Collisional Transfer between and Quenching of the \(3p \, ^3P\) and \(5P\) States of the Oxygen Atom
Collisional quenching and excitation transfer between the oxygen atom 3P 3P and 5P states have been investigated in a discharge/flow apparatus with O2 and N2 collisional partners. The 3P state was excited by two-photon excitation at 225.6 nm from the 2p 3P ground state, and temporal profiles of the 3P → 3S and 5P → 5S emission at 844.7 and 777.5 nm, respectively, to the lower 3S manifold were recorded. From an analysis of 3P decay curves as a function of quencher pressure, bimolecular rate constants for the removal of the 3P state were determined: \( k_3(\text{O}_2) = (7.8 \pm 0.8) \times 10^{-10} \) and \( k_3(\text{N}_2) = (5.87 \pm 0.15) \times 10^{-10} \) molecule\(^{-1}\) cm\(^3\) s\(^{-1}\). The intercept of the O2 Stern-Volmer plot yielded \( k' = 2.93 \pm 0.15 \times 10^7 \) s\(^{-1}\) for the 3P radiative decay rate. The collisional quenching rate constant for the 5P state by O2 was obtained by analysis of 5P decay curves: \( k_5(\text{O}_2) = (10.5 \pm 1.8) \times 10^{-10} \) molecule\(^{-1}\) cm\(^3\) s\(^{-1}\). Rate constants \( k_{35} \) for 3P → 5P excitation transfer were obtained from the ratio of the 5P → 5S to 3P → 3S emission intensities as a function of quencher pressure: \( k_{35}(\text{O}_2) = 6 \times 10^{-11} \) and \( k_{35}(\text{N}_2) = 2 \times 10^{-11} \) molecule\(^{-1}\) cm\(^3\) s\(^{-1}\).
COLLISIONAL TRANSFER BETWEEN AND QUENCHING OF THE 3p \(^3\)P AND \(^1\)P STATES OF THE OXYGEN ATOM

Collisional quenching and excitation transfer between the oxygen atom 3p \(^3\)P and \(^1\)P states have been investigated in a discharge flow apparatus with \(O_2\) and \(N_2\) collisional partners. The \(^1\)P state was excited by two-photon excitation at 225.6 nm from the 2p \(^3\)P ground state, and temporal profiles of the \(^3\)P -- 3S and \(^1\)P -- 3S emission at 844.7 and 777.5 nm, respectively, to the lower 3s manifold were recorded. From an analysis of \(^1\)P decay curves as a function of quencher pressure, bimolecular rate constants for the removal of the \(^1\)P state were determined: \(k_q(O_2) = (7.8 \pm 0.8) \times 10^{-11}\) molecule \(^{-1}\) cm \(^3\) s \(^{-1}\) and \(k_q(N_2) = (5.87 \pm 0.15) \times 10^{-11}\) molecule \(^{-1}\) cm \(^3\) s \(^{-1}\). The intercept of the \(O_2\) Stern-Volmer plot yielded \(k = (2.98 \pm 0.15) \times 10^{-11}\) s \(^{-1}\) for the \(^1\)P radiative decay rate. The collisional quenching rate constant for the \(^1\)P state by \(O_2\) was obtained by analysis of \(^1\)P decay curves: \(k_q(O_2) = (10.8 \pm 1.8) \times 10^{-11}\) molecule \(^{-1}\) cm \(^3\) s \(^{-1}\).

1. Introduction

There is a considerable need for well-characterized diagnostic techniques for the quantitative measurement of the concentrations of species in flames and other combustion environments. The use of multiphoton excitation schemes for the detection of light atoms, such as oxygen, has drawn considerable interest in recent years [1–13]. Two different approaches have been employed in these methods, namely observation of the fluorescence emission from the multiphoton-excited resonant state [1–9] or absorption of an additional photon to produce ionization [9–13]. Both of these schemes have been utilized for the detection of hydrogen and oxygen atoms in flames. The former method has advantages over the latter in that it does not require the insertion of a probe into the medium and can also be used to obtain two-dimensional images of atomic concentrations in flames, as has recently been demonstrated [14,15]. It is also easier to discriminate against background photon emission than ionization.

