Anion photoelectron spectroscopy has been employed to obtain vibrationally resolved spectra of the carbon molecules C₂ through C₁₁. The spectra of C₂ through C₅ are dominated by linear anion to linear neutral photodetachment transitions. Linear to linear transitions contribute to the C₁₁ spectrum, as well. From these spectra, vibrational frequencies and electron affinities are determined for the linear isomers of C₂-C⁹ and C₁₁. Term values are also obtained for the first excited electronic states of linear C₄ and C₆. The spectra of C₁₀ and C₁₁ show evidence for transitions involving cyclic anions and/or neutrals. Similar types of transitions are identified in the spectra of other smaller molecules, specifically C₆, C₇, and to a lesser extent C₅.
Vibrationally Resolved Spectra of C$_2$-C$_{11}$ by Anion Photoelectron Spectroscopy

Abstract

Anion photoelectron spectroscopy has been employed to obtain vibrationally resolved spectra of the carbon molecules C₂ through C₁₁. The spectra of C₂⁻ through C₅⁻ are dominated by linear anion to linear neutral photodetachment transitions. Linear to linear transitions contribute to the C₁₁⁻ spectrum, as well. From these spectra, vibrational frequencies and electron affinities are determined for the linear isomers of C₂ - C₅ and C₁₁. Term values are also obtained for the first excited electronic states of linear C₄ and C₆. The spectra of C₁₀⁻ and C₁₁⁻ show evidence for transitions involving cyclic anions and/or neutrals. Similar types of transitions are identified in the spectra of other smaller molecules, specifically C₅⁻, C₆⁻, and to a lesser extent C₇⁻.

Introduction

For several decades researchers have studied pure carbon molecules, attempting to elucidate their physical properties and the processes governing their formation. Carbon molecules have been identified as intermediates in soot formation, they exist in the vapor above heated graphite, and they have been detected in interstellar space, being produced in giant carbon stars. Recently, the verification of the icosahedral structure of the C₆₀ molecule has launched a new investigation of the formation processes of such novel cage structures. An excellent review of the vast amount of research performed on carbonaceous species through April 1989 has been given by Weltner and van Zee. Given the abundance of research on these molecules, surprisingly little is definitely known about the physical properties of pure carbon molecules containing more than three atoms. Before a model for the formation of the large complexes such as the fullerenes and soot can be fully developed, fundamental information about the building block carbon molecules must be compiled. Determination of the molecular properties of the smaller carbon molecules and how these properties change with molecular size should provide a more complete understanding of these processes.

One of the more controversial issues encountered in carbon molecule research is the determination of the lowest energy molecular geometries. Until recently, this question was addressed mainly by ab initio calculations. Early molecular orbital (MO) calculations by Pitzer and Clementi and Hoffman predicted that the carbon molecules would have cumulenic linear structures until reaching the size of C₁₀, at which time the energy stabilization gained by the formation of an additional bond would be larger than the destabilization created by ring strain...
and it would form a monocyclic ring. Recent experiments by Saykally, Bernath, Amano, and their co-workers\textsuperscript{3,9,10,11} as well as higher levels of theory\textsuperscript{12,13} have confirmed this hypothesis for the odd-numbered carbon molecules (up to C\textsubscript{9}), finding linear D\textsubscript{∞h} geometries for the 1\Sigma\textsuperscript{+} ground state of each of these species.\textsuperscript{13,14} However, calculations predict that planar monocyclic 1\Lambda\textsubscript{g} isomers exist for even-numbered carbon molecules as small as C\textsubscript{4}, with energies near those of the linear 3\Sigma\textsubscript{g}\textsuperscript{−} species. The relative energies of the two forms vary depending upon the level of the calculation, and the energy separations are often less than the error limits of the calculations. Even very high levels of \textit{ab initio} theory predict that the cyclic forms of these molecules may be energetically more stable than their linear counterparts.\textsuperscript{15} However, calculations considering entropic effects have shown that the high temperatures of natural formation conditions thermodynamically favor linear carbon molecules over their non-linear counterparts.\textsuperscript{16}

