ABSTRACT

This thesis presents the design, implementation and evaluation of two abstracted programming and communication interfaces for developing distributed programs on a network of Transputers. One interface uses a shared memory model for interprocess communication and synchronization. The other interface uses a message passing model for communication and synchronization. The programming interfaces allow development of distributed programs that are independent of the physical configuration of a network. This thesis also presents an evaluation of Transputer performance with a particular emphasis on the interaction of computation and inter-Transputer communication.
THESIS DISCLAIMER

The reader is cautioned that computer programs developed in this research may not have been exercised for all cases of interest. While every effort has been made within the time available to ensure that the programs are free of computational and logic errors, they cannot be considered validated. Any application of these programs without additional verification is at the risk of the user.

DEDICATION

I dedicate this thesis to my wife, Kathy, who gave me confidence and encouragement and to my children, Betsey and Rusty, who were patient and understanding.
I. INTRODUCTION

A. BACKGROUND

The Aegis Modeling Project in the Computer Science Department at the Naval Postgraduate School is engaged in researching advanced computer architectures for potential future application aboard naval ships. Currently, this research is centered on the application and evaluation of distributed computing architectures. A distributed architecture is particularly suited for shipboard applications. Shipboard locations at which processing capabilities are required are physically distributed, yet processors at all locations must cooperate to monitor and control a ship's sensors and systems. Such an architecture can also provide the necessary characteristics of high performance, fault tolerance, and extensibility.

One emphasis of the current research has been to investigate systems that are composed of relatively low cost, "off-the-shelf" components. The single chip microprocessor is such a component. A range of microprocessor-based distributed multicomputer systems are, therefore, being evaluated. One such system already developed and evaluated uses clusters of microprocessor-based single-board computers interconnected by a hierarchical bus structure [Ga86]. A distributed system architecture now being evaluated is based on the single chip microprocessor known as the Transputer.
B. THE TRANSPUTER

The Transputer is a single chip microprocessor that has been specifically designed to function as a computing element in a distributed multicomputer system. The name "Transputer" is an amalgam of the words transistor and computer. As the transistor was a building block for large and varied electronic circuits, the Transputer is intended by the manufacturer to be an analogous building block for distributed computing systems.

To facilitate the use of the Transputer as an element in a distributed system, the Transputer implements the concept of Communicating Sequential Processes (CSP). Communicating Sequential Processes is a paradigm which defines and describes the interaction of programs that execute in parallel (as is the case in a distributed system).

C. ABSTRACT PROGRAMMING INTERFACES

Program development for a network of Transputers is currently closely tied to the particular physical configuration of a given network. The physical configuration of a network must be considered early and throughout the software design process. In certain cases, the configuration can actually dictate aspects of software design. This thesis investigates isolating the software designer from this physical configuration through the use of an abstract programming interface.
D. AVAILABLE HARDWARE AND SOFTWARE

The Transputer hardware available to the Aegis Modeling Project is varied. The hardware includes Transputer interface cards for personal computers, Transputer-based serial interface and color graphics interface cards, and cards with multiple Transputers. Aspects of this hardware that pertain to portions of this thesis are discussed where applicable. A complete description of the hardware is available elsewhere [In86].

Programs included in this thesis were developed using the Transputer Development System (TDS) [In87a] and the OCCAM programming language [PoMa87]. OCCAM is a high-level block-structured language which includes constructs based on CSP to support programming in a distributed environment. An assembler and Pascal and C compilers for the Transputer are also available.

E. THESIS ORGANIZATION

Chapter II describes the Transputer and the basic concept of Communicating Sequential Processes.

This thesis investigates the basic performance characteristics of a Transputer as an element in a network of Transputers. Chapter III describes testing that was performed and documents the results of this testing.

Chapter IV and Chapter V describe and evaluate two different prototype abstract programming interfaces developed for a network of Transputers. One interface is based on a virtual globally shared memory. The other is based on message passing.
Chapter VI presents the conclusions reached as a result of developing, using, and evaluating the programming interfaces. Recommendations for further research are also provided in Chapter VI.
II. THE TRANSPUTER

A. OVERVIEW

Central to the Transputer is the concept of Communicating Sequential Processes (CSP) [Ho79]. The Transputer is, in fact, a hardware implementation of this concept. The programming language OCCAM, which is the primary language used for programming the Transputer, is based on this concept. A summary of CSP is presented in this chapter.

To effectively evaluate and use the Transputer requires an understanding of how the Transputer implements the concept of CSP. In addition, in many cases this thesis refers to Transputer architectural features and details. This chapter, therefore, also presents a brief description of Transputer architecture.

B. COMMUNICATING SEQUENTIAL PROCESSES

Communicating Sequential Processes (CSP) is one model for concurrent or parallel programming. In CSP, a program is composed of processes. A process consists of a list of commands or instructions that are to be executed in sequence. The different processes within a program are combined and specified to be executed in sequence or in parallel or in some sequential/parallel combination. The data spaces for any processes executed in parallel are constrained to be disjoint.

This requirement for parallel processes to have disjoint data spaces precludes using shared memory to communicate between the
processes. To provide for necessary process-to-process communication, CSP instead utilizes message passing. Messages are passed between any pair of parallel processes via synchronous, unbuffered, point-to-point communications channels connected between the processes. These communication channels also provide the means for synchronizing processes. To communicate between two processes, one process must include an instruction for performing an output to the other process and the other process must include a corresponding input instruction. Both processes must be at that point in their instruction execution where the communication is specified to occur (if one process reaches this point first, it waits for the other process to reach its point of communication). The communication is then performed. Since the communication only occurs when both processes are at their points of communication, the processes are synchronized at these points. In addition, CSP includes constructs for program control and sequencing and for conditional selection between multiple communications.

Figure 2.1 depicts a set of processes (represented as circles) interconnected by point-to-point communications links (represented as directed lines). This set of processes would operate independently and in parallel on a continuous stream of input values to produce a continuous stream of output values.
Processes to Calculate Unity Based on the Formula

\[ \sqrt{\sin^2 x + \cos^2 x} \]

![Diagram](image)

Figure 2.1. **Process Representation Example**

Groups of processes may be logically aggregated to form larger, more abstracted process constructs. Figure 2.2 shows one possible abstraction of a subset of the processes shown in Figure 2.1.

![Diagram](image)

Figure 2.2. **Process Abstraction Example**
C. TRANSPUTER ARCHITECTURE

A block diagram of a typical Transputer is shown in Figure 2.3. This figure depicts the major architectural components a Transputer. The following sections give a brief description of each of these components. In particular, these sections point out some architectural aspects of the Transputer that can influence the performance of programs written for the Transputer.

Several versions of the Transputer are currently available. This thesis considers only Transputer types T414 and T800. For this reason, the following sections describe the features of these Transputer types. A complete description of all currently available Transputers can be found elsewhere [In87b].

1. Processor

In general, the processor consists of a 32-bit integer arithmetic unit and a set of 32-bit registers. Figure 2.4 shows a block diagram of the processor. The I or instruction register points to the next instruction to be executed in a process. The W or workspace register is a pointer to the beginning of an area in memory that is the data space for a process. Together, these two registers can be thought of as representing the instructions and the data for a single process. The A, B, and C registers form a push-down evaluation stack. In general, all operations are performed on or using the values in these registers. For example, the load and store operations load and store the value of the A register. The add operation adds the values of the A and B registers leaving the result in the A register.
Figure 2.3. Transputer Functional Block Diagram
a. Instruction Set

Each byte in a program can be viewed as having a four-bit high-order half and a four-bit low-order half. The low-order half of an instruction byte contains a data value. The high-order half contains a function code. To execute such an instruction, the data value half of the instruction byte is loaded into the operand register and the function encoded in the other half of the instruction byte is performed. At this point, it would appear that this instruction format limits operand values to the range of 0 to 15 and that only 16 different functions could be performed. A means is provided, however, for representing larger data values and for encoding a greater number of functions. The O or operand register is used to form operands and multi-byte instructions from a sequence bytes. For data values represented by
more than four bits, special function codes cause individual four bit "pieces" of the data value to be extracted from a series of instruction bytes and accumulated in the operand register. The last function code in this series of instruction bytes will actually operate on the accumulated data value. Figure 2.5 shows an example of this operand formation process.

Figure 2.5. Example of Operand Register Operation
To encode functions with value representations greater than four bits, the value representing such a function is loaded into the operand register in the same manner as if it were data. A special function code then causes the value in the operand register to be executed as an instruction. Using this instruction formatting scheme, the instruction set has been optimized so that the most frequently used operations are encoded using only a single byte. Measurements show that about 70% of the instructions actually executed in a typical program are, in fact, encoded using only a single byte [In87c]. Having most instructions represented as single bytes not only reduces the memory requirements for program code but tends to improve program performance. This is because, since fewer bytes are fetched per instruction executed, fewer memory accesses will be required to execute the program.

This method of encoding instructions has other effects on processor performance. Each byte of a multi-byte instruction takes one processor clock cycle to load into the operand register for assembly or its operand. Because of this, instructions with a greater byte length take more time to assemble before they can be executed. In most cases, the length of an instruction is fixed. However, in some cases, the length of an instruction is dependent on the value or location of the instruction’s operand. Since these factors can be controlled by the programmer, it is useful to be aware of these types of instructions. For example, data values located in the first 16 locations above the base of the processor workspace require only one
instruction byte to be accessed. Data values located elsewhere require additional instruction bytes, which increases the time required to access these data values. Because of this, frequently accessed data values should be located closest to the base of the workspace. Also, loading a constant takes one instruction byte for each four bits of the constant’s length. This means that loading a 32-bit constant takes eight processor clock cycles. If such a constant is to be used repeatedly, it is often more efficient to name and store the constant as a data value and use that data value instead.

b. Concurrency

A single Transputer directly supports running concurrent processes. These processes may be either of two priority levels: high or low. To facilitate implementation of concurrency and prioritization, the Transputer has a micro-coded process scheduler. The operations performed by this scheduler can be examined based on whether a process is active or inactive. An inactive process is one that is waiting on communication or on a programmed time delay (operations for inactive processes are discussed later in this chapter). An active process is one that is not waiting and is ready to execute.

To manage the active processes, the process scheduler maintains a separate linked list of active processes for each priority level. Instructions are included in the instruction set for starting new processes by adding the process to an active process list. Processes are selected for execution from these active process lists based on the following generalized rules:
• High-priority processes are always executed in preference to low-priority processes. If a low-priority process is executing when a high-priority process is added to the high-priority active process list, the low-priority process is preempted and the high-priority process is executed. A high-priority process is executed until it completes or until it must wait for communication or for a programmed time delay.