Fig. 1 illustrates the scheme which has been used for the detection of oxygen atoms [1,3,5–7,9,14,15]. Here, oxygen atoms are excited in a two-photon transition to the 3p \(^3\)P state with 225.6 nm laser radiation and are detected by observation of the fluorescent emission to the 3s \(^3\)S state at 844.7 nm. A number of parameters are required for the use of this diagnostic tool in a quantitative fashion. Recently, Bamford et al. [9] have reported absolute cross sections for the two-photon absorption process, as well as for one-photon photoionization of the \(^3\)P state. Bimolecular collision quenching rate constants for this state have also been measured by several groups [1,6,7,9]. These data are required to account for collisional effects in finite-pressure environments.

Miziolek and DeWilde [5] have also shown the potential importance of collisional excitation transfer processes in the collisional removal of this highly excited atomic state. They excited oxygen atoms by two-photon absorption at 225.6 nm in an atmophere-pressure \(CH_4-N_2O-N_2\) flame and observed within and through the flame front not only \(^3\)P -- 3S emission at 844.7 nm, but also \(^3\)P -- 3S emission of even greater intensity at 777.5 nm. Similar detection...
The present experimental study was undertaken to investigate collisional excitation transfer from the oxygen 3p 3P to 3P states in a controlled low-pressure environment. Previous studies [1,6,7,9] of collisional processes involving the 3P state have centered on the measurement of total quenching rate constants with closed-shell collisional partners, such as the inert gases, nitrogen molecules, etc. Simple theoretical considerations [17] suggest that open-shell free radical species will be more effective in inducing spin-changing excitation transfer to the 3P state. Approach of an open-shell perturber species in a state of, say, doublet spin multiplicity to an oxygen atom in the 3p 3P state will yield both doublet and quartet molecular curves, while approach to the 3P state yields quartet and sextet states. Crossing of quartet curves originating from the 3P and 3P asymptotes will provide a spin-allowed mechanism for collision-induced transitions between the 3P and 3P states which is not possible with closed-shell partners. This argument ignores the possible importance of excitations in the collision partner.

In the present study, we compare the propensity of the stable open-shell oxygen molecule and the closed-shell nitrogen molecule to induce 3P to 3P transitions. Previous experiments [1,6,7,9] have determined the total bimolecular quenching rate constants for quenching of the 3P state by these molecules.

2. Experimental

The apparatus employed for these experiments is shown in fig. 2. Oxygen atoms were generated by passing a mixture of helium and oxygen (typical partial pressures of 1.2 and 0.2 Torr, respectively) through an Evansen–Broida 2450 MHz resonant cavity. UHP grade gases were obtained from Linde and used without further purification. The walls of discharge tube were coated with phosphoric acid to reduce atomic recombination on the surfaces [18]. The forward microwave power was kept relatively low (<25 W) in order to minimize the fractional dissociation of the oxygen molecules and production of other transient species. Nevertheless, this production scheme prepared sufficient densities of ground-state oxygen atoms for these experiments. The quenching gases, either N2 or additional O2, were

![Diagram](https://via.placeholder.com/150)

Fig. 1. Relevant energy levels for two-photon excitation of oxygen atoms and excited-state collisional energy transfer. The electronic energies, taken from ref. [16], are given in cm⁻¹ and allowed radiative transitions are denoted, with wavelengths given in nm. The denoted radiative and collisional rate constants are defined in section 3.2.