Most quantitative experimental information about carbon molecules containing more than three atoms has been obtained during the last five years. Researchers have employed ESR techniques to detect the linear forms of several even-numbered species in low-temperature matrices.\textsuperscript{17} Yang \textit{et al.}\textsuperscript{18,19} used anion photoelectron spectroscopy to obtain electron affinities and electronic structure for carbon molecules with up to 84 carbon atoms. They deduced that they were observing the linear forms of C\textsubscript{n} (n=2-9) and monocyclic ring forms of C\textsubscript{n} (n=10-29). Absorption experiments have been performed, both in matrices and in the gas phase. However, conclusive assignment of spectral peaks is often difficult due to the presence of multiple species with varying numbers of carbon atoms. As a result, several bands originally assigned in matrix isolation spectroscopy\textsuperscript{20} have necessarily been reassigned by techniques which are more
molecule-specific. Isotope studies in matrices have clearly assigned one vibrational frequency each for the linear forms of C₄,²¹ C₅,²² and C₆.²³ High resolution gas-phase spectra have been obtained for linear forms of C₄,²⁴ C₅,¹⁰ C₆,¹¹ and C₇,¹⁴ yielding rotational constants and at least one vibrational frequency for each.²⁵ While most experimentalists studying carbon molecules with less than ten atoms have detected only the linear forms of the molecules, evidence for non-linear isomers has been obtained by researchers using the Coulomb Explosion Imaging (CEI) technique, who reported the photodetachment of cyclic forms of C₇, C₅, and C₆.²⁶

Using an anion photoelectron spectroscopy technique similar to that of Yang et al.,¹⁸ but at considerably higher resolution, we have obtained vibrationally resolved photoelectron spectra of the anions C₇ through C₁₁. The use of an anion precursor allows study of the single mass-selected neutral molecule of interest, circumventing chromophore uncertainties encountered in absorption experiments. The photoelectron experiment also complements infrared absorption experiments by providing vibrational frequencies which are infrared inactive. In addition, since anion photodetachment is a vertical process, the length of the observed vibrational progression provides information about the difference in geometry between the anion and the neutral. The spectra presented here, with the exception of C₇, show evidence for transitions between linear carbon anions and linear carbon neutrals. Electron affinities (EA's) are measured for all the linear carbon molecules. Vibrational frequencies are determined for many of the linear neutral carbon species and excited electronic states are assigned for C₄ and C₆. In addition, the photoelectron spectra of C₁₀ and C₁₁, and to a lesser extent those of C₅, C₆, and C₇, show contributions from what are believed to be non-linear isomers of the carbon anions. The structures of the non-linear anions cannot be determined from these spectra, but it is apparent that
photodetachment of these anions results in a significant geometrical reorganization of the neutral.

Experimental

The apparatus used in these experiments is a modified version of our previously described anion time-of-flight photoelectron spectrometer.\textsuperscript{27} Carbon anions are generated in a Smalley-type laser vaporization/pulsed molecular beam source.\textsuperscript{28} A XeCl excimer laser is focused onto a rotating and translating graphite rod (0.25" diameter). The resulting plasma is swept through a 1 cm long, 0.25 cm diameter channel by helium carrier gas pulsed from a molecular beam valve (General Valve Series 9), operated at a backing pressure of about 5 atmospheres. The gas mixture expands, allowing relaxation of molecular vibrations and rotations by collisions with the carrier gas atoms. The anions generated in the plasma are injected into a Wiley-McLaren-type time-of-flight mass spectrometer\textsuperscript{29} with a pulsed electric field. After acceleration to an energy of 1 keV, the ions separate out by mass and are detected by a microchannel plate detector. The mass resolution of the instrument, $M/\Delta M$, is approximately 150. The ion of interest is selectively detached by a properly timed pulse of light from a pulsed Nd:YAG photodetachment laser. After photodetachment, a dual microchannel plate detector at the end of a one meter field-free flight tube detects a small fraction ($\approx 0.01\%$) of the detached electrons. Time-of-flight analysis yields electron kinetic energies (eKE); the instrumental resolution is 8 meV at 0.65 eV and degrades as $(\text{eKE})^{3/2}$ at higher electron kinetic energies.