• When no high-priority processes are available for execution, a low-priority process may be executed. A low-priority process is executed until it must wait for communication or for a programmed time delay. In addition, to ensure that one low-priority process does not monopolize the processor, a low-priority process that has been executing for more than about one millisecond is suspended. The suspended process is placed at the end of the low-priority active process list and the process at the beginning of the low-priority active process list is then executed.

2. **Floating Point Unit**

One version of the Transputer includes hardware for performing floating point arithmetic operations. Internally, the floating point unit includes a three-register floating-point evaluation stack that operates in the same manner as the “normal” or integer processor’s evaluation stack. The floating-point unit operates in parallel with the other components of the Transputer. Floating-point operations may, therefore, be performed in the floating-point unit at the same time that integer calculations are being performed in the integer processor. Currently, only the Transputer model T800 includes this floating-point unit.

3. **Links**

The hardware links provide the means for implementing CSP communication channels between processes executing on different Transputers. A link from one Transputer is connected to a link on another Transputer to provide a bidirectional pair of communications
channels. Each hardware link can perform simultaneous, independent input and output communication. Instructions are included in the Transputer's instruction set for performing input and output operations using the links. A block diagram of a communications link is shown in Figure 2.6. Each communications link consists of an independent direct memory access controller and serial communication logic.

![Figure 2.6. Hardware Communication Link Logical Block Diagram](image)

To perform a communication via a hardware link, the communication link address and the size and location of a message are specified, then the communications instruction is executed. This initializes the direct memory access controller with the size and location of the message to be communicated. The process executing the
communication instruction is suspended and a pointer for later resuming the process is saved (another ready process from an active process list may then be executed). When both the sending and receiving links have been initialized in this manner, the message communication is accomplished. When the communication is complete, the process which was suspended for communication is added to the end of the appropriate high- or low-priority active process list to wait its turn for execution.

Messages are transmitted by the links one byte at a time in a bit-serial format. After a receiver has recognized the reception of a byte and is capable of receiving another byte, the receiver transmits an acknowledge message. The transmitter will await reception of the acknowledge message before transmitting the next message byte. Since the link hardware performs no error checking on messages, the purpose of the acknowledge message is solely to control the flow of message bytes between the links. Figure 2.7 shows a formatted message byte and an acknowledge message.

![Data Packet and Acknowledge Packet](image)

Figure 2.7. **Serial Communication Link Protocol**

16
A method for communicating between processes executing on the same Transputer is also provided. To perform such a communication, a memory address and the size and location of a message are specified, then the communications instruction is executed (note that this is the same sequence required to initiate communication via a link). When both the sending and receiving processes are ready to communicate, the communication is accomplished by performing a memory-to-memory transfer of the message data.

4. **Memory**

The Transputer can address four gigabytes of memory. This memory space is divided into two non-overlapping segments: an internal or on-chip segment of memory and an external or off-chip segment of memory. Although these two segments of memory are logically the same, the physical characteristics of the two segments are quite different.

The on-chip memory consists of up to four kilobytes of static random access memory (depending on the type of Transputer being considered). Within the address space, the on-chip memory occupies the lowest block of addresses. The on-chip memory can be accessed for read or write via the internal processor bus in one processor clock cycle.

The off-chip memory forms the balance of the address space. The off-chip memory is accessed via an external memory interface. This external memory interface provides access to the external memory by multiplexing a 32-bit address and 32 bits of data onto a single
32-bit external bus. The timing for this multiplexing slows access to the external bus to a minimum access time of three processor clock cycles. The actual number of cycles required to access external memory is also dependent on the requirements of the external memory devices. For the Transputer systems available in our laboratory, the external memory access times range from three to five processor clock cycles. This difference in access times between the "fast" on-chip and "slow" off-chip memory can affect program performance. Frequently accessed variables or code segments should, therefore, be preferentially located in the "fast" on-chip memory.

Additionally, the external memory interface includes control logic for refreshing external dynamic random access memory devices. Control lines and signals are also provided to facilitate peripheral device direct memory access to the external segment of memory.

5. **Timers**

The Transputer provides two hardware timers. Each of these timers can be viewed as free-running 32-bit binary counters. One of the timers is accessible to high-priority processes; the other timer is accessible to low-priority processes. The high-priority timer increments at intervals of one μsecond, for a total cycle time of about 72 minutes. The low-priority timer increments at intervals of 64 μseconds, for a total cycle time of about 76 hours.

Instructions are provided for initializing the value of these timers and for reading the current value of a timer. An instruction is also provided for suspending execution of a process until a specified

18
timer value is reached. To implement this instruction, the Transputer maintains a linked list of suspended processes waiting on timer values. Separate lists are maintained for the high- and low-priority timers. These lists are ordered by the specified "wait-until" time value. The first "wait-until" time value in each list is loaded into a dedicated register and, using hardware, is compared with the current value of the high- or low-priority timer. When the "wait-until" timer value is reached, the suspended process is removed from the timer list and is added to the end of the appropriate active process list to wait its turn for execution. The next timer list entry is then loaded for comparison.

6. **External Event Input**

The external event input on the Transputer is similar to an external interrupt input. To the Transputer, this external event input appears as a communications channel which is capable of transmitting a signal to a user's program. A user's program requesting input from the external event channel will be suspended if the external event input is not being asserted. Then, when the external event input is asserted, the process will be added to the end of an active process list to wait its turn for execution. Either a high- or a low-priority process may request input from the external event channel.
III. TRANSPUTER PERFORMANCE

A. OVERVIEW

As has been described in the previous chapter, the Transputer is a complex microprocessor. Because of this complexity, the performance of even a single Transputer can be affected by many factors. Such factors might include whether or not the program and/or associated data is in on-chip or off-chip memory or if there is internal bus contention resulting from external communications link direct memory access. When considering a network of Transputers, the factors that can affect overall network performance are multiplied considerably.

Developing efficient Transputer-based systems in the face of this complexity requires a firm understanding of Transputer performance and the manner in which different factors influence that performance. Evaluating Transputer-based systems requires accurate methods for measuring the performance of individual and networked Transputers.

To begin to understand Transputer performance characteristics and to gain experience in measuring individual and networked Transputer performance, a series of timing and performance studies was conducted.

B. PRIOR RESEARCH

INMOS provides basic performance specifications for the Transputer [In87b and In87d]. The basic specifications list the
performance for individual machine-level and high-level language operations. The listed specifications consider the effects of some of the factors that can potentially affect performance. While it is expected that the manufacturer's performance specifications are accurate, it is necessary to independently confirm this.

Prior theses [Va87 and Ha87] document some detailed tests and analyses of Transputer performance. These theses point out, however, that some aspects of their performance test results do not appear to be consistent or cannot adequately be explained. They suggest that further research be performed in this area to resolve the identified problems and to extend the scope of performance testing.

C. TEST METHODOLOGY

This chapter documents the suggested further timing research and documents the results of an initial set of timing tests on the recently released T800 20 MHz Transputer. Two major categories of testing are addressed. The first category is testing to confirm the basic manufacturer's performance specifications for the Transputer. The second category is testing to determine the interaction that exists between the operation of the central processing unit and communication link direct memory access activity.

1. Configuration

To accomplish both types of testing, a single test configuration was developed. The test configuration consists of a central "target" Transputer and four "satellite" Transputers, each attached to the target Transputer by a communications link. In addition, there
are associated Transputers which perform the functions of control and of data routing and recording. A logical diagram of this test configuration is presented in Figure 3.1. A detailed diagram of the test set-up is presented in Appendix A.

![Diagram of Test Configuration](image)

Figure 3.1. **Logical Diagram of Test Configuration**

Although based on and quite similar to a previously used test configuration [Ha87], there is a subtle but significant difference between the two test configurations. In the prior test configuration, one of the satellites was the Transputer installed in the host development system. User programs executed on the Transputer in the host development system are run from within the Transputer Development System (TDS) "shell."
After some initial experimentation, it became apparent that, in some way, this shell affected the timing of programs run from within the shell. The timing of programs running on Transputers external to the shell but depending on communications to or from a program run from within the shell also appeared to be affected. It is postulated that some shell processes are active while the user program is executing and, to an extent, interfere with the user program. References to such processes can be found in [In87a].

Although it may be of interest to research this aspect of TDS in the future, it is sufficient for the purposes of the current timing tests to simply ensure that all timing measurements are performed external to and independent of the host development system Transputer.

2. **Software**

In general, the target Transputer performed some calculation in a loop while the satellite Transputers placed different link input and output communications loads on the target Transputer. The test software monitored the time required to perform link communications and the number of calculation loops that could be performed during those communications. Appendix A provides a listing of the programs used to measure and record processor performance.

3. **Conditions**

Because so many factors can interact and affect Transputer performance, it was necessary to set and hold some test conditions fixed so that the effects of variations in parameters of interest could be
properly interpreted. Constant for the tests documented by this thesis were:

- T414 Transputer processor speed was 15 MHz.
- T800 Transputer processor speed was 20 MHz.
- Communications link speed was fixed at 20 megabits per second for both Transputer types.
- Program code and scalar variable values in the calculation loop were located in the “fast” on-chip memory for both Transputer types.
- Scalar variables in the calculation loop were in “local” scope (i.e., within the first 16 bytes of the bottom of the workspace and accessible by single byte load and store instructions).
- Memory-to-memory transfer blocks were located in “slow” off-chip memory for both Transputer types.
- Communications data blocks were fixed at 100,000 bytes. Because this block size is much greater than the size of the on-chip memory, the block was located in “slow” off-chip memory for both Transputer types.
- Communications processes were run at high priority and the calculation loop was run at low priority.
- Time measurements were taken in the each Transputer using the high-priority one-μsecond resolution timer.

The effects of varying certain parameters of interest were investigated. The following list identifies the parameters of interest and the manner in which they were varied.

- The characteristics of the target Transputer calculation loop were varied by placing different types and numbers of operations within the loop. The operations used within the loop were no operation, assignment, addition, subtraction, multiplication, division, and 100- and 1000-byte memory-to-memory transfers. The number of individual operations of a type in a loop ranged from 0 to 4 operations per loop.
Communications conditions were varied by changing the number of links that were active at one time. Additionally, the communications conditions were varied by changing the size of a communications packet. The number of active communications links ranged from 0 to 4 input links active and from 0 to 4 output links active. The individual data packet size was varied in 16 steps from one byte per packet to 100,000 bytes per packet with an overall constant data block size of 100,000 bytes.

4. **Data Management**

From the number of possible combinations of test conditions, it was clear quite early that these timing tests would generate a large amount of test data. To more effectively handle this test data, it was decided to record the data in some database management system. Using a database management system provided for ease of access to selected aspects of the data. Additionally, since the potential exists for performing further timing tests, such a system will facilitate the incorporation and aggregation of any future timing data.