of 777.5 nm emission was subsequently observed in imaging studies of atomic oxygen in flames [14,15]. These observations suggest the occurrence of excitation transfer from the 3P to the 3P state (see fig. 1). The interpretation of these experiments in terms of specific bimolecular rate processes is not straightforward because of the high pressure and chemical complexity of these flames. In addition, at least in the experiment of Miziolek and DeWilde [5], the tightly focused laser probe was observed to be promoting multiphoton photolysis of the oxidizer as well as the fuel molecules, leading to a two-photon resonant formation of a microplasma. Nevertheless, even under conditions of no apparent laser probe volume perturbation, it appears that spin-changing collisions of the initially excited level could be a significant collisional removal pathway for laser-excited oxygen 3p 3P atoms. In order to employ two-photon excitation for quantitative measurements in combustion environments, such as propellant flames, it is necessary to understand the mechanism for transfer of the initial excitation energy.
OMD FDFD FUMployed were a 850 nm center wavelength, 25 nm bandpass interference filter for detection of the 164nr 3 P-I 3 S emission at 844.7 nm and a 780 nm center wavelength, 10 nm bandpass filter for observation of the 3P-→3S at 777.5 nm. The measured transmission of these filters was 56 and 66% at 844.7 and 777.5 nm, respectively.

The output from the photomultiplier was passed to a boxcar integrator (Stanford Research Systems) for measuring excitation spectra or to a digital oscilloscope (Tektronix 2430A) for capturing the temporal profiles of fluorescence waveforms. The boxcar integrator and oscilloscope were triggered with a synchronization pulse from the Nd: YAG laser Q switch. Some details about the specifications of the oscilloscope are relevant. The bandwidth of the analog section of this instrument is 125 MHz; the digital sampling rate is 100 megasamples s⁻¹, or 10 ns between channels. In our experiments we utilized an interpolation feature for repetitive signals, which allowed digitization on a finer grid to achieve the full bandwidth: The waveform from an individual laser pulse was obtained with the usual 10 ns spacing; however, successive waveforms were taken with a slightly shifted initial delay, controlled internally by the oscilloscope. To improve the signal-to-noise ratio, waveforms were also acquired using a 256-scan running average. Typical emission lifetimes ranged from 40 to 15 ns, while the laser excitation pulse length was 7 ns.

The waveforms acquired by the digital oscilloscope were transferred through an IEEE 488 interface to a microcomputer (Apple Macintosh Plus) for storage, generation of hard-copy plots, and analysis.

3. Results

3.1. Fluorescence waveforms

Fig. 3 displays typical fluorescence waveforms for emission at 844.7 and 777.5 nm. The noise in these traces is due to the effect of the interpolating feature of the oscilloscope (see section 2) and the large fluctuations in the fluorescence signal between successive laser shots. Under all pressure conditions investigated, the emission at 844.7 nm from the initially excited 3P level was much stronger. It should
\[
d\frac{dn_3}{dt} = -n_3 k_3
\]
and
\[
d\frac{dn_5}{dt} = n_3 k_3 - n_5 k_5.
\]
where \(n_3\) and \(n_5\) are the concentrations of the \(3P\) and \(5P\) states, respectively, and \(k_3\) and \(k_5\) are the total removal rates by both radiative and collisional processes for the respective atomic states:

\[
k_3 = k_5^* + k_{35}(M) [M]
\]
and
\[
k_5 = k_5^* + k_{55}(M) [M].
\]
Here the spontaneous decay rates are denoted by \(k_5^*\) and \(k_5^*\), while the bimolecular quenching rate constants are indicated as \(k_{35}(M)\) and \(k_{55}(M)\). Eqs. (3) and (4) are written assuming there is only one quenching species, of concentration \([M]\), present. The generalization to several collision partners is obvious. These quenching rate constants represent the total rate of collisional removal of the relevant atomic species. The quantity \(k_{35}\) in eq. (2) represents that portion of the collisional removal of the \(3P\) state which results in energy transfer to the \(5P\) state:

\[
O(3P) + M \rightarrow O(5P) + M.
\]

We write
\[
k_{35} = k_{35}(M) [M],
\]
where \(k_{35}(M)\) is the bimolecular rate constant for process (5).

