A very simple polynomial-time algorithm for linear programming

In this note we propose a polynomial-time algorithm for linear programming. This algorithm augments the objective by logarithmic penalty function and then solves a sequence of quadratic approximations of this program. This algorithm has a complexity of \( O(m^{1/2}L) \) iterations and \( O(m^{1/2}L) \) arithmetic operations, where \( m \) is a number of variables and \( L \) is the size of the problem encoding in binary. This algorithm does not require knowledge of the optimal value and generates a sequence of primal (dual) feasible solutions that converges to an optimal primal (dual) solution (the latter property provides a particularly simple stopping criterion). Moreover, this algorithm is simple and intuitive, both in the description and in the analysis - in contrast to existing polynomial-time algorithms. It works exclusively in the original space.
A Very Simple Polynomial-Time Algorithm for Linear Programming

by

Paul Tseng

Abstract

In this note we propose a polynomial-time algorithm for linear programming. This algorithm augments the objective by a logarithmic penalty function and then solves a sequence of quadratic approximations of this program. This algorithm has a complexity of $O(m^{1/2-L})$ iterations and $O(m^{3.5-L})$ arithmetic operations, where $m$ is the number of variables and $L$ is the size of the problem encoding in binary. This algorithm does not require knowledge of the optimal value and generates a sequence of primal (dual) feasible solutions that converges to an optimal primal (dual) solution (the latter property provides a particularly simple stopping criterion). Moreover, this algorithm is simple and intuitive, both in the description and in the analysis – in contrast to existing polynomial-time algorithms. It works exclusively in the original space.

KEY WORDS: linear program, Karmarkar method, quadratic approximation, logarithmic penalty functions

1. Introduction

Consider linear programming problems of the form

\[
\begin{align*}
\text{Minimize} & \quad \langle c, x \rangle \\
\text{subject to} & \quad Ax = b, \ x \geq 0,
\end{align*}
\]

where \( c \) is an \( m \)-vector, \( A \) is an \( n \times m \) matrix, \( b \) is an \( n \)-vector, and \( \langle \cdot, \cdot \rangle \) denotes the usual Euclidean inner product. In our notation, all vectors are column vectors and superscript \( T \) denotes the transpose. We will denote by \( \mathbb{R}^m (\mathbb{R}^n) \) the \( m \)-dimensional (\( n \)-dimensional) Euclidean space.

For any vector \( x \) in \( \mathbb{R}^m \), we will denote by \( x_j \) the \( j \)th component of \( x \). For any positive vector \( x \) in \( \mathbb{R}^m \), we will denote by \( D_x \) the \( m \times m \) positive diagonal matrix whose \( j \)th diagonal entry is the \( j \)th component of \( x \). Let \( X \) denote the relative interior of the feasible set for (P), i.e.

\[
X = \{ x \in \mathbb{R}^m \mid Ax = b, \ x > 0 \}.
\]

We will also denote by \( e \) the vector in \( \mathbb{R}^m \) all of whose components are 1's. "Log" will denote the natural log and \( \| \cdot \|_1, \| \cdot \|_2 \) will denote, respectively the \( L_1 \)-norm and the \( L_2 \)-norm. We make the following standing assumption about (P):

**Assumption A:**

(a) Both \( X \) and \( \{ u \in \mathbb{R}^n \mid A^Tu < c \} \) are nonempty.

(b) \( A \) has full row rank.

Assumption A (b) is made only to simplify the analysis and can be removed without affecting either the algorithm or the convergence results. Note that Assumption A (a) implies (cf. [3], Corollary 29.1.5) that the set of optimal solutions for (P) is nonempty and bounded. For any \( \varepsilon > 0 \), consider the following approximation of (P):

\[
\begin{align*}
\text{Minimize} & \quad f_\varepsilon(x) \\
\text{subject to} & \quad Ax = b,
\end{align*}
\]

(P_\varepsilon)
where we define \( f_\varepsilon : (0, \infty)^m \rightarrow \mathbb{R} \) to be the penalized function:

\[
    f_\varepsilon(x) = \langle c, x \rangle - \varepsilon \sum_j \log(x_j).
\]

(1.1)

Note that

\[
    \nabla f_\varepsilon(x) = c - \varepsilon \left( \begin{array}{c} 1/x_1 \\ : \\ 1/x_m \end{array} \right),
\]

\[
    \nabla^2 f_\varepsilon(x) = \varepsilon \left( \begin{array}{cc} 1/(x_1)^2 & \ldots & 0 \\ \vdots & \ddots & \vdots \\ 0 & \ldots & 1/(x_m)^2 \end{array} \right).
\]

(1.2)

The literature on Karmarkar's algorithm [1] is too vast to survey and we will not do so here. Our approach to solving (P), which is similar to that taken in [5]-[6], [11], is to solve, approximately, a sequence of problems \( \{P_{\varepsilon^r}\} \), where \( \{\varepsilon^r\} \) is a sequence of geometrically decreasing scalars. The approximate solution of \( P_{\varepsilon^r} \), denoted by \( x^r \), is obtained by solving the quadratic approximation of \( P_{\varepsilon^r} \) around \( x^{r-1} \). The novel feature of our algorithm is its simplicity, both in the description and in the analysis. And yet it has an excellent complexity. Also, our algorithm is unusual in that it is a primal affine-scaling algorithm that generates feasible primal and dual solutions.