Since the Ingres relational database management system was readily available on the departmental mini-computer, this system was selected for use. To facilitate loading of the timing database, conditions for a particular timing test and the test results were directed to a disk file on the host development system, then electronically transferred to the departmental mini-computer for loading into the Ingres timing database. Appendix B describes the Ingres database created for the timing data and gives some examples of accessing timing information from the database.
D. TEST RESULTS

Test runs covering the range of conditions described previously were completed and the resulting data was loaded into the Ingres timing test database. Data was extracted from this database to “view” several aspects of Transputer performance. These aspects of performance are:

1. **Isolated Processor Performance**

   The first view of the timing results is to compare measured instruction execution times with the manufacturer’s specified instruction times for a selected subset of Transputer instructions. This is intended as a confirmation of the manufacturer’s stated execution times. Additionally, if the timing results are consistent with the manufacturer’s specifications, it will tend to validate the timing test methodology that is being used.

   Determining the manufacturer’s specified execution time for a selected loop operation requires that the operation be examined at the machine-language level. Using a disassembler [Br87] to facilitate examination of the timing program object code, each of the selected operations was decomposed into its machine-level components. The manufacturer-specified number of processor clock cycles for each of these components of an operation was summed, then multiplied by the period of the processor clock. The result of this calculation is the expected execution time for a particular loop operation executed in on-chip memory. For example, the expected execution time for the multiply operation is determined as follows:
Multiply Operation:

\[ a := b \times c \]

Machine-Language Equivalent Multiply Operation:

\begin{align*}
\text{ldl} & \quad b \quad \text{(2 cycles)} \\
\text{ldl} & \quad c \quad \text{(2 cycles)} \\
\text{pfix; mult} & \quad \text{a} \quad \text{(1 cycle)} \\
\text{stl} &
\end{align*}

Execution Time Calculation (T800 @ 20 MHz):

\[ 44 \text{ cycles} \times \frac{0.050 \mu\text{sec}}{\text{cycle}} = 2.200 \mu\text{sec} \]

Note that execution of instructions in “slow” off-chip memory affects the calculation of expected execution times. To determine the expected time for such an off-chip operation, the same basic method described above is used, except that a separate accounting of on-chip and off-chip cycle counts is maintained. The off-chip cycle count is then multiplied by a hardware-dependent scale factor. This scale factor is the number of processor cycles required to make a single access to the off-chip memory. In the case of the hardware used for these timing tests, this scale factor is 4 for the T414 Transputer and 5 for the T800 Transputer.

In addition, in the particular hardware configuration used for these timing tests, off-chip memory consisted of dynamic random access memory devices. Such devices must periodically be “refreshed” to maintain their data. Although this refresh operation is relatively fast and is handled automatically by the Transputer
hardware, access to the off-chip memory is restricted during a short period of time. In the worst case, this increases the average time required to access off-chip memory by a factor of 1.0237 for the T414 Transputer and 1.0213 for the T800 Transputer [In87b]. The worst-case overall time for an off-chip operation is, then, the sum of the on-chip time and the scaled and "refresh delayed" off-chip time. An example calculation for execution of an off-chip memory-to-memory transfer follows:

Memory-to-Memory Transfer Operation:

\[
\text{[array FROM 0 FOR 1000]} := \text{[array FROM 0 FOR 1000]}
\]

Machine Language Equivalent Operation:

\[
\begin{align*}
\text{pfix; pfix; ldc } & \text{ #$800 } (1 + 1 + 1 \text{ cycles}) \\
\text{pfix; mint } & \text{ (1 + 1 \text{ cycles}) } \\
\text{wsub } & \text{ (2 cycles) } \\
\text{stl } & \text{ temp } (1 \text{ cycle}) \\
\text{pfix; pfix; ldc } & \text{ #$800 } (1 + 1 + 1 \text{ cycles}) \\
\text{pfix; mint } & \text{ (1 + 1 \text{ cycles}) } \\
\text{wsub } & \text{ (2 cycles) } \\
\text{ldl } & \text{ temp } (2 \text{ cycles}) \\
\text{pfix; pfix; ldc } & \text{ #$3E8 } (1 + 1 + 1 \text{ cycles}) \\
\text{pfix; move } & \text{ (1 + 8 \text{ cycles maximum}} \\
& \text{500 off-chip cycles)}
\end{align*}
\]

Execution Time Calculation (T414 15 MHz):

\[
29 \text{ cycles } \times \frac{0.067 \mu\text{sec}}{\text{cycle}} = 1.933 \mu\text{sec}
\]
500 cycles $\times \frac{0.067 \mu\text{sec}}{\text{cycle}} \times (4 \times 1.0237) \text{ off-chip} = 136.493 \mu\text{sec}$

$1.933 \mu\text{sec} + 136.493 \mu\text{sec} = 138.426 \mu\text{sec}$ maximum

Measured execution times for different operations were derived from the timing data as follows:

- Consider only timing data where no external communication links were active.
- Calculate the average time per loop for a test set with no operations in the loop. (The average loop time is simply the time of measurement divided by the number of loops executed during that time.)
- Extract the average time per loop for a test set with 1, 2, 3, and 4 instances of a selected operation in the loop.
- Subtract the no-operation loop time from each of the selected operation loop times. These loop times have now been "adjusted" to remove any loop overhead time.
- The incremental increase in adjusted loop times for the selected operation loops is the expected time required to perform a single operation.

Tables 3.1 and 3.2 list the expected and measured execution times for the selected loop operations. These results show that, except for the divide operation, the measured results are consistent with the expected results. The expected time for the divide operation is based on the operation taking 39 processor clock cycles [In87d]. The measured results indicate that the divide operation takes 38 processor clock cycles. Subsequent to performing the timing tests, it was confirmed with the manufacturer that the divide operation, in fact, takes 38 clock cycles as measured in the timing tests [Pe88].

2. **Isolated Communications Link Performance**

The Transputer manufacturer also provides specifications for communications link performance [In87b and In87c]. The measured
performance of a communications link can also be calculated from timing test data. Measured communications link performance is calculated by dividing the size of the largest single data block communicated over a single link by the time required for the communication. The largest block size was selected to minimize the affects of any communications set-up overhead that might exist. For the timing tests performed, the largest block size was 100,000 bytes. The specified and measured communications data rates are compared in Table 3.3. This table shows that the specified and measured data rates are consistent.

</table>

Of particular interest here is the bidirectional data rate for the T800 Transputer. For the T414 Transputer, the bidirectional data rate is approximately 2 times the unidirectional data rate. For the T800, however, the bidirectional data rate is only about 1.35 times the unidirectional data rate. Since in the worst case of the external off-chip memory the processor bus data rate is at least 20 megabytes per
second, accessing data from memory should not limit link performance. Taking a closer look at the link communications protocol provides the key to understanding this problem.

In unidirectional communication for the T800, the acknowledge packet from the receiving Transputer is returned to the transmitting Transputer before the transmitter completes its transmission. Because of this, the transmitter is able to transmit bytes "head-to-tail" without any intervening delays. This results in a maximum theoretical unidirectional data rate of

\[
\frac{20 \text{ Mbits sec}}{1} \times \frac{1 \text{ byte}}{11 \text{ bits transmitted}} = \frac{1.82 \text{ Mbytes sec}}{1}
\]

which is consistent with the actual unidirectional link data rate. In bidirectional communications, however, each Transputer must "sandwich" acknowledge packets between data packets. This increases the total number of bits transmitted by a Transputer per data byte from 11 to 13 and results in a maximum theoretical bidirectional data rate of

\[
\frac{20 \text{ Mbits sec}}{1} \times \frac{1 \text{ byte}}{13 \text{ bits transmitted}} \times 2 = \frac{3.08 \text{ Mbytes sec}}{2}
\]

This is less than double the unidirectional rate. Additionally, because a receiving Transputer is also transmitting its own data, it may not immediately be able to return an acknowledge packet for data received. The transmitter may, therefore, be delayed in transmitting its next data byte, further reducing the data rate. However, since the
internal timing threshold requirements of the link hardware are not known, it is not possible to exactly quantify this effect.

Because of this bidirectional link communications limitation, two separate unidirectional communications links between T800 Transputers will provide about a 1.1 megabyte greater bidirectional communications throughput than will a single communications link operated bidirectionally.

Since the T414 unidirectional communication rate is significantly less than the maximum possible rate for a 20 Mbit/second data link, space already exists between successive transmitted packets to "insert" an acknowledge packet for a received data packet. Because of this, the T414 does not show the prominent bidirectional communications protocol limitation shown for the T800.

3. Communication Link Interaction

Prior research [Va87] has shown that, for the T414 Transputer, there is minimal interaction between links when multiple links are operated simultaneously. It was desired to determine whether this is also a characteristic of the T800 Transputer with its greater communication link data rates. Figures 3.2 and 3.3 show communications link performance for both the T414 and the T800 under conditions when multiple links are active. Except for the bidirectional protocol limitation previously discussed, these figures show that there is minimal interaction when multiple links are being operated. Note that in Figure 3.2, the number of links active includes both unidirectionally and bidirectionally active links. Because of this, each number
of active links may include more than one data point. For example, two links active on Figure 3.2 include the data points for both the case when two unidirectional links are active and the case when one bidirectional link is active.

Figure 3.2. **T414 Multiple Link Effects on Communications Rate**

Figure 3.3. **T800 Multiple Link Effects on Communications Rate**
Additionally, for the T414, it has been shown that individual data packet size can affect the overall communications data rate [VA87]. In general, as the data packet size is decreased, the overall communications data rate also decreases. This is because the overhead time associated with the set-up of a data transmission is more significant when the size of the data packet to be communicated is small. The current test configuration and software was used to extend the scope of testing to further investigate this phenomenon. The results of this testing for the T414 and the T800 are shown in Figures 3.4 and 3.5. These graphs, as well as others in this chapter, were conducted with various numbers of links active. The number of links active for a particular graph are identified on that graph. Figures 3.4 and 3.5 show that communications throughput decreases rapidly when the packet size decreases below a threshold point of from about 200 down to 50 bytes per packet.

Further, note the communications characteristics shown in Figure 3.5. This graph shows the protocol limited nature of bidirectional link operations for the T800 Transputer. Compare the plots for the two bidirectional links case with those of the four unidirectional links case. In either of these cases, a total of four links are operating. As packet size increases from one byte per packet, the plots for both links are at first identical. However, as the packet size passes about 20 bytes per packet, the two plots begin to diverge. The four unidirectional link case data rate continues to increase but the bidirectional link case becomes protocol limited and data rate levels off.
Figure 3.4. **T414 Packet Size Effects on Communication Rate**

Figure 3.5. **T800 Packet Size Effects on Communication Rate**
4. **Communication Link Effects on Processor Performance**

One of the key questions raised about Transputer performance has been the extent to which communications link activity interferes with processor execution speed. There are two ways in which such interference can occur. First, both the processor and the communication links contend for access to the same internal data bus. Secondly, the set-up of a communication and the rescheduling of a process upon completion of its communication require some processor overhead. Recalling the timing test methodology, where operations in a loop were conducted in parallel with a variety communications load conditions, timing data is available to address this issue.