We assume that the two-photon laser excitation to the \(3P\) state yields a concentration \(n(0)\) in this state at \(t=0\). Eqs. (1) and (2) may be readily integrated. The \(3P\) state follows a simple exponential decay,

\[
n_5 = n(0) \exp(-k_5 t),
\]
while the time dependence of the \(5P\) state is given by the difference of two exponentials,

\[
n_5 = \frac{n(0) k_{35} \left[ \exp(-k_5 t) - \exp(-k_5 t) \right]}{k_5 - k_3}.
\]

Thus, we see that the time dependence of the \(3P\) population follows the usual exponential decay, while that of the \(5P\) state builds up to a maximum after some delay.

Eq. (7) shows that the \(3P\) radiative lifetime and
quenching rate constants may be determined by measurement of the decay lifetime \( \tau = k_3^{-1} \) as a function of quench gas pressure, in the usual Stern–Volmer treatment. The corresponding quantities for the \(^3\)P state must be determined in a non-linear least-squares treatment of the \(^3\)P concentration as a function of time, according to eq. (8). The time dependence of the \(^1\)P and \(^3\)P concentrations can be determined from the emission intensities at 844.7 and 777.5 nm, respectively.

The \(^3\)P→\(^1\)P transfer rate \( k_{35} \) cannot be determined from analysis of the fluorescence waveforms alone, but rather from the ratio of the integrated emission intensities. The integrated fluorescence intensity for the decay of the \(^3\)P state is proportional to

\[
I_3 = k_{31} \int_0^\infty n_3 \, dt. \quad (9a)
\]

With the help of eq. (7), this equals

\[
I_3 = n^{1/3} \left( \frac{k_{35}}{k_3} \right) k_{35}. \quad (9b)
\]

The quantity in parentheses in eq. (9b) may be identified with the fluorescence quantum yield for the \(^3\)P state. The integrated emission intensity for the \(^1\)P state is given by

\[
I_1 = \int_0^\infty n_1 \, dt, \quad (10a)
\]

which, with eq. (8), becomes

\[
I_1 = k_{13} n^{1/3} k_{35} k_5. \quad (10b)
\]

Thus, the ratio of these integrated emission intensities equals

\[
I_3/I_1 = \left( \frac{k_{35}}{k_3} \right) \left( \frac{k_{35}}{k_5} \right). \quad (11)
\]

The rightmost quantity in parentheses in eq. (11) is the \(^3\)P fluorescence quantum yield, while the ratio of \( k_{35}/k_3 \) represents the ratio of \(^3\)P→\(^1\)P energy transfer collisions to \(^1\)P radiative decay events.

3.3. Quenching rate constants

Quenching rate constants for the \(^3\)P state were determined from linear least-squares fits of the logarithm of the \(^1\)P→\(^3\)S emission as a function of time from fluorescence decay curves, similar to that presented in fig. 3a, at different quencher concentrations. A Stern–Volmer plot for \(O_2\) is presented in fig. 4a. In this figure, the abscissa is the \(O_2\) partial pressure including oxygen passing through the microwave discharge and added downstream. For measurement of both \(O_2\) and \(N_2\) quenching rate constants, helium and oxygen, at typical pressures of approximately 1.3 and 0.2 Torr, respectively, were passed through the discharge. Using the previously measured [6,7] quenching rate constant for helium, we calculate that collisional removal by this species is small under our conditions, approximately \(0.07 \times 10^7 \) s\(^{-1}\). In principle, the transient free radical species generated by the discharge could also contribute to collisional quenching. However, we found that the decay rate \(k_3\) was the same with low (20 W) or high (50 W) microwave power applied to the cavity.

