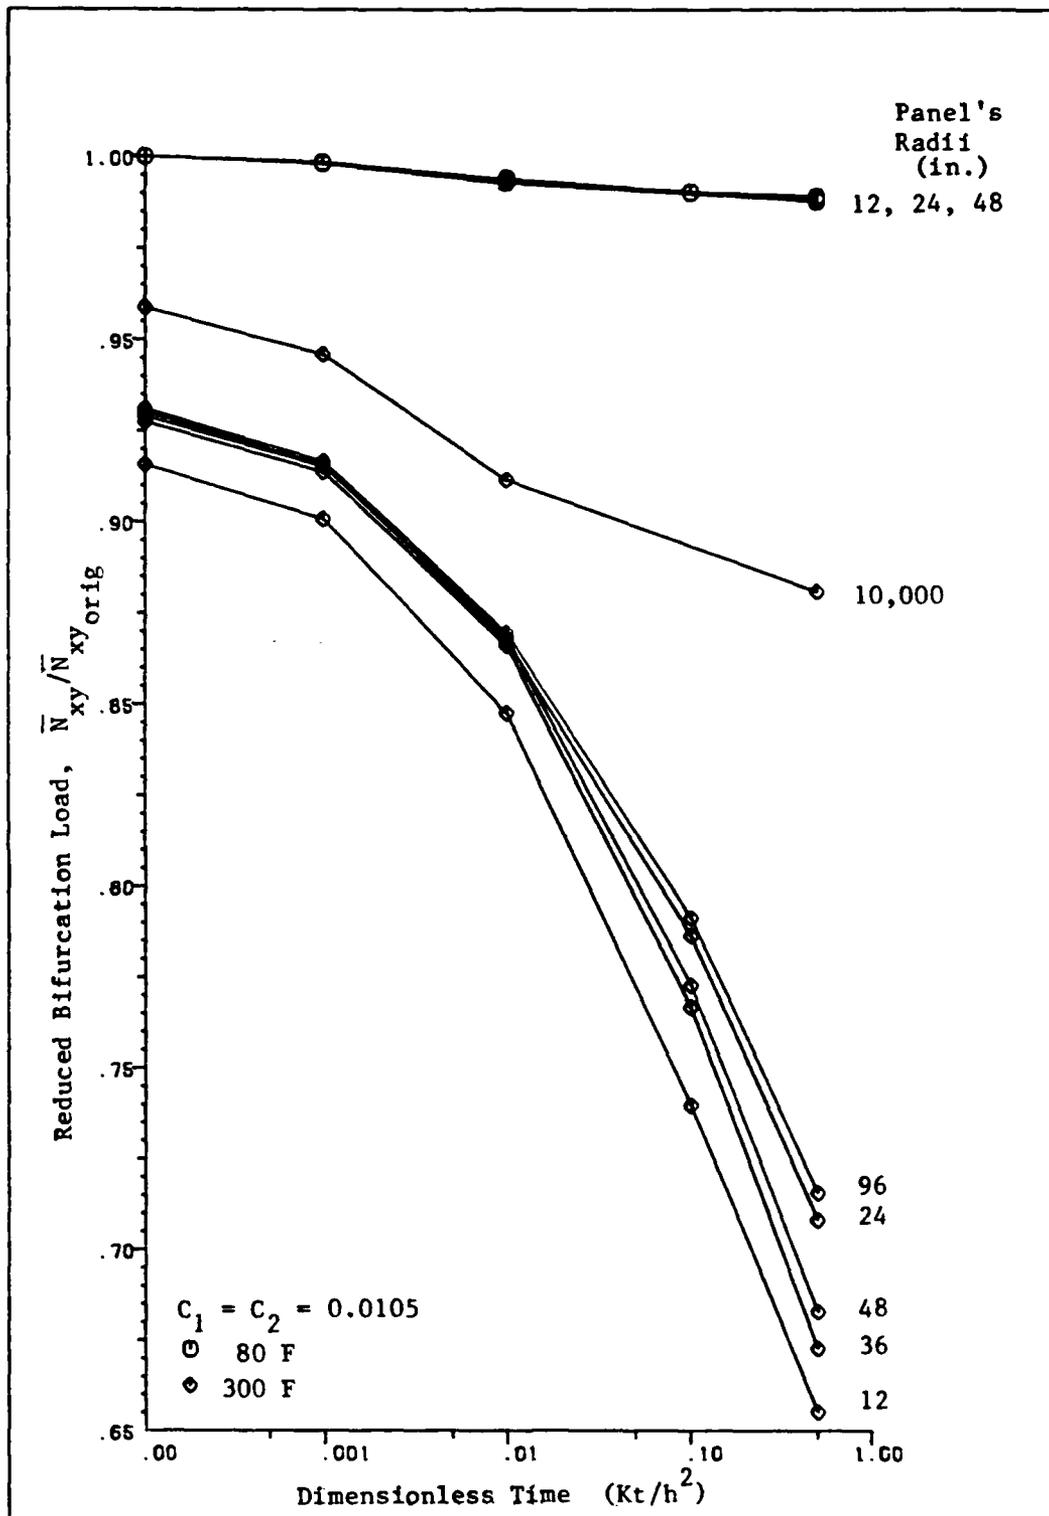

Figure 5.10 Effects of Curvature on Degradation in N_{xy} for the $[45/-45]_{2s}$ Laminate