For the purposes of comparing processor performance, the average number of loops that were performed per unit time under each set of test conditions was taken as the relative measure of target processor performance. For each set of test conditions, processor performance has been normalized by dividing performance measurements by the "no communication" performance for that set of test conditions.

Figures 3.6, 3.7, 3.8 and 3.9 present representative results from this analysis. As can be seen from these figures, processor performance drops dramatically as the communications packet size is decreased below a certain threshold value. In some cases, performance was reduced to the point where the processor made no progress on its looping calculation; the processor was completely communications bound.
Figure 3.6. **T414 Performance Degradation with No Loop Operation**

Figure 3.7. **T414 Performance Degradation with Four Divide Operations**
Figure 3.8. **T800 Performance Degradation with No Loop Operation**

Figure 3.9. **T800 Performance Degradation with Four Divide Operations**
In the left-hand region of the performance graphs, where the individual data packet size is small, the processor overhead associated with the communication is the primary contributor to performance degradation. As the data packet size is increased, the time associated with actually transmitting the data packet increases. As the actual packet transmission time increases, the overhead associated with communicating a packet becomes less significant. Therefore, when the packet size is very large, any processor performance degradation will be due to processor and communications link internal bus contention. Towards the right-hand side of the performance graphs, processor performance degradation can be seen asymptotically approaching this bus contention-only degradation characteristic.

As can be seen by comparing the different performance graphs, the type of calculation performed within the loop also affects the amount of performance degradation. Although there is only a minimal difference in the overhead limited (left-hand) area of the graph, there is a noticeable difference in the bus contention limited (right-hand) portion of the graph. In general, the difference in the bus contention limited area of the graph is directly related to the frequency of memory access required by the calculation loop. For short instructions (such as assignment) that require frequent bus access, the performance degradation is greater than for long instructions (such as division) that require infrequent bus access. Figures 3.10 and 3.11 illustrate this characteristic.
Figure 3.10. **T414 Bus Access Frequency Effects on Performance Degradation**

Figure 3.11. **T800 Bus Access Frequency Effects on Performance Degradation**
5. **Processor Effects on Communications Link Performance**

As a corollary to the question of communications effects on processor performance, it is reasonable to ask what effect an actively executing process has on the performance of a communications link. It might be expected that if the processor is slowed by the effects of communication link bus contention, a communication link would also be slowed by the effects of processor bus contention. Data was extracted from the timing database to determine if such effects did in fact exist. A typical sample of this data is shown in Table 3.4.

Table 3.4 shows that the effects of processor activity on communication link performance is not significant. The reason for this is that, when the communicating process is of an equal or higher
priority to the executing process, the communication link has priority access to the data bus [In86e]. The communication link is, therefore, virtually unaffected by bus contention. Bus arbitration priority was defined in this manner so that the lower bandwidth communications links would not be idled [Ha87].

6. Summary

Through the timing tests that have been performed, it has been seen that a strong relationship exists between the calculational performance of the Transputer and the operation of its communications links. Additionally, the size of individual communications packets has a pronounced effect on both the calculational and communications performance of the Transputer. Knowledge of these characteristics can be used by the software designer to develop more efficient software.
IV. SHARED MEMORY MODEL PROGRAMMING INTERFACE

A. BACKGROUND

The concept of Communicating Sequential Processes as implemented by the Transputer is one methodology for interprocess communication and synchronization. An alternative concept utilizes globally shared memory as a means for interprocess communication and synchronization. A body of software and development experience that makes use of this shared memory concept exists and could be useful in developing programs for a network of Transputers. In particular, distributed programs developed in the ADA language environment use a shared memory model.

In a large network of Transputers, the physical connectivity of the network is limited by the availability of only four bidirectional communications links per Transputer. This limited connectivity often imposes restrictions upon the distributed systems software designer. The software designer must be aware of and consider the physical configuration of the network. As a result, the designer must often work around the limitations that the configuration imposes. The use of a shared memory model in a network of Transputers is one methodology that might be used to isolate the software designer from these physical configuration limitations.

These factors have motivated the development of prototype software to implement a shared memory model environment in a network.
of Transputers. The purpose of this prototyping effort was to gain experience in developing such a system for a distributed system. This chapter describes the design, implementation, and evaluation of this prototype.

B. EVENT COUNTS AND SEQUENCERS

When multiple processes are sharing a common resource, as in the case of a shared memory system, some means must be available for the processes to coordinate or synchronize their use of the resource. One means for this synchronization is through the use of Event Counts and Sequencers [ReKa79].

As its name implies, an event count is a value representing the cumulative total number of events of a particular type that have occurred in a system. An event count might be used, for example, to record and monitor the number of times a particular shared memory location has been written to or modified. Many separate event counts may be defined in a system for use in monitoring different types of events.

A sequencer is also a value representing a count. This count is used to control the sequence in which events occur. Each sequencer count value can be thought of as a reservation for a process to use a shared resource. These reservations are issued in sequencer count order to requesting processes. Processes with reservations are then permitted access to the controlled resource in sequencer count order. For example, several processes writing to the same memory location may use a sequencer to ensure that only one process writes to the
location at a time. As with event counts, many sequencers may be
defined in a system to control access to different shared resources.

Several primitive operations are defined for event counts and
sequencers. These operations are:

- read(event_count)—The read operation returns the current value
  of a specified event count.
- advance(event_count)—The advance operation increments the
  value of a specified event count.
- await(event_count, count_value)—The await operation suspends
  the process executing the await command until the value of a
  specified event count has at least reached the identified count
  value. Note that execution of the suspended process is not neces-
  sarily resumed immediately when the specified count value is
  reached. The process might not resume until some time after the
  count is reached.
- ticket(sequencer)—The ticket operation returns the value of the
  next available reservation “slot” for a specified sequencer.

C. IMPLEMENTATION

The model of event counts and sequencers was selected as the
paradigm for implementing the prototype shared-memory model.
Since a network of Transputers does not physically share any memory,
the implementation must make use of software to simulate a sharing of
memory. The core of the implementation is a distributed software
kernel which executes on each node in the network. Figure 4.1
depicts the general physical configuration of a network with this
kernel.
Figure 4.1. **Physical Configuration of Shared Memory Kernel**

The kernel contains the system’s shared memory and maintains the system’s event count and sequencer values. The system’s shared memory as well as the event count and sequencer values are apportioned amongst the kernels operating on different nodes. The kernel also “hides” the specific physical configuration of the network from the application program by managing all communications between program modules and network nodes. Figure 4.2 shows the
distributed application program's view of the kernel. A detailed description of the kernel is provided in this section.

Figure 4.2. Logical Configuration of Shared Memory Kernel

The prototype implementation also includes a library of procedures for interfacing with the kernel. This library includes the basic primitive operations defined for event counts and sequencers. In addition, primitive operations have been defined and included for
accessing shared memory segments. The procedures in this library are also listed in this section.

1. **The Kernel**

Figure 4.3 shows a logical diagram of the software kernel. As shown, the kernel consists of three major parts: the input/output buffers, the communications manager, and the shared memory manager.

![Shared Memory Kernel Logical Block Diagram](image)

**Figure 4.3. Shared Memory Kernel Logical Block Diagram**
a. Input/Output Buffers

A set of input and a set of output buffers are provided for the hardware communications links. These buffers decouple the relatively slow link data transfers from the operation of the kernel. The buffers enable the kernel to operate in parallel with network data transfers.

b. Communications Manager

All communications between a kernel and the library interface procedures and between kernels on different nodes are formatted as packets. Two different packet formats are used. One format is used for communication between a kernel and a library interface procedure and one is used for communication between kernels on different nodes in the network. The communications manager perform any necessary conversions between the two packet formats. Figure 4.4 depicts an example of each type of communications packet. A listing of all the packet types is included in Appendix C.

<table>

<table>
<thead>
<tr>
<th>Packet Format Used Between Kernels on Different Nodes</th>
</tr>
</thead>
<tbody>
<tr>
<td>action code</td>
</tr>
</tbody>
</table>

Figure 4.4. **Kernel Communication Packet Formats**
The communications manager processes all received packets. If a packet destination is a remote node, the packet is routed to the node via the hardware communications link identified by the node.link data structure. If the packet is for a local application program module interface procedure, the packet is routed to that interface procedure via the appropriate local link. Otherwise, the packet is processed by the node's shared memory manager.

c. Shared Memory Manager

The shared memory manager actually performs the operations defined by the various library interface procedures. As a result of external requests, this module accesses the kernel data structures and, if a response is required, generates appropriate message packets for return to the requesting process.

2. Data Structures

Operation of the kernel is best described by examining the set of data structures that support the kernel. These data structures are central to operation of the kernel. Diagrams of these data structures and their interrelation are shown in Figures 4.5, 4.6, and 4.7.

a. node.link

This array is used to represent the physical configuration of a network. Each node in the network is assigned a unique identifying number. By convention, the assigned numbers start at zero and are consecutive. The node.link data structure is a one-dimensional array with one element for every node in the network. The value of the ith element in the array identifies the number of the hardware
link that is used to send messages to the network node with identifying number \( i \). This does not necessarily mean that the \( i \)th node is at the other end of the specified link. Rather, it means that the node on the other end of the specified link is the next node in the path to the \( i \)th node.

Note that the node.link array may be viewed as one row extracted from a type of adjacency matrix that defines the network. Such an adjacency matrix array is, in fact, used at compile time to define the individual node.link arrays. As a result, each kernel holds a portion of the overall matrix. Currently, the programmer defines the contents of this matrix as the last step of the software development process.

b. **count.node**

As was done to uniquely identify nodes, each event count and sequencer in the system is assigned a unique identifying number. Again, by convention, these numbers start at zero and are consecutive. The count.node structure is a one-dimensional array with one element for each event count and sequencer in the system. The value of the \( i \)th element in the array identifies the number of the node that maintains the count assigned identifying number \( i \). This array identifies which processor in the network is responsible for maintaining each event count.

c. **count.array**

This is a two-dimensional array that contains four elements for each event count and sequencer maintained by a kernel at a
node. The first two of these elements are the current values of the event count and sequencer. The third element is either a nil pointer or a pointer to the base of a shared memory segment associated with the event count and sequencer. The fourth element is either a nil pointer or a pointer to a list of processes which have been suspended by executing the await library procedure. This list is ordered by value of the count value specified when a processes executed the await procedure. Each event count and sequencer has a separate waiting process list associated with it.

d. count.array.indices

This is a one-dimensional array that has one element for each event count in the system. For counts maintained at a particular node, this array contains the index of that count's data in the count.array data structure. For counts not maintained at the node, the array contains the nil token. Use of this array speeds access to a count's data in the count.array data structure by providing a direct pointer to the desired row and avoiding having to search through the count.array to find the correct row.

e. node.awaits

As was mentioned earlier, associated with each event count and sequencer is a list of suspended processes waiting for particular count values to be reached. These lists of suspended processes are stored using the node.awaits data structure. The data structure is a two-dimensional array where each row of the array represents an entry for one suspended process. There are four data elements for
each entry. The first element of the entry is the count value for which the suspended process is waiting. The next two elements identify which process at which node has been suspended. The final element is either a nil pointer or a pointer to the next entry in that particular waiting process list. These pointers and the waiting process pointers in the count.array data structure are row index values of the node.awaits data structure. Figure 4.5 shows an example waiting process list.