Linear least-squares fits (the solid line in fig. 4a) of these data yields the following bimolecular rate constants.
constants listed in table 1 for the total collisional removal rate of the $^3P$ state. The intercept for the $O_2$ plot yields a decay rate of $(3.05 \pm 0.15) \times 10^7$ s$^{-1}$. Correcting for the expected contribution due to helium quenching (see above), we obtain the radiative decay rate for the $^3P$ state: $k_5 = (2.98 \pm 0.15) \times 10^7$ s$^{-1}$. This corresponds to an estimated $^3P$ radiative lifetime of $33.3 \pm 1.7$ ns. The quoted uncertainties for all rate constants represent three standard deviations.

The collisional and radiative decay rate for the $^1P$ state was obtained from analysis of $^3P$-$^1S$ decay curves such as that presented in fig. 3b. Because of the weakness of the $^3P$-$^1S$ emission signals, this analysis was carried out only for $O_2$ quencher. The total decay rate $k_s$ was determined by non-linear least-squares fits [19] using the expected functional form in eq. (8) for the time dependence of the $^3P$ population. In this fit, the decay rate $k_s$ for the $^3P$ state was fixed at the value calculated from the Stern-Volmer plot in fig. 4a for the $O_2$ partial pressure in the given scan. Parameters allowed to vary in this non-linear fit were the decay rate $k_s$, an overall normalization constant (proportional to $k_5$), and the channel for which $t=0$. The solid line in fig. 3b represents the fit to the experimental data given in that plot.

The derived decay rates $k_s$ from non-linear least-squares analysis of $^3P$-$^1S$ emission waveforms are presented in fig. 4b. It can be seen that the scatter of the calculated rate constants is large. This is due mainly to the smallness of these emission signals, which arise not directly from the initially populated state but rather by collisional transfer. A Stern-Volmer analysis of these rate constants was performed (solid line in fig. 4b) and yield the following estimates for the bimolecular quenching rate constant by $O_2$ and the radiative decay rate: $k_5^3(O_2) = (10.8 \pm 1.8) \times 10^{-10}$ molecule$^{-1}$ cm$^3$ s$^{-1}$ (included in table 1) and $k_5 = (2.01 \pm 0.35) \times 10^7$ s$^{-1}$. This corresponds to an estimated radiative lifetime of $50 \pm 9$ ns.

3.4. Energy transfer rate constants

Eq. (11) shows that measurement of the ratio of the integrated emission intensities for $^3P$-$^1S$ and $^3P$-$^1D$ fluorescence decay can yield the rate constant $k_{53}$ for collisional transfer from the $^3P$ to the $^1P$ state. Accordingly, a series of experiments were carried out to record these waveforms under identical pressure conditions. For a given partial pressure of added quench gas, the fluorescence waveform for one of these radiative decay paths was recorded; then the filter was switched and the other recorded immediately thereafter. The integrated signals were calculated and their ratios corrected for the relative detection sensitivity at 844.7 and 777.5 nm.

Fig. 5 displays the derived integrated $^3P$-$^1S$ to $^3P$-$^1D$ intensity ratios, corrected for the wavelength response of the photomultiplier, as a function of both added $O_2$ and added $N_2$ gas. The scatter in these data is again large, reflecting the large fluctuations in the fluorescence signal from laser shot to shot. Nevertheless, it can be seen that for both collision partners this ratio is always small and never increases beyond 5%.

In spite of the large experimental uncertainties in

* Estimated experimental uncertainty of a factor of 2.
The quantity $n_o$ can be calculated from the Stern-Volmer analysis (fig. 4b) for the $3P$ state and equals $1.9 \times 10^{16}$ molecules cm$^{-3}$ (or 0.58 Torr).

Thus, eq. (12) can be fit to the data in fig. 5a by a linear least-squares fit \cite{9} to determine the coefficient $A$ in eq. (12). Using our derived value for the $3P$ radiative decay rate $k'_3$, we find that the rate constant $k_{3S}(O_2)$ equals $6 \times 10^{-11}$ molecule$^{-1}$ cm$^3$ s$^{-1}$.