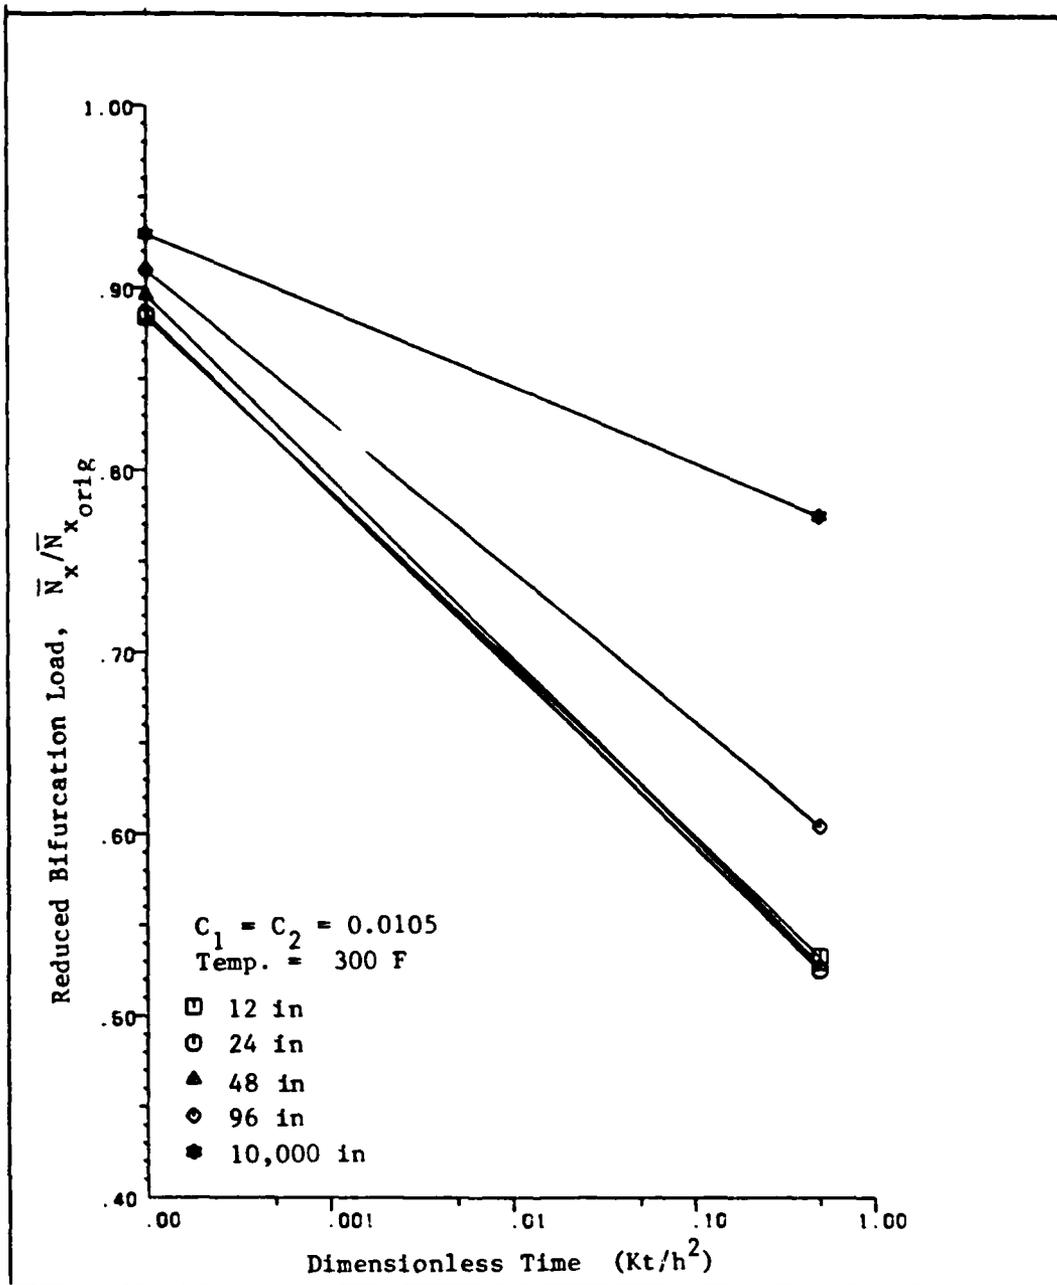

Figure 5.11 Effects of Curvature on Degradation in \bar{N}_x for the $[45/-45]_2s$ Laminate

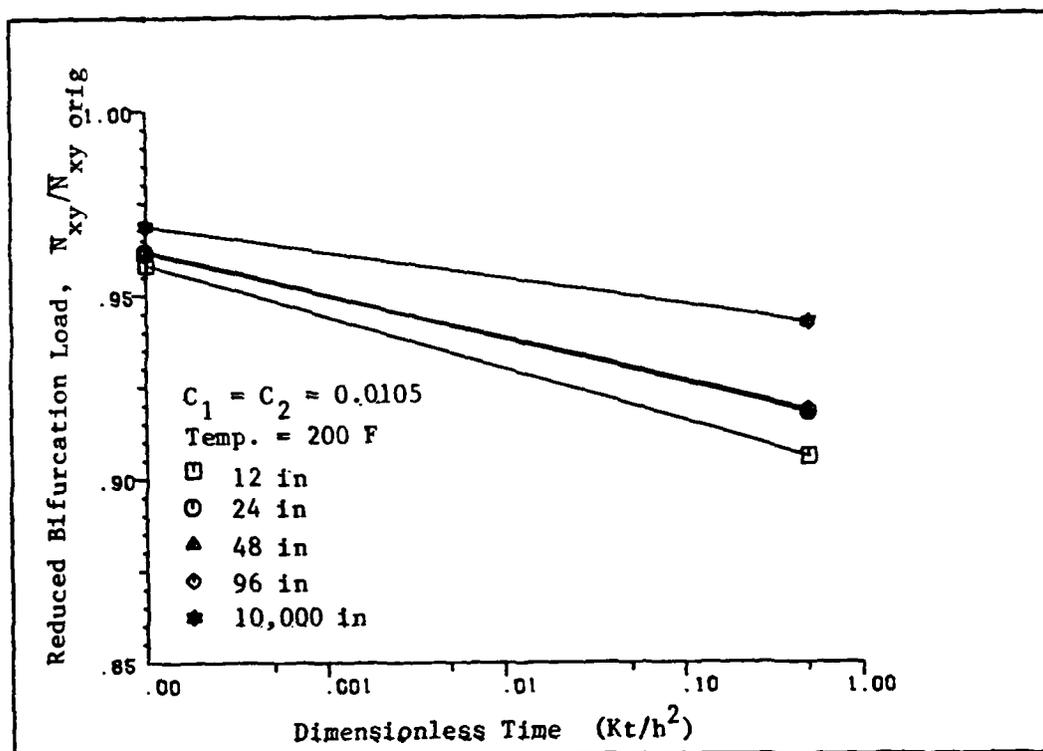

Figure 5.12 Effects of Curvature on Degradation in \bar{N}_{xy} for the $[45/-45]_2$ Laminate at 200°F

the same radius of curvature. Note that although only a few points are plotted in Figure 5.11 the trend is still quite visible.

Looking at Figures 5.10 and 5.12, one can see that the influence of curvature is also a function of the laminate's temperature. These figures are plots of the reduced bifurcation load for the $[45/-45]_{2s}$ laminate for moisture condition 2. Figure 5.10 has the plots for temperatures 80 and 300°F, while Figure 5.12 is a plot for the temperature of 200°F. It is apparent from these plots that for a temperature of 80°F the effects of curvature can be neglected, and that as the temperature increases to 300°F the effects of curvature becomes more important and cannot be neglected. As the temperature increases, the effects of curvature tends to decrease the influence of moisture and temperature on the reduced bifurcation load. This difference can be seen best by comparing the maximum reduction in the bifurcation loads for the panels of radius 12 in. and 10,000 in. The 12 in. panel has a 35 percent reduction in the bifurcation load while the 10,000 in. panel has only a 12 percent reduction. This is a 23 percent decrease in the effects of moisture and temperature on the reduced bifurcation load. This reduction is also apparent at intermediate temperatures, (Figure 5.12) but to a lesser extent. Examination of the same panel but at moisture condition 1 also shows the effect of curvature on the reduced bifurcation load (See Figure 5.13). However, the overall effect is not as drastic as it is for moisture condition 2. Note that this plot is for the worst case only, which is at a temperature of 300°F.