Figure 4.5. **Kernel Waiting Process List Structure**
f. free.list

This is a one-dimensional array that has one element for each array position in the node.awaits data structure. The free.list data structure holds a list of node.await data structure row indices that are not in use and may be allocated to any event count and sequencer's waiting process list. As entries are removed from wait process lists, the associated node.awaits row indices are returned to this free list.

A pointer into the free.list data structure identifies the value of the next available node.awaits row index. When this next index is allocated, the pointer is incremented to find yet the next available node.awaits row index. When an index is returned to the free.list data structure, the pointer is decremented and the returned index is stored. Figure 4.6 illustrates the use of the free list and associated pointer.

g. count.size

This is a one-dimensional array with one element for each event count and sequencer in the system. The value of the ith element in the array identifies the number of bytes of shared memory that are to be associated with count i.

h. node.data

This array is the block of shared memory available at a node. Segments of this memory block are apportioned based on the values in the count.size data structure for counts being maintained at that node. The memory pointers in the count.array data structure
Figure 4.6. **Kernel Waiting Free List Management**

point to the start of individual shared memory segments in this block of memory. Figure 4.7 shows how this shared memory array is configured and accessed.

3. **Library Procedures**

A functional description of each of the library interface procedures is provided below. Each procedure includes a reference to a "link" parameter. This parameter is a bidirectional communication channel that links or connects a distributed application program module to the kernel. The program module does not directly use the
channel for any communication. The library interface procedures use this channel internally for communicating with the kernel. The detailed source code for the procedures is provided in Appendix C.

Figure 4.7. **Kernel Shared Memory Access Data Structures**
a. **read(link, count.id, count.value)**

This procedure performs the read operation on the specified event count. The value of count.value is set to the current value of the count.

b. **advance(link, count.id)**

This procedure increments the value of the specified event count. If other processes are waiting on the new value of the event count, these waiting processes are resumed.

c. **await(link, count.id, count.value)**

The executing process is suspended until the value of the specified count reaches the argument count.value. If the value of the specified count is already greater or equal to the argument count.value, the process executing the await call continues execution.

d. **ticket(link, count.id, ticket.value)**

This procedure sets the value of ticket.value to the value representing the next available reservation for the specified sequencer.

e. **put(link, count.id, index, byte.array)**

This procedure provides write access to the shared memory segment associated with the specified event count. The array of bytes passed to the procedure is stored in the shared memory segment offset from beginning of the shared memory segment by the number of bytes specified by the value of the index parameter.
The get procedure complements the put procedure by providing read access to the shared memory segment associated with the specified count. The array of bytes passed to the procedure is read from the shared memory segment offset from beginning of the shared memory segment by the number of bytes specified by the value of the index parameter. The number of bytes read is based on the size of the byte.array parameter.

The procedure for the kernel is itself included in the library. This procedure is executed on each node in the system. The link.array parameter for the kernel is an array of all the individual links that connect the application program modules at a node to the kernel. The other kernel parameters are described in detail in the data structures section of this chapter.

D. PROGRAMMING

This section presents a brief overview of how to program using the shared memory interface. A detailed programming example is presented in Appendix D. Programming using the shared memory interface is accomplished in three basic steps.

The first programming step is to divide the program into modules that should operate in parallel and to define the shared memory segments and event counts and sequencers that will be required for communication between and synchronization of the modules. This
step should performed without considering the physical configuration of a network.

The next step is to code the individual modules using the library interface procedures to manipulate the event counts and sequencers and to access the shared memory segments. Since this step is also accomplished without considering the physical configuration of the network, the modules may be coded independently.

The final step of the software development process is to apportion modules and shared memory segments amongst different processors in a network. Although any apportionment of the modules and memory segments is logically equivalent, this placement process may be influenced by practical considerations. For example, one would not want to place all the computationally intensive modules on the same processor. Further, it would seem reasonable to locate modules sharing the same memory segment physically close to the network location of the memory segment. To help quantify the factors that may influence the network placement of modules and shared memory segments, the following section evaluates the performance of the shared memory interface under a variety of conditions.

E. EVALUATION

To evaluate the prototype programming interface, a set of tests was conducted using the interface. The objective of this testing was to provide a representative measure of the communications performance of a network when using the programming interface. It was desired to determine how the network communications performance was
affected by variations in certain parameters. This testing utilized T414 Transputers operating with a clock speed of 15 MHz and a link speed of 20 Mbits per second. These tests are described in the following paragraphs. It should be noted that the prototype programming interface was not optimized for maximum performance. Because of this, the interface performance documented here can likely be improved. Chapter VI describes some ways in which the programming interface performance can be improved.

1. Basic Interface Procedure Timing

As the first step in examining the performance of the programming interface, it was chosen to measure the execution times of the various interface procedures. A test program was developed to execute each of these procedures in a loop. The time required to execute the loop with each of the interface procedures was measured. The time required to execute the loop without an interface procedure (i.e., a "null loop") was measured and subtracted from the interface procedure loop times. The resulting time was used to determine the average time required for a single interface procedure execution.

Interface procedure execution times were measured under several sets of conditions. Specifically, the network distance between an interface procedure and its target event count and sequencer was varied and, for the put and get operations, the size of the argument data element was varied. The results of this testing are shown in Figures 4.8, 4.9, and 4.10.
Figure 4.8. **Primitive Operation Timing Test Results**

Figure 4.9. **Put Operation Timing Test Results**
Figure 4.10. **Get Operation Timing Test Results**

Figure 4.8 shows two basic types of execution behavior. First, the execution times for one group of interface procedures is relatively constant over the range of conditions tested. This group of procedures includes those that do not require any response from the distributed kernel. The procedure can pass its communications packet to the kernel and the application program module can proceed without waiting for a reply. Since communication between the interface procedure and the kernel is via memory-to-memory transfer, the transmission of a communications packet is fast and relatively insensitive to variations in data element size over the range of kernel operation. Note also in Figure 4.9 that the execution time for the put operation is significantly less for the zero-hop (same node) case than for the one-hop case. This is because the zero-hop case is executed by
performing a memory-to-memory transfer of data as opposed to the slower physical link transfer of data in the one-hop case.

The second type of behavior is for interface procedures that do require a response from the distributed kernel. As can be seen in Figure 4.8 for the read, ticket, and await procedures and in Figure 4.10 for the get procedure, execution times are strongly dependent on the test conditions. As the network distance is varied, the overall execution time increases because the "round trip" communication time in the network increases. Further, since data transfer between nodes via the hardware links is significantly slower than the memory to memory transfer, the effects of data size on execution time for the get procedure become significant.

The results of this testing imply that there is a preferred location for the counts and shared memory segment for a producer and consumer of data located at different nodes in the network. Since the put operation is relatively insensitive to network distance and since the get operation is greatly affected by network distance, it would appear that the shared memory segment for a producer consumer pair should be located at the consumer's node. A test was performed to confirm this. In this test, the count and shared memory segment for a producer and consumer pair were placed at the producer's node, then at the consumer's node. The resulting data communication rates were measured for various data element sizes. The results of this testing are shown in Figure 4.11 for a network distance of seven nodes. The results of this test show that the highest
communications rate is obtained when the shared memory segment and associated event count for a producer/consumer pair is located at the consumer's node.

![Graph showing communications data rate vs. data element size](image)

Figure 4.11. **Count and Shared Memory Location Effects on Communication Rate**

2. **Node Distance Effects on Communication Rate**

The distance between an application program module producing data and the application program module consuming that data can be measured as the number of physical links or "hops" in the communications path between the node locations of the modules. A test was performed to determine the effect that hop distance could have on the overall data communication rate between application program modules. In this test, a producer and consumer of data were
separated by increasing hop distances. The library interface procedures were used to transfer data between the producer and consumer at the maximum possible rate. In addition, since the size of a communication message has a demonstrated effect on performance (Chapter III), the size of the data element being communicated using the programming interface was varied. The resulting communications data rates are shown in Figure 4.12.

![Figure 4.12. Hop Distance Effects on Communication Data Rate](image)

This graph shows that as the hop distance increases, the maximum data rate decreases. This decrease is rapid for first few hops but less significant as the hop distance is further increased. This is because each additional hop represents a proportionally smaller increment of in-line delay to the data transfer. As was shown in
Chapter III for the Transputer in general, communication of larger data elements is more efficient when using the programming interface.

Processes executing on the nodes between the producer and consumer may also be affected by the data transfer through a node. To examine this, a looping calculation was initiated on a node immediately between a producer and consumer pair. The number of loops executed per unit time during a data transfer was measured and compared to the no-data transfer looping rate. Again, varying sizes of data elements were used. The results of this testing are shown in Figure 4.13.

Figure 4.13 shows that lowest performance of about 70 percent of normal occurs when using the smallest-sized data elements. As the size of the data element increases, the performance increases to a maximum of about 80 percent of normal. Performance of the intermediate process improves when the data element size is increased because the overhead associated with communicating a single message becomes relatively smaller. This is the same general effect as was shown in Chapter III for communication with varying sized data packets.

3. **Hardware Link Sharing Effects on Communication Rate**

When using the programming interface, it is likely that data communication between several pairs of producers and consumers will be conducted using the same hardware communications link. In this case, the kernel in the node on either end of the link is also involved
in the communication. A test was performed to determine what effects this link sharing had on the overall data communications rate between the nodes. In this test, producers and consumers were placed on adjacent nodes. Producers were placed on each node in the same number to provide balanced bidirectional utilization of the hardware link. The number of producers on each node and the size of a communication data element was varied. The results of this test are shown in Figure 4.14. This plot shows that, although some degradation in communications performance does occur due to kernel overhead, a substantial data rate can be maintained when a hardware link is shared between several users.