We estimate an uncertainty of approximately a factor of 2 in this value, due to the scatter in the determined intensity ratios given in fig. 5 and the uncertainty in the relative detection sensitivity. The contribution to the uncertainty in $k_{3S}(O_2)$ due to possible error in $k'_3$ is less than that from the scatter in the measured intensity ratios. The solid curve in fig. 5a represents the best fit to the integrated intensity ratio as a function of added $O_2$.

Because of the presence of a small amount of $O_2$ to generate oxygen atoms, the dependence of the integrated intensity ratio on added $N_2$ density $n(N_2)$ differs somewhat from eq. (12). In this case, we have

\begin{equation}
\frac{I_5}{I_3} = \frac{B + Dn(N_2)}{C + n(N_2)} \frac{1 + n(O_2)}{n_{o}},
\end{equation}

where

\begin{equation}
B = k_{3S}(O_2)/k'_3,
\end{equation}

\begin{equation}
C = 1 + n(O_2)/n_{o},
\end{equation}

\begin{equation}
D = k_{3S}(N_2)/k'_3,
\end{equation}

and

\begin{equation}
n_{o} = k'_3/k_{3S}(O_2).
\end{equation}

The parameters $R$ and $C$ are known from the analysis of the $O_2$ data. We have not studied the quenching of the $3P$ state by $N_2$. In view of the similarity of the $3P$ and $3S$ quenching rate constants by $O_2$, within the large experimental uncertainties particularly of the latter, we assume that $k_{3S}(O_2)$ in eq. (19) equals the corresponding rate constant for the $3P$ state. We thus calculate $n_{o}$ to equal $3.4 \times 10^{16}$ molecules cm$^{-3}$ (or 1.05 Torr).

The transfer rate constant $k_{3S}(N_2)$ may be calculated by a linear least-squares fit, similar to that used for the corresponding rate constant for $O_2$, to determine the parameter $D$ in eq. (15). We find that $k_{3S}(N_2)$ equals $2 \times 10^{-11}$ molecule$^{-1}$ cm$^3$ s$^{-1}$, with an estimated factor of 2 uncertainty. The solid curve in the integrated intensity ratio, we may still obtain estimates of the rate constants for $3P$ to $3$P collisional transfer. For the case of $O_2$, for which the data are displayed in fig. 5a, the integrated intensity ratio can be expressed as a function of the $O_2$ density $n(O_2)$ as

\begin{equation}
\frac{I_5}{I_3} = \frac{An(O_2)}{1 + n(O_2)/n_{o}},
\end{equation}

where

\begin{equation}
A = k_{3S}(O_2)/k'_3
\end{equation}

and

\begin{equation}
n_{o} = k'_3/k_{3S}(O_2).
\end{equation}
in fig. 5b represents the best fit to the integrated intensity ratio as a function of added N₂. This value for \( k_{11}(N₂) \) depends on assuming that the \(^3\)P and \(^3\)P quenching rate constants for N₂ are the same. If the \(^3\)P rate were only half as large, then the derived value for \( k_{11}(N₂) \) would be reduced by \( \approx 30\% \), which is within the estimated experimental uncertainties. To show that \(^3\)P \( \rightarrow \) \(^1\)P collisional transfer is significant with N₂ collision partner, we have also plotted with a dotted curve in fig. 5b the expected integrated intensity ratio if \( k_{11}(N₂) \) were equal to zero. The rate constants \( k_{11} \) for both O₂ and N₂ are also included in table 1.

4. Discussion

Table 1 compares our quoted \(^3\)P total quenching rate constants with those determined in previous studies. Our value for O₂ agrees well with that of Bamford et al. \[9\] and is somewhat higher than the most recent result \[7\] from Kohse-Höinghaus and co-workers. The present result for the corresponding rate constant for quenching by N₂ is also slightly higher than that of Kohse-Höinghaus and co-workers \[7\]. By contrast, the earliest measurement of the N₂ quenching rate constant by Bischel et al. \[1\] is considerably smaller than the present result and that of ref. \[7\]. We do not know the reason for this discrepancy.