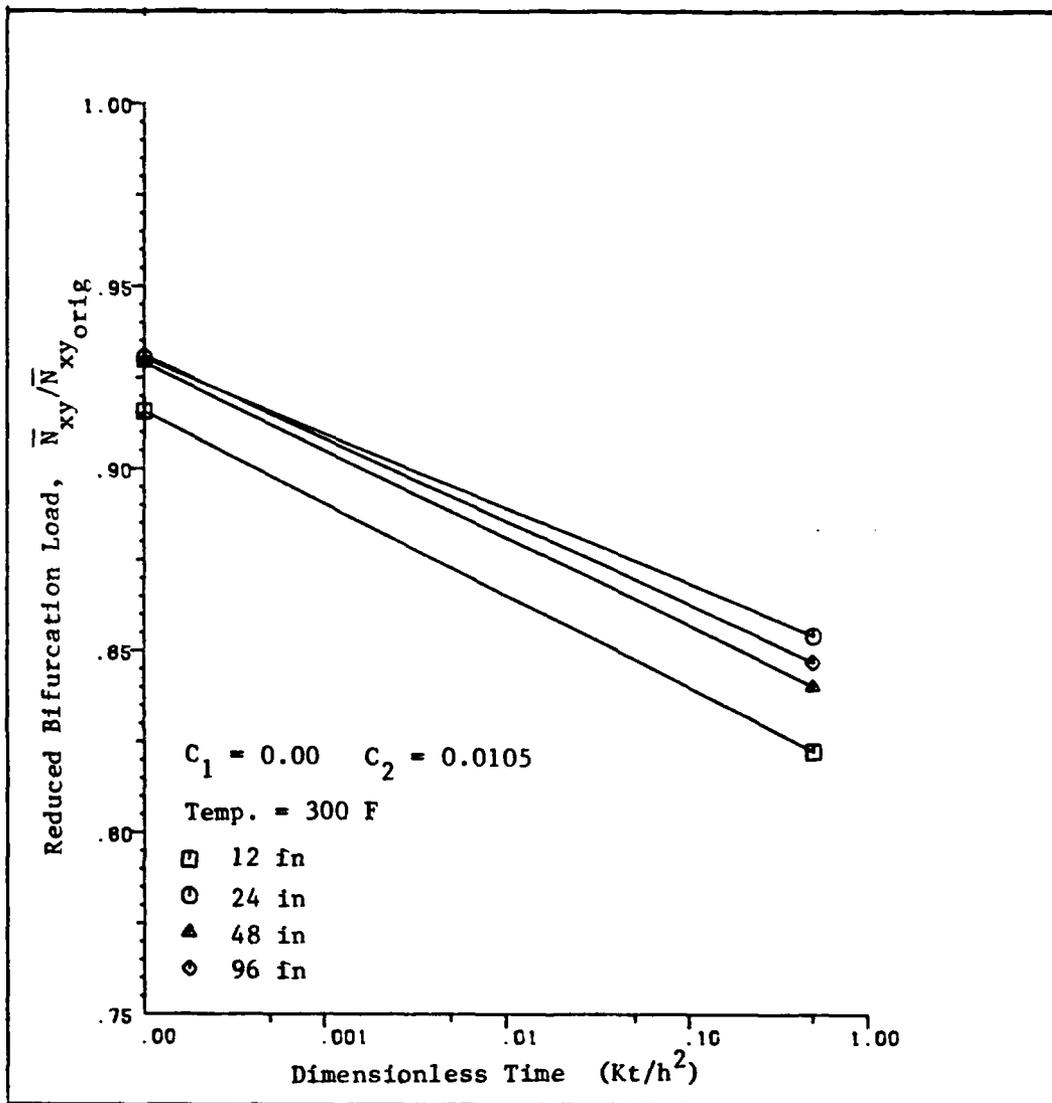

Figure 5.13 Effects of Curvature on Degradation in \bar{N}_{xy} for the $[45/-45]_2$ Laminate, Moisture Condition 1