Figure 4.13. **Intermediate Process Degradation During Communication**

![Intermediate Process Degradation During Communication](image-url)
4. Multiple Link Effects on Communication Rate

In most cases, several links on each Transputer in a network will be connected and utilized at any one time. To test the communications performance of the kernel under these conditions, a varying number of hardware links on one Transputer were bidirectionally loaded. The resulting data rates were measured for different data element sizes. The results of the test are shown in Figure 4.15.

Figure 4.14. Shared Hardware Link Communications Rates

![Graph showing data rates for different data element sizes and number of producers.](image-url)
Figure 4.15. **Multiple Hardware Link Communications Rates**

Figure 4.15 shows that, as the number of links used increases, the data actually communicated via each link decreases. However, in Chapter III it was shown that link communication rate was essentially independent of the number of links active. The kernel must, therefore, the cause of this reduced link utilization. Since all data messages must be processed by the kernel and since the kernel can only process and transfer a fixed maximum number of messages in any time period, a limit on the data rate through the kernel must exist. Since Figure 4.15 shows the communication rate per link decreasing by more than a factor of two when a second link is activated, it appears that the kernel data rate limit is less than the capacity of a single communication link. Activating additional links,
therefore, except to reduce the hop distance between nodes in a network, does not increase the overall communication bandwidth of the network. Chapter VI discusses potential changes to the kernel which may improve the programming interface performance.
V. MESSAGE-PASSING MODEL PROGRAMMING INTERFACE

A. BACKGROUND

The shared memory model is one method for isolating the distributed systems software designer and programmer from having to consider the physical configuration of a network of Transputers. It is also possible, however, to utilize a message passing model to provide for this isolation. To investigate this alternative, a prototype programming interface based on message passing has been developed. This chapter describes and evaluates this prototype.

B. IMPLEMENTATION

Since the Transputer is based on the concept of Communicating Sequential Processes (CSP), using this concept as a basis for a message-passing prototype was a natural choice. Communications in the message-passing prototype are, therefore, based on CSP communications "rules." Specifically, message passing is logically point-to-point, synchronous, and unbuffered.

A significant goal in the development of this interface was to permit application program modules to be written in the Transputer's "native" high-level language, OCCAM, without requiring any additional external procedure references. In this way, existing modules programmed in OCCAM could be used with the interface.

As with the shared-memory model prototype, the core of the message-passing prototype is a distributed kernel that executes on
each node in the network. Figure 5.1 shows the physical configuration of such a network. Note that this physical configuration is very similar to the physical configuration used in the shared-memory model prototype.

![Physical Configuration of Message-Passing Kernel](image)

**Figure 5.1. Physical Configuration of Message-Passing Kernel**

Figure 5.2 depicts the logical configuration of the message-passing network as seen by the application. The logical configuration of the
message-passing network shows individual application program modules interconnected by a network of global message-passing channels.

Figure 5.2. *Logical Configuration of Message-Passing Kernel*

This chapter frequently uses the terms "local channel" and "global channel" when referring to the operation of the message-passing prototype. A local channel is an actual communications path that exists between a process and a kernel. Figure 5.1 shows several examples of local channels. Global channels, as shown in Figure 5.2, are the virtual communication paths that exist between two processes. These virtual communications paths are established and maintained by
the distributed kernel. Local channels may be thought of as connecting processes to the ends of global channels.

1. **The Kernel**

Figure 5.3 shows a block diagram of the message-passing kernel. As shown, the kernel consists of three major parts: the Input/Output Buffers, Channel Controllers, and the Communications Manager. In addition, the kernel performs some initialization of the network. Each node broadcasts to the network a list of the global channel ends that it has been assigned. This information is used by the kernel to create a global routing table for network communications.

a. **Input/Output Buffers**

These buffers are identical to those used in the shared memory model prototype. They decouple the relatively slow link data transfers from the operation of the kernel. The buffers enable the kernel to operate in parallel with network data transfers.

b. **Channel Controllers**

The kernel creates one channel controller process for each local channel at a node. The channel controller is the physical connection between a local channel and the kernel and is the logical connection between a local channel and the appropriate global channel. Communication over the global channel is controlled using a simple protocol which is managed by these channel controllers. When the receiving end of a global channel is ready to receive an application program module message, the receiving end channel controller
transmits a "ready to receive" message to the sending end controller. The sending end controller is then released to accept the application’s message and send it to the receiving application program module via the global channel.

![Message Passing Kernel Logical Block Diagram](image)

Figure 5.3. **Message Passing Kernel Logical Block Diagram**
c. **Communications Manager**

As in the shared memory interface, messages communicated over the network are formatted as packets. Figure 5.4 diagrams the packet format used. Each packet received from a hardware link or from a channel controller is processed by the communications controller and routed to its packet header identified destination.

![Packet Format Used Between Kernels on Different Nodes](image)

**Figure 5.4. Kernel Communications Packet Format**

At the current state of the kernel's development, messages transmitted from an application program module over a global channel are restricted to only one of the simple protocols predefined in the OCCAM language [PoMa87]. The available protocol provides for transmission of variable-length byte arrays (INT::[]BYTE). This is not a particularly limiting restriction since any structure in OCCAM can easily be RETYPED into an array of bytes for communications purposes.

2. **Data Structures**

The message-passing prototype kernel maintains a set of data structures that defines the characteristics of the physical and logical communications network. The overall operation of the kernel is fundamentally dependant on the interrelation of these structures. The
kernel data structures are described in the following paragraphs. Figure 5.5 is an example of the manner in which these data structures are interrelated at two different nodes.

a. node.link

This data structure is identical to the node.link data structure used in the shared-memory model. The value of the $i^{\text{th}}$ element in the array identifies the number of the hardware link that connects to the next node in the path leading to node $i$. The array defines the node's view of a network. Currently, the programmer defines the contents of this data structure at the end of the software development process based on the particular network configuration that is to be used.

b. gchan.node

This structure is used to identify the end locations of network global channels. This is a two-dimensional array which has a two-element entry for each global channel defined in the distributed system. Each global channel in the network is assigned a unique identifying number. By convention, the assigned numbers start at zero and are consecutive. This array is indexed by a global channel's unique identifying number. The first element of an entry identifies the node location of the process that outputs to the global channel. The second element identifies the node location of the process that inputs from the channel. During kernel initialization, each node broadcasts a listing of global channel ends at the node. The kernel uses these

broadcast messages to construct this array. As a result, each node in
the system has an identical copy of this data structure.

c. \textit{gchan.lichan}

If a global channel end is connected to a local channel at
a particular node, this structure identifies which local channel the
connection is to. This is also a two-dimensional array indexed by a
global channel's unique identifying number. Each entry in the array
consists of two elements. In general, the first element of an entry is
the identifier of the local channel that outputs to the global channel;
the second element is the identifier of the local channel that inputs
from the global channel. At a particular node, this array only includes
local channel identifiers for the global channels that output from or
input to that node. All other entries in the array are nil at that node.

d. \textit{loc.chan}

This data structure is an array of OCCAM communication
channels. This array, potentially different at each node in the net-
work, defines all the local channels that connect to global channels at
a particular node.

e. \textit{lichan.gchan}

This is a one-dimensional array with an element for each
local channel at a node. The value of the \textit{i}th element in the array is the
identifier for the global channel to which local channel \textit{i} is connected.

f. \textit{chan.map}

Each node in a network has a different version of this
data structure. The data structure is an array that holds two elements
for each local channel defined at a node. For the $i$th channel defined in the loc.chan array, the $i$th entry in the chan.map array defines the end of the global channel "connecting to" that local channel. The first element of an entry is the unique identifier for the global channel. The second element of an entry identifies whether the local channel is connected to the sending or receiving end of the global channel.

2. **Library Procedures**

The Library for the message passing interface consists only of the distributed kernel procedure:

```c
void csp.kernel(node.id, node.link, chan.map, loc.chan);
```

This kernel procedure is executed on each node in the system. In general, the parameters for this procedure identify the physical and logical channel mappings for that node.

C. **PROGRAMMING**

This section presents a brief overview of how to develop a program using the message-passing interface. A detailed programming example is presented in Appendix F. Programming using the message-passing interface is accomplished in essentially the same three basic steps as is programming using the shared memory interface. The first step is to divide the program into modules that should operate in parallel and to define the point-to-point channels that will be required for communication between the modules. This modularization need not, however, consider the physical four-link limitation of an
individual Transputer or the actual connectivity of a particular network.

The next step is to code the individual modules using OCCAM programming guidelines [PoMa87]. Thus far, the program development methodology is the same as would be used for developing any program in OCCAM.

The final step of the software development process is to apportion modules amongst different processors in a network. The same practical considerations that influence the placement of channels when using the shared memory model also need to be considered when using the message passing model.

**D. EVALUATION**

The same types of testing were performed for the message-passing interface as were performed for the shared-memory interface. This section provides the results of the message-passing model interface kernel testing and compares the test results of the two interfaces. The message-passing interface testing also utilized T414 Transputers operating with a clock speed of 15 MHz and a link speed of 20 Mbits per second. Since the message passing interface has no separate set of procedures for use in application program modules, separate interface procedure timing tests were not needed.

1. **Node Distance Effects on Communications Rate**

   A test was performed to determine the effect increasing distance between nodes has on the overall data communication rate between application program modules. In this test, a producer and
consumer of data were separated by increasing hop distances. Data messages were sent from the producer to the consumer at the maximum possible rate. The resulting communications data rates for different data message sizes are shown in Figure 5.6. Figure 5.7 provides a comparison of the maximum data communications rates for the two interfaces.

![Figure 5.6](image.png)

**Figure 5.6. Hop Distance Effects on Communications Data Rate**

Figure 5.6 shows that as the hop distance increases, the maximum data rate decreases. This decrease is rapid for first few hops, but less significant as the hop distance is further increased. This is because each additional hop represents a proportionally
smaller increment of in-line delay to the data transfer. This same effect was shown for the shared memory kernel in Chapter IV.

Figure 5.7. **Comparison of Hop Distance Effects**

Figure 5.7 shows that for smaller network distances, the message passing interface has a significant data communications rate advantage over the shared memory interface. However, as the network distance between the producer and consumer nodes increases, the communication performance difference between the two interfaces decreases. In both cases, minimizing the difference between the producing and consuming nodes improves performance.

With the message-passing model's greater data communication rate, it might be expected that performance of processes on
nodes in the path between a producer and consumer would be degraded to a greater degree with the message-passing model than with the shared-memory model. Figure 5.8 shows the intermediate process degradation for both interfaces.

![Figure 5.8. Intermediate Process Degradation During Communication](image)

As can be seen, the degradation for the message-passing model is less than for the shared-memory interface. The reason for this behavior appears to lie in the number of messages an intermediate node must process when using the two interfaces. In the shared-memory model case, each production/consumption cycle requires at least the transmission of three messages between nodes (an await message, an advance message, and either a put or a get.
message). The message-passing model only requires that two messages be sent (a receiver ready message and a data message). As shown in Chapter III, a greater degradation should be expected when using more messages to communicate a given sized data element.