This note proceeds as follows: in §2 we show that, given an approximately-optimal primal dual pair of \( P_{\varepsilon^r} \), an approximately-optimal primal dual pair of \( P_{\alpha \varepsilon^r} \), for some \( \alpha \in (0,1) \), can be obtained by solving a quadratic approximation of \( P_{\varepsilon^r} \). In §3 and §4 we present our algorithm and analyze its convergence. In §5 we discuss the initialization of our algorithm. Finally, in §6 we give our conclusion and discuss extensions.
and let \( \bar{x} \) be any element of \( X \) and let \( \bar{u} \) be any element of \( \mathbb{R}^n \). We replace the objective function by its quadratic approximation around \( x = \bar{x} \). This gives (cf. (1.2))

\[
\begin{align*}
\text{Minimize} & \quad \langle c - \varepsilon(\bar{b})^{-1}e, z \rangle + \varepsilon(z, (\bar{b})^{-2}z)/2 \\
\text{subject to} & \quad Az = 0,
\end{align*}
\]

where we denote \( \bar{b} = D\bar{x} \). The Karush-Kuhn-Tucker point for this problem, say \((z, u)\), satisfies

\[
\begin{align*}
c - \varepsilon(\bar{b})^{-1}e + \varepsilon(\bar{b})^{-2}z - A^T u &= 0, \quad (2.1a) \\
Az &= 0. \quad (2.1b)
\end{align*}
\]

Let \( d = (\bar{b})^{-1}z \). Solving for \( d \) gives

\[
\begin{align*}
ed &= [(I - (A\bar{b})^T(A\bar{b}^2A^T)^{-1}A\bar{b})]r, \quad (2.2)
\end{align*}
\]

where we denote

\[
\bar{r} = -\bar{b}c + \varepsilon e + (A\bar{b})^T\bar{u}.
\]

Note that, since the orthogonal projection is a nonexpansive mapping (with respect to the \( L_2 \)-norm), we have from (2.2)

\[
\|d\|_2 \leq \|\bar{r}\|_2/\varepsilon. \quad (2.3)
\]

Let

\[
x = \bar{x} + z, \quad (2.4)
\]

\( D = D_x \), and \( \Delta = D_d \). Then \( D = \bar{b} + \Delta \bar{b} \) and hence

\[
-Dc + \varepsilon e + (AD)^T u = [-\bar{b}c + \varepsilon e + (A\bar{b})^T u] + \Delta[-\bar{b}c + (A\bar{b})^T u] = \varepsilon d + \Delta[-\bar{b}c + (A\bar{b})^T u] = \Delta[\varepsilon e - \bar{b}c + (A\bar{b})^T u]
\]
where the second and the fourth equality follow from (2.1a). This implies that (with $d_j$ denoting the $j$th component of $d$)

$$\|I-Dc + \epsilon e + (AD)Tu\|_2 = \epsilon \|\Delta d\|_2$$

$$\leq \epsilon \|\Delta d\|_1$$

$$= \epsilon \sum_j (d_j)^2$$

$$= \epsilon (\|d\|_2)^2$$

$$\leq (\|r\|_2)^2/\epsilon,$$

(2.5)

where the first inequality follows from properties of the $L_1$-norm and the $L_2$-norm and the second inequality follows from (2.3).

Consider any $\beta \in (0,1)$ and any scalar $\alpha$ satisfying

$$(\beta^2 + m^{1/2})/(\beta + m^{1/2}) \leq \alpha < 1. \quad (2.6)$$

Let $\epsilon' = \alpha \epsilon$ and $r' = -Dc + \epsilon' e + (AD)^Tu$. Then

$$\|r\|_2/\epsilon' = \|I-Dc + \epsilon e + (AD)Tu\|_2/(\alpha \epsilon)$$

$$\leq \|I-Dc + \epsilon e + (AD)Tu\|_2/(\alpha \epsilon) + (1-\alpha) \cdot m^{1/2}/\alpha$$

$$\leq (\|r\|_2/\epsilon)^2/\alpha + (1/\alpha - 1) \cdot m^{1/2},$$

where the first inequality follows from the triangle inequality and the second inequality follows from (2.5). Hence, by (2.6), if $\|r\|_2/\epsilon \leq \beta$, then $\|r\|_2/\epsilon' \leq \beta$. Furthermore, by (2.3), we have that $\|d\|_2 \leq \beta < 1$. Hence $e+d > 0$ and (cf. (2.4)) $x > 0$. Also, by (2.1b) and (2.4), $Ax = A(\bar{x} + z) = b$.