An interesting anomaly in Figure 5.10 is that the decrease in the reduced bifurcation load is not sequential in increasing radii. This can be seen by comparing the curves for 24, 36, and 48 in. at 300°F. The panel with a 24 in. radius falls above the panels with a 36 in. and 48 in. radius. This is contrary to what the theory indicates in Eq. (16), the strain-displacement relationships, where the curvature shows up as a linear dependent variable, which indicates that the curves should be sequential. Since Figure 5.10 is a plot for a normalized bifurcation load, $\bar{N}_{xy}/\bar{N}_{xyorig}$, the question arose, "Is this anomaly actually in the bifurcation load or is it due to the normalizing factor?" Looking at the bifurcation load first, Figure 5.14 shows that as the radius increases the bifurcation load decreases for a given temperature and moisture condition. This was also shown in Figure 5.9. Both of these figures show that the bifurcation load is following the trend indicated by the theory. However, Figure 5.14 also shows that the rate of decrease is dependent on the moisture content for the given temperature. To correlate Figure 5.14 to Figure 5.10, the bifurcation loads were translated to a value of 150 lb/in so that each curve would have the same maximum (See Figure 5.15). This figure clearly shows that the plot of the bifurcation loads does not show the anomaly shown in Figure 5.10. Therefore, this anomaly must be due to the normalizing factor.

All the plots for the reduced bifurcation loads were normalized to the room temperature, 80°F and zero moisture concentration bifurcation load, \bar{N}_{xyorig} . The bifurcation load is dependent, in general, on the prebuckled bending moments and membrane forces, with the curvature of