The experiments described below were performed with the third and fourth harmonic frequencies (355 nm, 3.49 eV and 266 nm, 4.66 eV, respectively) of a Nd:YAG laser. The plane-polarized laser beam can be rotated using a half-wave plate. In the spectra shown, unless otherwise specified, the laser beam is polarized at $\theta = 54.7^\circ$ (magic angle)\textsuperscript{30} with respect to the
direction of electron collection. The spectra presented here are averaged for 100,000 - 500,000 laser shots at 20 Hz repetition rate, and smoothed by convolution with a 5 meV FWHM Gaussian. In order to account for the small background electron signal which results from scattered light interacting with the photodetachment chamber surfaces in the 4.66 eV spectra, a background spectrum is collected, smoothed and subtracted from the data.

Results

The photoelectron spectra of the odd carbon anions, $C_{2n+1}^-$ ($n=1-4$), obtained using a photon energy of 4.66 eV, are presented in Figure 1. In these and all other photoelectron spectra, the electron kinetic energy (eKE) is related to the internal energy of the neutral molecule by the expression:

$$eKE = h\nu - EA - T_o + T_o^- - E_v^o + E_v^-.$$  \hspace{2cm} (1)

Here, $h\nu$ is the laser photon energy, $EA$ is the electron affinity of the neutral species, $T_o$ and $T_o^-$ are the term values of the specific neutral and anion electronic states, respectively. $E_v^o$ and $E_v^-$ are the vibrational energies (above the zero point energy) of the neutral and anion, respectively. Rotational contributions to molecular internal energy are neglected. As indicated by Equation (1), the peaks occurring at lowest eKE in the photoelectron spectrum correspond to the highest internal energy states of the neutral.

As $n$ increases for the $C_{2n+1}$ molecules, the spectral features shift to lower eKE, indicating an increase in electron affinity. In the $C_3^-$ spectrum, there are poorly resolved features at high eKE which correspond to the ground state of $C_3$. However, there is a single well-resolved peak
at low eKE which corresponds to an excited electronic state of C₇. In each of the spectra of C₇, C₇, and C₇, there is a short, congested progression extending to lower eKE.

Since our experimental resolution degrades at higher eKE, experiments using a lower photon energy (3.49 eV) yield better resolved spectra of the ground state progressions of C₃ and C₅. Figure 2 and Figure 3. The C₇⁻ spectrum contains two peaks which have multiple shoulders. The peaks and shoulders are indicated with letters and arrows, respectively. The higher resolution spectrum of C₇⁻ contains many small peaks in addition to the large peak A, indicating that vibrational excitation of C₃ occurs upon photodetachment of the C₇⁻ anion. Peak positions and assignments for the C₇⁻, C₇⁻ and C₇⁻ spectra, discussed in more detail below, are summarized in Table I.

The photoelectron spectra obtained at 4.66 eV for the even carbon anions, C₂n⁻ (n=1-4), are shown in Figure 4. As was the case for the C₂n⁺₁ spectra, the C₂n⁻ spectra strongly resemble each other, but the electron affinities of the even numbered species are higher than their neighboring C₂n⁺₁ counterparts. In the C₂⁻ and C₄⁻ spectra, there are several peaks extending over a larger energy range than the progressions of the C₂n⁺₁ spectra, with a somewhat irregular intensity pattern. Only limited portions of the C₆⁻ and C₈⁻ spectra are obtainable with the 4.66 eV photon energy due to the high EA’s of C₆ and C₈. The peak positions and assignments for the C₂⁻ spectrum are in Table II, and those for the C₄⁻ and C₆⁻ spectra are listed Table III.