2. **Hardware Link Sharing Effects on Communication Rate**

In the message-passing model, several global channels will likely use the same physical link for network communication. As with shared-memory interface testing, a varying number of producer/consumer pairs were executed on two adjacent nodes to examine the kernel's performance. The results of this test are shown in Figure 5.9. Despite some performance degradation, these results show that a link can be effectively shared between global channels.

![Graph showing communication rates](image)

**Figure 5.9. Shared Hardware Link Communication Rates**

87
3. **Multiple Link Effects on Communication Rate**

Testing of the message-passing interface with a varying number of links active was performed for the message-passing interface. The results of this testing are shown in Figure 5.10. This testing revealed the same type of kernel data rate limitation found when testing the shared-memory model interface. Although the data rate of the message-passing kernel is significantly greater than that of the shared memory interface, the message passing kernel’s data rate limit remains less than the capacity of one hardware communications link.

![Figure 5.10. Multiple Hardware Link Communication Rates](image-url)
VI. CONCLUSIONS AND RECOMMENDATIONS

A. CONCLUSIONS

This thesis has evaluated the performance of an isolated Transputer and the performance of two abstract programming interfaces with distributed kernels for a network of Transputers. The results of the evaluation show that, although the use of a distributed kernel reduces the effective performance of individual Transputers in the network, the performance remains relatively high. In general, the performance of the message-passing interface was superior to that of the shared-memory model interface. This comparison should not, however, be taken as absolute. There are improvements discussed in this chapter that can be made to both interfaces which could significantly affect this comparison.

Thus far, all evaluation of the abstract programming interfaces has been based on testing. The programming interfaces also need to be examined on the basis of whether or not they can be effectively used in the development of distributed programs. By its nature, such an assessment is subjective and prone to be influenced by one's prior experience and personal programming style preferences. Based on the experience of developing test and example programs for use with the interfaces, it appears that both of the interfaces do simplify the programming of a physical network of Transputers. The primary factor in this is that the programmer is isolated from having to consider a specific physical configuration of a network at all stages of program
development. Only after the program is developed need a particular configuration be considered, at which point the physical configuration is described by a set of simple data tables.

Both interfaces accomplish the goal of isolating the software designer from physical configuration considerations. There was, however, no clear choice as to which interface methodology was the overall "best" from a programming standpoint. Each methodology had certain advantages and disadvantages. In general, the initial design, development, and coding of a distributed program was most effectively accomplished using the message-passing model. However, once past the initial implementation of a program, modifications, either to add additional functionality or to correct initial design errors, are usually required. In most cases, these modifications and additions were easier to make when using the shared-memory model interface.

**B. RECOMMENDATIONS**

As was mentioned previously, the programs for these prototype interface implementations are not fully optimized. As a direction for further work in developing the abstract interfaces for a network of Transputers, several modifications to the interface implementation should be considered. In general, the same types of changes can be made to both interfaces to improve performance. Some suggested changes are listed as follows:

- The message packet format can be improved. The current message format is actually scheduled as three separate transmissions: transmission of the header, transmission of a size value, and transmission of the data array. Efficiency can be improved by reducing the number of required transmissions. For example, the
header information and the data array could be combined into a single array transmission preceded by a size transmission. This would eliminate one scheduled transmission each time a message is handled.

- The transmission of messages within the kernel uses OCCAM communications channels. This transmission is performed by processor-controlled memory-to-memory transfer. When the size of a data message is large, this decreases the performance of a node. A simple memory manager could be incorporated into the kernel to allocate space for messages in transit so that the transfer of messages within the kernel could be performed by communicating pointers or handles to the messages via the OCCAM channels.

- In the case of the shared-memory model, the interface only transfers data from a shared-memory segment to a remote node when an application program module at the remote node requests the data. If it is known in advance that certain remote nodes or modules will require frequent access to a node’s shared memory segment, performance could be improved by having the distributed kernel automatically and periodically transfer selected segments of globally shared memory between nodes.

- Many of the data structures within the kernels are sparse. As the size of a network becomes larger, the storage required for these structures will also become larger. At some point, it is likely that a compressed storage scheme for the kernel data structures will need to be adopted.

In addition to these performance improvements, the kernel should be modified to include a distributed algorithm for examining the network to determine a network's physical configuration. Use of such an algorithm would save the software designer from having to specify the physical configuration of a network as the last step of the design process. More importantly, however, to support fault tolerance, such an algorithm could be used to identify an altered physical configuration so that alternate message routing paths could be established.
APPENDIX A

DETAILED TRANSPUTER TIMING TEST CONFIGURATION

AND SOURCE CODE

A. SUMMARY

The purpose of the timing test configuration and associated test code is to provide a general framework for testing Transputer performance characteristics. The detailed configuration of the test set-up is shown in Figure A.1. The test set-up consists of a central "target" Transputer and four "satellite" Transputers, each attached to the target Transputer by a communications link. In addition, there are associated Transputers to perform the functions of control and of data routing and recording.

APPENDIX B

TIMING DATABASE DESCRIPTION

A. DISCUSSION

The large volume of data generated by individual timing tests was loaded into a database management system to facilitate ease of access and aggregation of any future test results. The Ingres Relational Database Management System, currently available on the departmental mini-computer, was selected for this purpose. The Ingres database management system provides a wide range of tools for accessing and manipulating data. These tools range from a database query language that can be used to program complex data manipulations and operations to a completely menu-driven interactive shell for accessing the database.

This appendix documents the format of the Ingres timing database. Also, some examples are provided on ways in which timing data can be accessed through the use of the query language. Complete documentation for the use of the many features of the Ingres relational database system may be found in [Re85].

B. DATABASE DESCRIPTION

A relational database consists of a set of relations. A relation is, in turn, composed of a set of data fields. A relation can be thought of as a table where the data fields represent the columns of the table. One
row of the table then represents one individual set of data entered in the table.

In the timing database, there are several relations that are defined. The first of these relations, shown in Table B.1, is the relation that actually holds the timing test data. This table shows each of the fields in the timing relation, the type of data the field is formatted for and the length of the data field (in bytes).

TABLE B.1
TIMING DATA RELATION DEFINITION

<table>
<thead>
<tr>
<th>Relation Name: timing</th>
</tr>
</thead>
<tbody>
<tr>
<td>column name</td>
</tr>
<tr>
<td>processor</td>
</tr>
<tr>
<td>procspeed</td>
</tr>
<tr>
<td>linkspeed</td>
</tr>
<tr>
<td>opcode</td>
</tr>
<tr>
<td>opcount</td>
</tr>
<tr>
<td>looppri</td>
</tr>
<tr>
<td>looploc</td>
</tr>
<tr>
<td>commpri</td>
</tr>
<tr>
<td>commloc</td>
</tr>
<tr>
<td>linksin</td>
</tr>
<tr>
<td>linksout</td>
</tr>
<tr>
<td>blocksize</td>
</tr>
<tr>
<td>packcount</td>
</tr>
<tr>
<td>packsize</td>
</tr>
<tr>
<td>loopcount</td>
</tr>
<tr>
<td>looptime</td>
</tr>
<tr>
<td>arm0time</td>
</tr>
<tr>
<td>arm1time</td>
</tr>
<tr>
<td>arm2time</td>
</tr>
<tr>
<td>arm3time</td>
</tr>
</tbody>
</table>
The name of this relation is "timing." Note that the fields defined in this relation are the same as the data elements written to the host system file by the timing test program of Appendix A.

There are two additional relations in the timing test database. These relations, shown in Tables B.2, B.3, and B.4, provide for translating the numerically encoded calculation loop operation codes, the timing test priorities, and memory locations in the "timing" relation into a text description of the corresponding test condition.

TABLE B.2
RELATION DEFINITION FOR CONVERTING ENCODED OPERATION CODE NAMES

<table>
<thead>
<tr>
<th>Relation Name: opcodenames</th>
</tr>
</thead>
<tbody>
<tr>
<td>column name</td>
</tr>
<tr>
<td>-----------------</td>
</tr>
<tr>
<td>opcode</td>
</tr>
<tr>
<td>opcodename</td>
</tr>
</tbody>
</table>

TABLE B.3
RELATION DEFINITION FOR CONVERTING ENCODED PRIORITY NAMES

<table>
<thead>
<tr>
<th>Relation Name: prinames</th>
</tr>
</thead>
<tbody>
<tr>
<td>column name</td>
</tr>
<tr>
<td>-----------------</td>
</tr>
<tr>
<td>pri</td>
</tr>
<tr>
<td>priname</td>
</tr>
</tbody>
</table>
TABLE B.4
RELATION DEFINITION FOR CONVERTING ENCODED LOCATION NAMES

<table>
<thead>
<tr>
<th>Relation Name: locnames</th>
</tr>
</thead>
<tbody>
<tr>
<td>column name</td>
</tr>
<tr>
<td>loc</td>
</tr>
<tr>
<td>locname</td>
</tr>
</tbody>
</table>

C. EXAMPLES

There are three database operations that are provided as examples of query language interaction with the database. These operations are: loading an external text file of data into the database, retrieving information from the database, and, finally, transferring data from the database to an external text file.

1. **Data Loading**

   Figure B.1 is a listing of the query language instructions for transferring a file of test data from the timing test program into the timing database. For the most part, these instructions are self explanatory. Of note are the formatting codes, "c0tab" or "c0nl," associated with each of the fields. These formatting codes mean that the text file representation of a field's data is a variable length character string terminated by a tab character or by a new line character.
Figure B.1. **Query Language Listing for Loading the Database**

2. **Data Retrieval**

Figures B.2 and B.3 are examples of query language data retrievals. In Figure B.2, the time (in \( \mu \)seconds) for single link bidirectional communication of 100,000 bytes with a packet size of 10 bytes is retrieved for all types of processors. The results of this retrieval are also displayed.

In Figure B.3, the same retrieval is processed but, instead of displaying the results, the results of the query are used to form the new relation “new_relation.”

```
copy timing
(
    processor = c0tab,
    procspeed = c0tab,
    linkspeed = c0tab,
    opcode = c0tab,
    opcount = c0tab,
    looppri = c0tab,
    looploc = c0tab,
    commpri = c0tab,
    commloc = c0tab,
    linksin = c0tab,
    linksout = c0tab,
    blocksize = c0tab,
    packcount = c0tab,
    packsize = c0tab,
    loopcount = c0tab,
    looptime = c0tab,
    arm0time = c0tab,
    arm1time = c0tab,
    arm2time = c0tab,
    arm3time = c0nl
)
from "~/work/ingres/time.file"
```
retrieve
(
    timing.processor,
    timing.looptime
)
where
    timing.linksin = 1 and
    timing.linksout = 1 and
    timing.packsize = 10 and
    timing.opcode = opcodenames.opcode and
    opcodenames.opcodename = "null loop"
sort by
    timing.processor,
    timing.looptime

Executing . . .