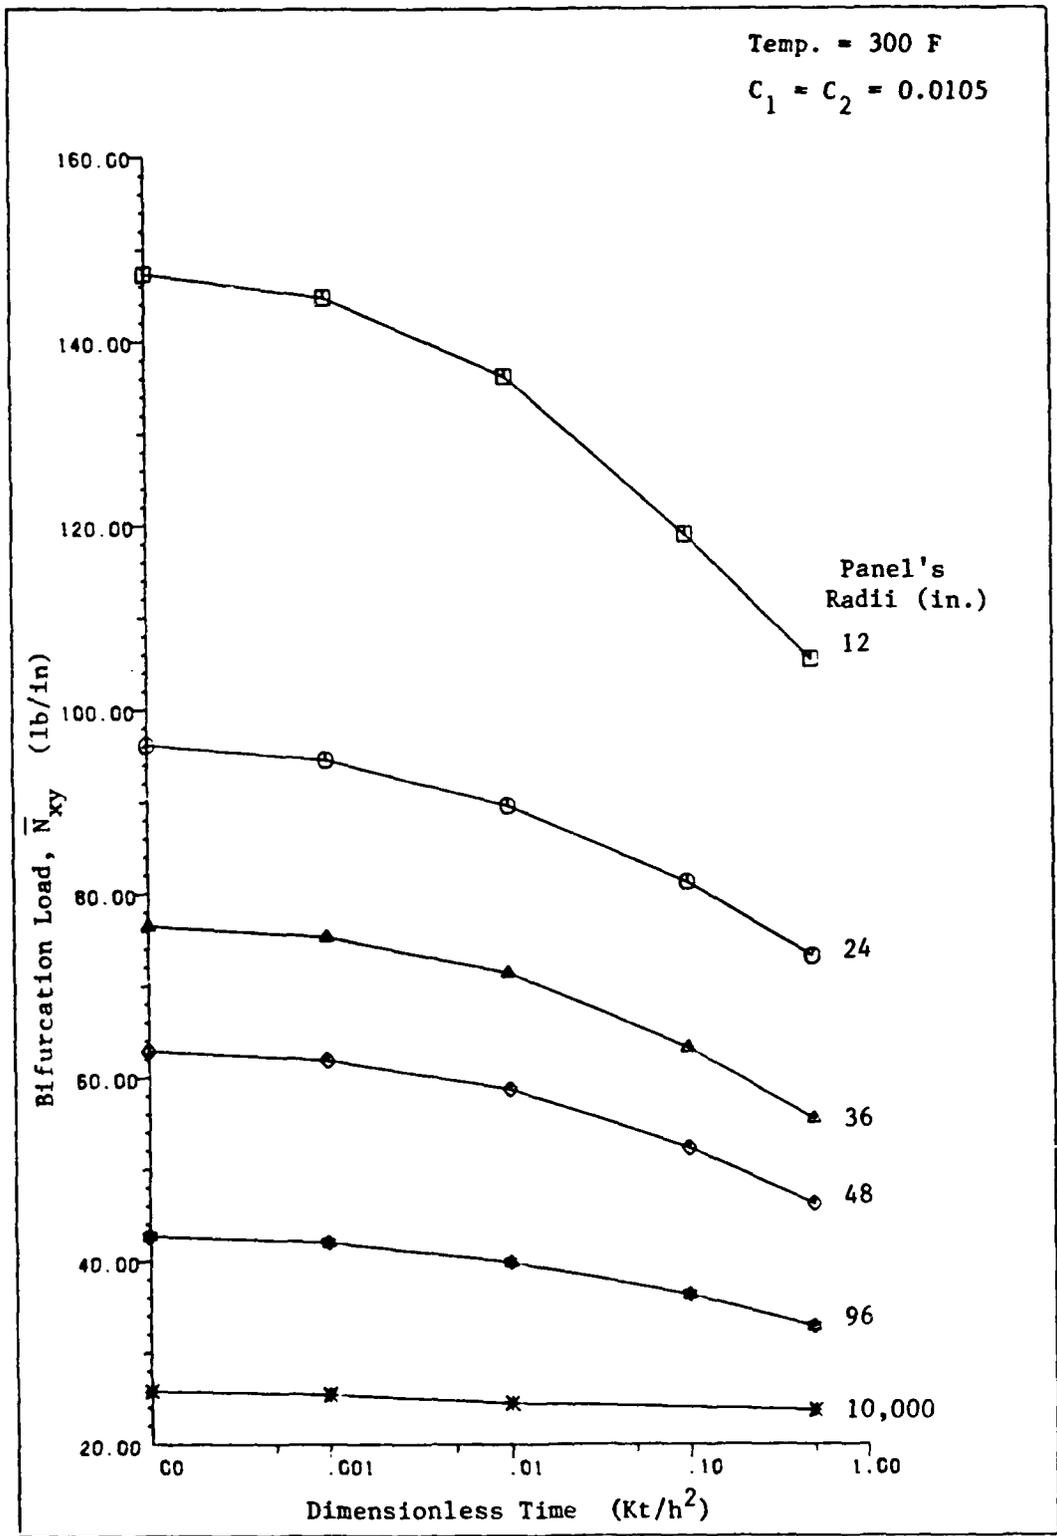

Figure 5.14 Effects of Curvature on the Bifurcation Load \bar{N}_{xy} ,
 $[45/-45]_{2s}$ Panel