The present result for the \(^3\)P radiative lifetime \((33.6 ± 1.7 \) ns\), derived from the intercept of the Stern-Volmer plot for \(^3\)P quenching by O₂ (fig. 4a), agrees reasonably well with previous determinations of this lifetime. By similar observation of time-resolved two-photon laser-induced fluorescence, Bamford et al. \[9\], Bittner et al. \[7\], and Kröll et al. \[20\] obtain values of \(34.7 ± 3.7\), \(36.2 ± 0.69\), and \(36 ± 4\) ns, respectively. The measurement of Bischel et al. \[1\], who also monitored the emission after two-photon laser excitation and report \( \tau(\(^3\)P) = 39.1 ± 1.4 \) ns, and that of Bromander et al. \[21\], who employed a high frequency electron beam deflection technique and find \( \tau(\(^3\)P) = 40 ± 3 \) ns, yield lifetimes somewhat longer than the more recent experimental results. There have been several earlier determinations, involving absolute emission intensity measurements, of the \(^3\)P \( \rightarrow \) \(^1\)S radiative decay rate, and hence \(^3\)P radiative lifetime, since the upper state has only one electric-dipole-allowed decay pathway. The compilation of Wiese et al. \[22\] gives a value of \( \tau(\(^3\)P) = 35.7 \) ns. The theoretical calculations of Pradhan and Saraph \[23\] yields a somewhat smaller result: \( \tau(\(^3\)P) = 30.3 \) ns. The former is in reasonable agreement with recent time-resolved experiments, while the latter appears to be slightly small.

Our experimental determination of the \(^3\)P radiative lifetime, \( \tau(\(^3\)P) = 50 ± 9 \) ns, appears to be somewhat longer than previous estimates of this quantity. The present measurement suffers from difficulties in extracting the \(^3\)P decay rate \( k₅ \) in a non-linear least-squares fit to \(^3\)P \( \rightarrow \) \(^1\)S emission waveforms with low signal to noise ratio such as that displayed in fig. 3b. There has been only one other time-resolved determination of the \(^3\)P radiative lifetime. Using the high-frequency electron beam deflection technique, Bromander et al. \[21\] report \( \tau(\(^3\)P) = 39 ± 2 \) ns. The compilation of Wiese et al. \[22\] yields a value of 29 ns, while a result of 28 ns is obtained from the calculations of Pradhan and Saraph \[23\]. The oscillator strengths computed by Pradhan and Saraph \[23\] have recently been shown by comparison with electron scattering results to be reliable to better than 20\%, at least for transitions out of the ground \(^2\)P \( ^1\)P state \[24\].

To our knowledge, there have been no previous experimental determinations of collisional properties of the \(^3\)P \( ^1\)P state. While the exact value for the \(^3\)P quenching rate constant by O₂ may be uncertain because of difficulties such as those discussed in the previous paragraph, the present experiment nevertheless indicates that this quenching is large and comparable to that for the neighboring \(^1\)P state. In attempting to understand the variation of the rate constants for quenching of the nitrogen atom \(^3\)P \( ^1\)D state by the inert gases, Copeland et al. \[8\] noted the importance of the availability of excited states in both the excited atom and the quencher to understand the mechanism of quenching. For the oxygen atom, it is interesting that the overall quenching rate for the \(^3\)P and \(^3\)P states by O₂ are both large, despite the fact that the former can be removed by excitation transfer to the \(^1\)P state, which lies only \( \approx 2000 \) cm\(^{-1}\) lower, while excitation transfer to lower O atom \(^3\)S states for the latter would require removal of \( \approx 12000 \)
We are indebted to Dr. Chen Hsu, of CRDEC at Edgewood, MD, for the loan of a frequency mixing crystal while our crystal was being repolished. BEF and AWM acknowledge partial support from the Air Force Office of Scientific Research, Directorate of Aerospace Sciences, contract number 88-0013. The work at Johns Hopkins University was supported in part by the National Science Foundation and the US Army Research Office.