Photoelectron spectra of C₁₀⁻ and C₁₁⁻, taken with a 4.66 eV photodetachment energy, are displayed in Figure 5. These two spectra have a significantly different appearance than the spectra of C₂ through C₇. The C₁₀⁻ spectrum, Figure 5, contains broad unresolved band structure possibly indicative of transitions involving multiple electronic states. However, in the C₁₁⁻
spectrum, there are resolved peaks superimposed on a broad spectrum which resembles the C\textsubscript{10} spectrum. A long low-intensity tail extends to the high eKE regions of both spectra. These long tails also appear in the C\textsubscript{8}\textsuperscript{−} and C\textsubscript{7}\textsuperscript{−} spectra and with significantly less intensity in the C\textsubscript{5}\textsuperscript{−} spectrum. This is discussed further in section 4 of the Analysis and Discussion.

Data collected for C\textsubscript{4}\textsuperscript{−} at two different laser polarizations are shown in Figure 6. The important difference between the two spectra is the variation of the relative intensities of peaks B and D as a function of laser polarization angle; these peaks are essentially absent in the \( \theta = 90^\circ \) spectrum. This behavior will be addressed in greater detail below.

**Analysis and Discussion**

In this section, the C\textsubscript{7}\textsuperscript{−} and C\textsubscript{8}\textsuperscript{−} photoelectron spectra are analyzed in considerable detail and used to lay the framework for the discussion of the larger carbon molecules. The spectroscopy of C\textsubscript{2}\textsuperscript{31,32} and C\textsubscript{3}\textsuperscript{9,33} has been studied intensely for several years using a variety of techniques, including anion photoelectron spectroscopy.\textsuperscript{18,34,35} Therefore, the discussion of these systems will be limited to the new information provided by the photoelectron spectra presented here. The spectra of the larger molecules are treated more qualitatively.

The analyses for all the spectra presented here are done within the Franck-Condon approximation. The transition intensity, \( I \), for the process,

\[
\text{C}_{n}^{-}(v'') \rightarrow \text{C}_{n}^{-}(v') + e^{-} \quad (2)
\]

is governed by the expression,
Here \( \tau_e \) is the electronic transition dipole moment and the Franck-Condon factor, \( |\langle \Psi'_\nu | \Psi_{\nu} \rangle|^2 \), depends upon the spatial overlap of the vibrational wavefunctions of the anion and the neutral.\(^{36}\) In this approximation, it is assumed that \( \tau_e \) does not change significantly over the spatial range covered by the nuclear wavefunction and is treated as a constant in the spectral simulations.

1) \( \text{C}_2 \)

Diatomic carbon, \( \text{C}_2 \), has been thoroughly investigated using both absorption and emission spectroscopy.\(^{37}\) \( \text{C}_2^- \), one of the few anions known to possess bound excited electronic states,\(^{38}\) has also been well characterized.\(^{39}\) Recently, Ervin and Lineberger have obtained a vibrationally resolved photoelectron spectrum of the \( \text{C}_2^- \) anion.\(^{35}\) The use of a higher photodetachment energy (4.66 eV) in the experiments described here reveals transitions to excited vibrational levels and an excited electronic state of \( \text{C}_2 \) which could not be seen by Ervin and Lineberger.