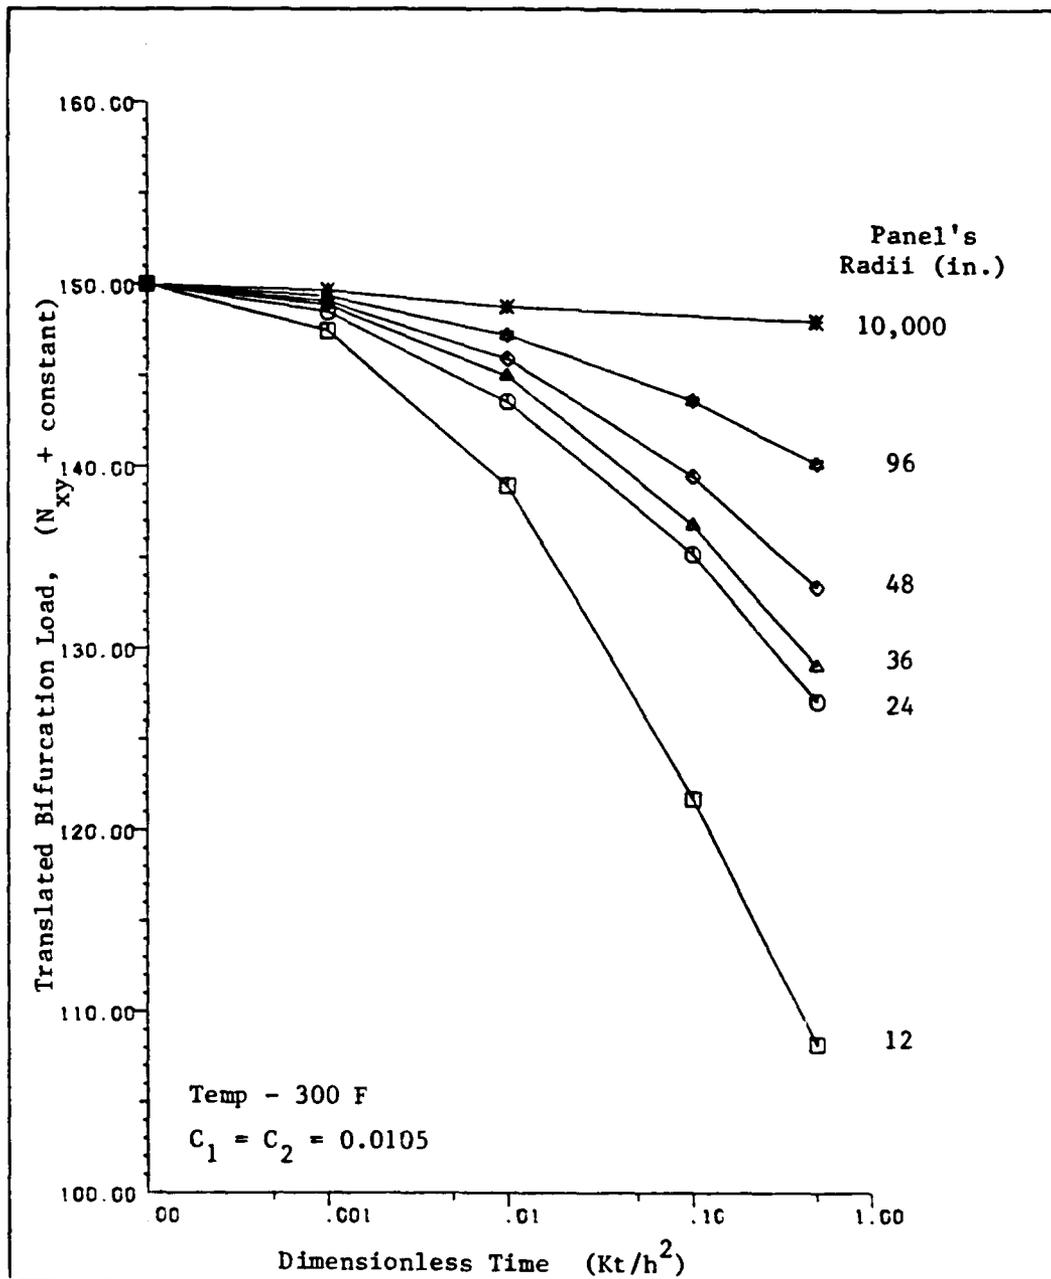

Figure 5.15 Effects of Curvature on the Translated Bifurcation Load \bar{N}_{xy} , $[45/-45]_{2s}$ Panel

the panel governing which load is more dominant. For a flat panel the dominant loads, which cause buckling, are the membrane forces and as the panels curvature increases the bending moments become important. What is being seen in Figure 5.10 is a transition in the dominant cause for buckling from membrane to bending. This is visible since the normalizing factor is the relative shear bifurcation load.

Prebuckled Displacement, w and Eigenvector Characteristics

Figures 5.16, 5.17, and 5.18 show that there is a similarity in the appearance of the prebuckled displacements, w , when comparing the effects of temperature and moisture for a panel with a 12 in. radius. The primary difference being one of deflection magnitude. The terms 'Max.' and 'Min.' in these figures correspond to the maximum and minimum out-of-plane displacement caused by the unit line load N_{xy} applied on the panel's boundaries while the term 'Contour Step Size' indicates the increment between contour lines. As the radius increases there is a change in the panel's prebuckled displacement's, w , pattern. The area of negative displacement becomes greater, for increasing radii, due to decreasing effects of the prebuckle bending moments.

The eigenvectors, Figures 5.19 thru 5.21, are also not dependent on the moisture conditions and temperature, but they are dependent on the curvature, similar to the prebuckle displacement. The eigenvector for the panel with a 12 in. radius exhibits five half sine waves while a 10,000 in. radius exhibits two half sine waves. This also indicates

that the energy needed to buckle the panel, with a 12 in. radius, is greater than that for a 10,000 in. radius. Additional displacement, w , and eigenvector contour plots for representative cases of moisture, temperature, and curvature are included in Appendix C.

VI Conclusions

The following conclusions can be made for cylindrical, graphite/epoxy composite panels with various radii of curvature subject to moisture exposure and elevated temperatures, when loaded in simple shear.

1. The results for the STAGS-C1 finite element analysis, using flat plate elements, compare well to solutions obtained by Whitney[1], using the Galerkin method with the Donnell strain displacement relations, for relatively flat shells. (Radius/thickness ≥ 1000)

2. The bifurcation load of a composite panel, with a resin material whose elastic moduli are reduced by absorbed moisture and elevated temperature, will degrade with increasing moisture concentrations and temperatures.

3. The trend for the reduction in bifurcation load of a composite panel subjected to a simple shear load is comparable to that found for an axial compression load at a given radius.

4. The extent of the degradation in the bifurcation load is influenced by the moisture concentration, the temperature, the panel's ply orientation, and panel's curvature. At 300°F, a radius of 12 in., and a symmetric moisture weight gain of 1.05 percent, the $[0/45/-45/90]_S$ panel experienced a 25.6 percent degradation and the $[45/-45]_{2S}$ panel experienced a 34.5 percent degradation.