<table>
<thead>
<tr>
<th>processor</th>
<th>looptime</th>
</tr>
</thead>
<tbody>
<tr>
<td>414</td>
<td>191659</td>
</tr>
<tr>
<td>800</td>
<td>123143</td>
</tr>
</tbody>
</table>

Figure B.2. Example of Retrieval for Display

retrieve into new_relation
(
    timing.processor,
    timing.looptime
)
where
    timing.linksin = 1 and
    timing.linksout = 1 and
    timing.packsize = 10 and
    timing.opcode = opcodenames.opcode and
    opcodenames.opcodename = "null loop"
sort by
    timing.processor,
    timing.looptime

Figure B.3. Example of Retrieval for Forming a New Relation
As can be seen in Table B.5, which lists the characteristics for this new relation, the fields in the new relation inherit their characteristics from the relation from which the field originated.

### TABLE B.5

**RELATION DEFINITION FOR THE RETRIEVED NEW_RELATION**

<table>
<thead>
<tr>
<th>column name</th>
<th>type</th>
<th>length</th>
</tr>
</thead>
<tbody>
<tr>
<td>processor</td>
<td>integer</td>
<td>2</td>
</tr>
<tr>
<td>looptime</td>
<td>integer</td>
<td>4</td>
</tr>
</tbody>
</table>

3. **Data UnLoading**

Figure B.4 shows the query language listing for transferring the previously created relation "new_relation" to an external text file. As with the loading of data into the database, a formatting code is associated with each field to be transferred to the external text file. The interpretation of these formatting codes is the same as for the formatting codes for loading the database.

```sql
COPY new_relation
    (processor = c0tab, looptime = c0nl)
INTO "/work/ingres/text.file"
```

Figure B.4. **Query Language Listing for Unloading the Database**

{{
| description |
| This procedure buffers output to hardware communications links. |
| To improve performance, the buffer is sized to hold one message |
| for each process at the node. The buffer is organized in a ring |
| configuration. WARNING: This implementation uses variables |
| shared between parallel processes. The ring buffer itself, and |
| next in and out pointers are shared. When this procedure is run |
| at high priority, the sequencing of the code guarantees that |
| there will be no access conflicts to these shared structures. |
| The purpose for this sharing is that the implementation is |
| slightly faster under average case loading conditions and is no |
| worse than a 'normal' request-next-item buffer under any conditions. |

APPENDIX D

SAMPLE PROGRAM USING THE SHARED-MEMORY INTERFACE

A. DESCRIPTION

This appendix provides an example of the methodology employed to write a program using the shared-memory interface developed for this thesis. The programming example selected to demonstrate the methodology is the bounded buffer problem. In this problem, a producer passes data to a consumer via a bounded buffer or queue. The buffer serves to "smooth out" variations in the data production and consumption rates. To add slightly to the single producer bounded buffer problem, this implementation of the problem will provide for two producers of data.

B. MODULARIZATION

This particular problem can be naturally subdivided into three basic modules. Each of these are listed and described below.

1. Producers

Each instantiation of this module generates a continuous stream of data elements at a specified average rate with some characteristic random variation in the rate. The data elements produced are placed in a segment of memory shared with the consumer of the data. Access to the shared-memory segment is controlled using an event count and a sequencer. The sequencer controls the access of the two producers to the buffer. The associated
event count is advanced when either producer uses its ticket to add data to the buffer.

2. Consumer

This module continuously removes data elements from the shared memory buffer at a specified average rate with some characteristic random variation in the rate. The average rate for the single consumer should be at least equal to the total of the producer's rates. If not and the consumer can not keep up with the producers, the buffer will eventually fill and the producers will be forced to remain idle while waiting for the consumer.

An event count associated with the consumer is advanced when a data element is removed from the buffer. Note that if the producer and consumer event counts are initially equal, the number of data elements in the buffer will be equal to the difference between the event counts.

C. MODULE CODING

The code for each of the program modules should then be developed. The following sections provide an abbreviated listing of the code for the modules.

1. Producers

```
PROC producer([2]CHAN OF ANY link,
              VAL INT in, out)
```

```
#USE "\ecslib\ecsproc.tsr" -- the interface library
#USE "globals.tsr" -- global constants

INT my.ticket :
```
[data.element.size]BYTE data.element :

WHILE TRUE
SEQ

-- insert code to produce a data element
ticket(link, in, my.ticket)
await(link, in, my.ticket)
await(link, out,
    (my.ticket - data.buffer.size) + 1)
put(link, in,
    (my.ticket + 1)\data.buffer.size, data.element)
advance(link, out)

2. Consumer

PROC consumer([2]CHAN OF ANY link, 
    VAL INT in, out)

#USE "ecslib\ecsproc.tsr" -- the interface library
#USE "globals.tsr" -- global constants

INT my.count :
[data.element.size]BYTE data.element :

SEQ
    my.count := 0
    WHILE TRUE
        SEQ
            my.count := my.count + 1
            await(link, in, my.count)
            get(link, out,
                my.count\data.buffer.size, data.element)
            advance(link, out)

-- insert code for consuming the data element

D. APPORTIONMENT OF MODULES

To best demonstrate the nature of the abstracted programming interface, the apportionment of modules will be done in two different ways. The first way will assign all modules, shared memory, and event
counts to a single Transputer. The second way will distribute the modules, shared memory, and event counts on three different Transputers.

1. **Single Transputer**

```hs
Library aport.tsr

#USE "globals.tsr" -- global constants

-- symbolic constants for counts
VAL in IS 0:
VAL out IS 1:

### Procedures

**PROC get.local(local, return)**

```plaintext
PROC get.local(CHAN OF ANY local, return)
```

#### Description

- This procedure broadcasts local channel map data to all nodes for network global structure initialization.

#### Declarations

- For receiving acknowledgment of remote broadcast

```plaintext
INT acknowledge :
```

#### Sequences

**Broadcast start signals**

- Open a path to all nodes in the system.
- Intermediate nodes receiving these start tokens and relaying them will not shut-down until a corresponding stop token is received.

```plaintext
SEQ to.node = 0 FOR num.nodes
  IF to.node <> node.id
    SEQ local ! [INIT.START, to.node, node.id]; 0
    return ? acknowledge
  ELSE
    SKIP
  ENDSEQ
```

**Broadcast all local link data**

- Scan the channel map and build the local structures.

```plaintext
SEQ chan.no = 0 FOR no.l.chan
  SEQ chan.map[chan.no] :
    VAL [INT global.ident RETYPES chan.map[chan.no] :
    VAL [BYTE ident.array RETYPES chan.map[chan.no] :
    VAL INT global.chan.id IS global.ident[0] :
    VAL INT chan.mode IS global.ident[1] :
    VAL INT link.no IS chan.no + no.h.links :
  ]
```
to.node <> node.id
SEQ
  local ! [INIT.DATA, to.node, node.id]; 8::ident.array
  return ? acknowledge
ELSE

APPENDIX F

SAMPLE PROGRAM USING THE MESSAGE-PASSING INTERFACE

A. DESCRIPTION

This appendix provides an example of the methodology employed to write a program using the message-passing interface developed for this thesis. The programming example selected is the same bounded buffer problem used in Appendix D to demonstrate programming with the shared-memory interface. This problem consisted of two producers and one consumer with a bounded buffer or queue between them.

B. MODULARIZATION

The modularization of the bounded buffer problem for programming under the message-passing interface is similar to that specified for programming with the shared memory interface. As with the shared memory modularization, the producers and consumer are individual modules. However, with the shared memory interface, the buffer between the producers and consumer is a natural consequence of the memory shared between the modules. In the message-passing scheme, however, this buffer must be defined and coded as a separate module.

1. Producers

Each instantiation of this module generates a continuous stream of data elements at a specified average rate with some charac-
teristic random variation in the rate. The data elements produced are output to a buffering process via a global communications channel.

2. **Consumer**

   This module continuously attempts to input data elements from a global communications channel. Data elements input are consumed at a specified average rate with some characteristic random variation in the rate. The average rate for the single consumer should be at least equal to the total of the producer’s rates. If not and the consumer can not keep up with the producers, the buffer will eventually fill and the producers will be forced to remain idle while waiting for the consumer.

3. **Buffer**

   This module inputs communications from two global channels and queues the input data elements for output on a third global communications channel. Internally, this buffer should exhibit first-in, first-out queue characteristics.

C. **MODULE CODING**

   The code for each of the program modules should then be developed. The following sections provide an abbreviated listing of the code for the modules.

1. **Producers**

```c
PROC producer(CHAN OF ANY output)

#USE "\csplib\cspproc.tsr"  -- the interface library
#USE "globals.tsr"        -- global constants
```

151
[data.element.size]BYTE data.element:

WHILE TRUE
SEQ

-- insert code for producing a data element

output ! data.element

:______________________________

2. **Consumer**

PROC consumer(CHAN OF ANY input)

#USE "\csplib\cspproc.tsr" -- the interface library
#USE "globals.tsr" -- global constants

[data.element.size]BYTE data.element:

WHILE TRUE
SEQ

input ? data.element

-- insert code to consume data element

:______________________________

3. **Buffer**

PROC buffer(CHAN OF ANY buff.in.1, buff.in.2, buff.out)

-- Note, procedure written in a manner to illustrate some
-- features of the OCCAM programming language; not for
-- efficiency

#USE "\csplib\cspproc.tsr" -- the interface library
#USE "globals.tsr" -- global constants

[buffer.size]CHAN OF ANY buff.chan :

PAR

-- accept input from either producer
[data.element.size]BYTE data.element:

WHILE TRUE

ALT
buff.in.1 ? data.element
buff.chan[0] ! data.element
buff.in.2 ? data.element
buff.chan[0] ! data.element

-- buffer the input
PAR i = 0 FOR buffer.size - 1
[data.element.size]BYTE data.element :
WHILE TRUE
SEQ
buff.chan[i] ? data.element
buff.chan[i + 1] ! data.element

-- send from the buffer
[data.element.size]BYTE data.element :
WHILE TRUE
SEQ
buff.chan[buffer.size - 1] ? data.element
buff.out ! data.element

D. APPORTIONMENT OF MODULES

As is done for the shared-memory interface, the apportionment of modules for the message-passing interface is done in two different ways. The first way will assign all modules to a single Transputer. The second way will distribute the modules on four different Transputers.

1. Single Transputer

Library aport.tsr

#USE "globals.tsr"

-- global constants

-- symbolic constants for global channels
VAL pro1.global IS 0 :
VAL pro2.global IS 1 :