For any $\epsilon > 0$, let $\rho_\epsilon : (0,\infty)^m \times \mathbb{R}^n \to [0,\infty)$ denote the function
\[ \rho_{\varepsilon}(y,p) = \|D_y c + \varepsilon e + (AD_y)^T \|_2/\varepsilon. \] 

(2.7)

We have then just proved the following important lemma:

**Lemma 1** For any \( \varepsilon > 0 \), any \( \beta \in (0,1) \) and any \((\overline{x}, \overline{u}) \in X \times \mathbb{R}^n \) such that \( \rho_{\varepsilon}(\overline{x}, \overline{u}) \leq \beta \), we have

\[ (x,u) \in X \times \mathbb{R}^n, \quad \rho_{\alpha \varepsilon}(x,u) \leq \beta, \]

where \( \alpha = (\beta^2 + m^{1/2})/(\beta + m^{1/2}) \) and \((x,u)\) is defined as in (2.1a), (2.1b), (2.4).

3. The Homotopy Algorithm

Choose \( \alpha = (1/4 + m^{1/2})/(1/2 + m^{1/2}) \). Lemma 1 and (2.1a)-(2.1b), (2.4) motivate the following variant of Karmarkar's algorithm, parameterized by two positive scalars \( \gamma \leq \varepsilon \):

**Homotopy Algorithm**

**Step 0:** Choose any \((x^1,u^1) \in X \times \mathbb{R}^n\) such that \( \rho_{\varepsilon}(x^1,u^1) \leq 1/2 \). Let \( \varepsilon^1 = \varepsilon \).

**Step r:** Compute \((z^{r+1},u^{r+1})\) to be a solution of

\[
\begin{bmatrix}
\varepsilon f(D_{x^r})^2 - AT \\
A & 0
\end{bmatrix}
\begin{bmatrix}
z \\
u
\end{bmatrix}
= \begin{bmatrix}
\varepsilon f(D_{x^r})^{-1} e - c \\
0
\end{bmatrix}.
\]

Set \( x^{r+1} = x^r + z^{r+1}, \quad \varepsilon^{r+1} = \alpha \varepsilon^r \).

If \( \varepsilon^{r+1} \leq \gamma \), terminate.

[Note: For simplicity we have fixed \( \beta = 1/2 \).] We gave the above algorithm the name "homotopy" because it solves (approximately) a sequence of problems \{\( (P_{\varepsilon^r}) \)\} that approaches \( (P) \) (see [2]).
4. Convergence Analysis

By Lemma 1, the homotopy algorithm generates, in at most \((\log(\gamma) - \log(\varepsilon))/\log(\alpha)\) steps, an 
\((x,u) \in X \times \mathbb{R}^n\) satisfying

\[
\| - D_x c + \gamma e + (AD_x)^T u \|_2 \leq \gamma/2, \tag{4.1}
\]
\[Ax = b.\]

Since \(\gamma > 0\), (4.1) implies that

\[0 < D_x c - (AD_x)^T u \leq (3\gamma/2) \cdot e.\]

Since \(D_x\) is a positive diagonal matrix, multiplying both sides by \((D_x)^{-1}\) gives

\[0 < c - A^T u \leq (3\gamma/2) \cdot (D_x)^{-1} e.\]

This in turn implies that, for each \(j \in \{1, \ldots, m\},\)

\[0 < c_j - \langle A_j, u \rangle \leq 3\gamma^{1/2}/2 \quad \text{if } x_j \geq \gamma^{1/2},\]
\[0 < c_j - \langle A_j, u \rangle \quad \text{otherwise,}\]

where \(c_j\) denotes the \(j\)th component of \(c\) and \(A_j\) denotes the \(j\)th column of \(A\) (note that an analogous argument shows that \(u^r\) is dual feasible for all \(r\)). Also, since

\[
\log(1-\delta) = -\delta - \delta^2/2 - \delta^3/3 - \delta^4/4 - \ldots \\
\leq -\delta (1 + (\delta/2) + (\delta/2)^2 + (\delta/2)^3 + \ldots) \\
= -\delta/(1-\delta/2) = -1/(1/\delta-1/2),
\]

for any \(\delta \in (0, 1)\), we have that

\[\log(\alpha) = \log(1-(2+4m^{1/2})^{-1})\]
Hence we have just proved following:

**Lemma 2.** For any positive scalars $\gamma \leq \varepsilon$, the homotopy algorithm generates, in at most 

$$(3/2+4m^{1/2}-(\log(\varepsilon)-\log(\gamma)))$$

steps, a pair of optimal primal and dual solutions to a perturbed problem of (P), where the costs are perturbed by at most $3\gamma^{1/2}/2$ and the lower bounds are perturbed by at most $\gamma^{1/2}$.