Shown in Figure 7 is the \( \text{C}_2^- \) photoelectron spectrum obtained at 4.66 eV photodetachment energy. The spectrum has been simulated (Figure 7, bottom) using molecular constants obtained from high resolution data\(^32\) by varying the vibrational temperature, electron affinity and relative intensities of different electronic transitions. Both \( \text{C}_2 \) and \( \text{C}_2^- \) have low-lying excited electronic states. As a result, several photodetachment transitions are energetically accessible using the 4.66 eV detachment photon energy. Some peak assignments are indicated in Figure 7 and details are given in Table II. One-electron photodetachment of \( \text{C}_2^- \) \( X^2\Sigma_g^+ \) \( (\ldots 2\sigma_u^2 1\pi_u^2 3\sigma_g^1) \) can produce the \( \text{C}_2 \) \( X^1\Sigma_g^+ \) \( (\ldots 2\sigma_u^2 1\pi_u^2) \), \( \text{a}^3\Pi_u \) and \( \text{A}^1\Pi_u \) states \( (\ldots 2\sigma_u^2 1\pi_u^2 3\sigma_g^1) \) for the latter excited states, \( T_a = 0.089 \text{ eV} \) and 1.040 eV, respectively.\(^{32}\) Peaks A and B in Figure 7 are the origins of the \( \text{C}_2 \) \( X^1\Sigma_g^+ \leftarrow \text{C}_2^- \)
$X^2Σ^+_u$ and $C_2 a^3Π_u \leftarrow C^−_2 X^2Σ^+_g$ transitions, respectively. The $C_2 X^1Σ^+_u (v' = 1) \leftarrow C^−_2 X^2Σ^+_g (v'' = 0)$ and $C_2 a^3Π_u (v' = 1) \leftarrow C^−_2 X^2Σ^+_g (v'' = 0)$ transitions, which were near the cutoff region for the energy analyzer of the Lineberger experiment, are clearly defined in Figure 7 (peaks C and D, respectively). At even lower eKE, peak F represents the origin of the $C_2 A^1Π_u \leftarrow C^−_2 X^2Σ^+_g$ transition. From peak A, we obtain a value of $3.273 \pm 0.008$ eV for $C_2$. This agrees well with the value of $3.269 \pm 0.006$ eV recently measured by Ervin and Lineberger.

It is apparent in the $C^−_2$ spectrum that peaks corresponding to π-electron photodetachment from the $C^−_2 X^2Σ^+_g$ state (peaks B, D and F) are less intense than the those representing σ-electron photodetachment from the same electronic state of $C^−_2$ (peaks A and C). This pattern suggests that the photodetachment cross-section for removal of a 3σ electron from this state is higher than that for removal of a 1π electron from the $C^−_2 X^2Σ^+_g$ state.

As in Lineberger’s spectrum, the $C_2 X^1Σ^+_u (v' = 0) \leftarrow C^−_2 X^2Σ^+_g (v'' = 1)$ and $C_2 a^3Π_u (v' = 0) \leftarrow C^−_2 X^2Σ^+_g (v'' = 1)$ 'hot' band transitions occur (labelled as a and b, respectively). While the vibrational distribution of the ions produced in our laser vaporization source could be controlled to a considerable extent for the other carbon anions, $C^−_2$ could only be generated under conditions that produced anions with considerable vibrational excitation. The best fit to the spectrum was obtained assuming a vibrational temperature of 3000 K. In addition to the 'hot bands', the anion vibrational excitation gives rise to many sequence bands under the $v' = 0$ and $v' = 1$ peaks of the progressions in the $X^1Σ^+_u$ and the $a^3Π_u$ states of $C_2$.

The spectrum also shows photodetachment transitions from the low-lying $C^−_2 A^1Π_u$ first excited state. Signal resulting from the photodetachment of this anion state is observed because its lifetime ($τ_{rad} = 50$ μs$^4$ is comparable to the amount of time between anion formation and
photodetachment. One-electron transitions can occur from $\text{C}_2^- \ A^3\Pi_u \ (\ldots 2\sigma_u^2 1\pi_u^2 3\sigma_g^2, \ T_u = 0.494 \ eV)$ to $\text{C}_2$ in the $a^3\Pi_u, b^3\Sigma_g^- (\ldots 2\sigma_u^2 1\pi_u^2 3\sigma_g^2, \ T_g = 0.798 \ eV)$ and $A^1\Pi_u$ excited states. Peak c in the spectrum is assigned to the origin of the $\text{C}_2 \ a^3\Pi_u \leftarrow \text{C}_2^- \ A^3\Pi_u$ transition. Label E in the spectrum represents the energy at which signal is expected for the $\text{C}_2 \ A^1\Pi_u \leftarrow \text{C}_2^- \ A^3\Pi_u$ transition; a very small peak may be present there in the experimental spectrum. Electrons resulting from the $\text{C}_2 \ b^1\Sigma_g^- \leftarrow \text{C}_2^- \ A^3\Pi_u$ transition are expected to appear at $eKE = 1.1 \ eV$, close to peak D. However, there does not appear to be a significant contribution to the spectrum from this transition.