5. The cylindrical panel's bifurcation load is influenced by the ply orientation, and curvature.

6. The bending - extension coupling induced by the unsymmetric initial moisture condition did not significantly influence the bifurcation load.

7. Increasing the cylindrical panel's radius decreased the panel's bifurcation load and can significantly change the moisture- and temperature-induced degradation characteristics for a given temperature.

8. If curvature is an important variable in a given problem, the use of the normalized bifurcation load, with respect to the membrane forces, can lead to conclusions that are invalid if one is trying to model the rate of change in the bifurcation load.

Appendix A
Computer Program

The main program calculates the moisture concentration at the mid-point of each lamina using Fick's Second Law of Diffusion. The main program calls the following subroutines.

- Subroutine Header -- Creates tape6 which contains the matrices A, B, and D and the \bar{Q}_{ij} 's.
- Subroutine Calc1 -- Calculates the reduced transverse and shear moduli and the value for ν_{21} for AS/3501-5, given the moisture concentration in the ply.
- Subroutine Calc2 -- Calculates the values for \bar{Q}_{ij} , A_{ij} , B_{ij} , and D_{ij} .
- Subroutine Stags1
and
Subroutine Stags2 -- Creates tape7 the input for STAGS-C1.

APPENDIX C

Prebuckled Displacement, w and Eigenvector Contour Plots

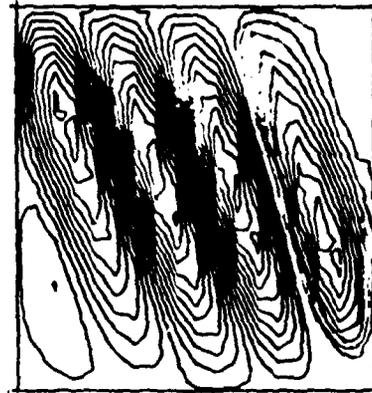

The terms 'Max.' and 'Min.' in this appendix correspond to the maximum and minimum out-of-plane displacement. For the prebuckled displacement, w , this out-of-plane displacement was caused by a unit line load, N_{xy} , applied at the panel's boundaries. The term 'Step' indicates the increments between the contour lines.

Vita

Mr. Anthony D. Straw was born on April 8, 1952 in Decatur, Indiana. Anthony graduated from Crestview High School, in Convoy, Ohio, in June 1970 and then attended The Ohio State University from which he received the degree Bachelor of Science in Aeronautical and Astronautical Engineering in March of 1975.

He began his professional career as an intelligence analyst, investigating foreign structural mechanics research, with the Foreign Technology Division in June of 1977. Anthony married Barbara Trager in Van Wert County, Ohio in July of 1980. In June of 1984, he entered the School of Engineering, Air Force Institute of Technology, under the Long Term Full Time Training program.

Abstract

An analytical study was conducted to determine the influence of moisture, temperature, and curvature on the bifurcation load of cylindrical, composite panels subjected to a simple shear loading. Two laminate ply orientations, $[0/45/-45/90]_S$ and $[45/-45]_{2S}$, were analyzed for six radii, four temperatures, and two initial moisture conditions. The eight-ply composite panels were assumed to be manufactured from a graphite/epoxy, AS/3501-5. To evaluate the influence of moisture and temperature, the transverse modulus, E_2^* , and shear modulus, G_{12}^* , were degraded based on experimental test data for the AS/3501-5 system. Each ply orientation, for a 12 in. panel radius, was evaluated at 20 time/temperature conditions that ranged from 80 to 300°F, and moisture concentrations ranging from a zero moisture content to an equilibrium moisture distribution. The investigation of curvature was conducted only for the $[45/-45]_{2S}$ laminate and at a limited number of time/temperature conditions.

The bifurcation loads were determined using the STAGS-CI finite elements shell analysis program. This analysis used the prebuckled linear displacement option to calculate the bifurcation loads. An increase in temperature and moisture absorption was found to cause a reduction in the panels bifurcation load ranging from a maximum of 25.6 percent for the $[0/45/-45/90]_S$ laminate to 34.5 percent for the $[45/-45]_{2S}$ laminate for the panels with a 12 in. radius. This reduction in the bifurcation load is significantly influenced by the change in curvature at elevated temperatures and moisture content. The maximum reduction in the bifurcation load varied from 34.5 percent for a 12 in. panel radius to 11.9 percent for a 10,000 in. panel radius a decrease of 22.6 percent for the $[45/-45]_{2S}$ laminate.