Thus if we choose $\varepsilon = 2\Theta(L)$ and $\gamma = 2\cdot\Theta(L)$, where L denotes the size of the problem encoding in binary (defined as in [1]), the homotopy algorithm would terminate in $O(m^{1/2}L)$ steps with an optimal primal dual solution pair to a perturbed problem of (P) and the size of the perturbation is $2\cdot\Theta(L)$. An optimal primal dual solution pair to (P) can then be recovered by using, say, the techniques described in [7] (also see [1]). Since the amount of computation per step is at most $O(m^3)$ arithmetic operations (not counting Step 0), the homotopy algorithm has a complexity of $O(m^{3.5}L)$ arithmetic operations. [We assume for the moment that Step 0 can be done very "fast". See §5 for justification.] This complexity can be reduced to $O(m^{3.31}L)$ by using Strassen's (impractical) matrix inversion method [10]. It may be possible to reduce the complexity to $O(m^3L)$ by using the rank-one update technique described in [1], [11].

5. **Algorithm Initialization**

In this section we show that, for $\varepsilon$ sufficiently large, Step 0 of the homotopy algorithm (i.e. to generate a primal dual pair $\langle x,u \rangle \in X \times \mathbb{R}^n$ satisfying $\rho_\varepsilon(x,u) \leq 1/2$) can be done very "fast".

Suppose that (P) is in the canonical form considered by Karmarkar (see §5 of [1] for details on how to transform general linear programs into this canonical form). We claim that, for $\varepsilon = 2\|c\|_2$, a point $\langle x,u \rangle \in X \times \mathbb{R}^n$ satisfying $\rho_\varepsilon(x,u) \leq 1/2$ can be found immediately. To see this, note that in Karmarkar's canonical form, $A$ and $b$ have the form
where $A'$ is some $(n-1) \times m$ matrix, and the point $e$ is assumed to satisfy $Ae = b$. Let $x = e$ and $p = (0, ..., 0, -1)^T$. Then

$$e + (AD_x)^T p = e + A^T p = e - e = 0.$$ (5.1)

Hence, by (2.7), $x = e$, and the triangle inequality,

$$\rho_e(x, ep) = \|x - e\| + \|e + (AD_x)^T p\| \leq \|x - e\| + \|e\| + \|AD_x\|^T \|e\|_2 \leq 1/2.$$ 

Alternatively, we can solve the following problem

$$\text{Maximize } \sum_j \log(x_j)$$
subject to $Ax = b,$

whose Karush-Kuhn-Tucker point $(x, p)$ can be seen to satisfy (5.1) (such a point exists if the feasible set for $(P)$ is bounded). Then, for $\epsilon = 2\|D_x\|_2$, we also have $\rho_e(x, ep) \leq 1/2$. The (unique) primal solution of (5.2) is sometimes called the analytic center [8] of the convex polyhedron \{ $x$ | $Ax = b, x \geq 0$ \}. Polynomial-time algorithms for solving (5.2) are described in [8] and [9] (note that (5.2) does not have to be solved exactly).

6. Conclusion and Extensions

In this note we have proposed a very simple polynomial-time algorithm for linear programming. This algorithm solves a sequence of approximations to the original problem, each augmented by a
9

logarithmic penalty function, and, unlike many other Karmarkar-type algorithms, uses no space transformation of any kind. This algorithm uses a number of steps (namely $O(m^{1/2}L)$) that is the lowest amongst interior point methods for linear programming. Because the primal and dual solutions obtained at each step are respectively primal and dual feasible, determining termination is particularly simple: terminate if the difference in their costs is below a prespecified tolerance.

There are many directions in which our result can be extended. Can the complexity be decreased further? Can our algorithm extend to quadratic programming or to problems with upper bound on the variables? Does there exist a general class of convex functions $h_\varepsilon: \mathbb{X} \rightarrow \mathbb{X}$, where $\mathbb{X}$ is a convex set in $\mathbb{R}^m$, such that $h_\varepsilon(x) \rightarrow h_0(x)$ pointwise as $\varepsilon \downarrow 0$ and, given an approximate minimum of $h_\varepsilon$, an approximate minimum of $h_{\alpha\varepsilon}$ (\(\alpha\) is a sufficiently small scalar in $(0, 1)$) can be obtained very "quickly"?