2) $\text{C}_3$

$\text{C}_3$ has been shown to be a linear but floppy molecule. The $\text{C}_3^-$ anion is predicted to be linear\(^{42}\) with a $^2\Pi_u (\ldots 4\sigma_u^2 3\pi_u^2 1\pi_u^4 1\pi_u^1)$ ground state which is considerably more rigid than $\text{C}_3$ due to the partly filled $\pi_u$ orbital. The 4.66 eV photoelectron spectrum of $\text{C}_3^-$, Figure 1, shows transitions to the two electronic states of $\text{C}_3$ which are energetically accessible via one-electron photodetachment of $\text{C}_3^-$. While photodetachment of the $1\pi_u$-electron leaves $\text{C}_3$ in its $\tilde{X}^1\Sigma_g^+$ ground state ($\ldots 4\sigma_u^2 3\pi_u^2 1\pi_u^4 1\pi_u^1$), removal of the $3\sigma_u$-electron produces the $\text{C}_3 \ a^3\Pi_u$ first excited state ($\ldots 4\sigma_u^2 3\pi_u^1 1\pi_u^4 1\pi_u^1$). The spectrum of $\text{C}_3^-$ obtained with a photodetachment energy of 3.49 eV (Figure 2) reveals vibrational details of the $\text{C}_3 \ \tilde{X}^1\Sigma_g^+$ ground state.

Understanding the features of this spectrum requires consideration of the Franck-Condon principle for molecules with more than one vibrational mode. For an anion and neutral belonging to the same symmetry point group, transitions can occur from the anion ground state to any quantum state of a totally symmetric vibrational mode. Excitation of these modes occurs primarily when there is a difference in bond lengths between the anion and neutral. Typically,
excitation occurs in those vibrational modes which most strongly resemble the change in geometry upon anion photodetachment. For non-totally asymmetric vibrational modes, symmetry forbids transitions from the anion ground state to odd quanta of excitation in the neutral. Only transitions to even quanta of these neutral vibrational modes will be observed, and transitions to states with \( v > 0 \) only occur when there is a large difference in vibrational frequency between the anion and the neutral. The \( \text{C}_1 \) symmetric stretch, \( v_1 \), is totally symmetric while the bend and the antisymmetric stretch (\( v_2 \) and \( v_3 \), respectively) are non-totally symmetric modes.

In the 3.49 eV photoelectron spectrum of \( \text{C}_3^- \) (Figure 2), peaks A and B are assigned to the 0-0 and the \( 1^0 \) members of the \( \text{C}_1 \bar{X}^1\Sigma^+_g \leftarrow \text{C}_3^\prime \bar{X}^2\Sigma^+_g \) transition, respectively. Our peak spacing of 1200 ± 100 cm\(^{-1}\) for the neutral symmetric stretch agrees well with the value of 1224 cm\(^{-1}\) from higher resolution studies.\(^{43,44}\) The dominance of peak A indicates a fairly small bond length difference between \( \text{C}_3^- \) and \( \text{C}_3 \), in agreement with the \textit{ab initio} results.\(^{42}\) Peak a is a hot band assigned to the \( 1^0 \) transition, providing a frequency for the \( \text{C}_3^- v_1 \) symmetric stretch of 1075 ± 100 cm\(^{-1}\), in good agreement with \textit{ab initio} results (1175 cm\(^{-1}\)).\(^{42}\) The intensity of peak a indicates that the anion vibrational temperature is less than 450 K.

Peaks A and B are considerably broader (≈ 0.15 eV) than the experimental resolution (≈ 0.025 eV). This breadth is due to underlying vibrational structure which appears as a series of poorly resolved shoulders (indicated by arrows). Lineberger and co-workers partially resolve these transitions in their higher resolution \( \text{C}_3^- \) photoelectron spectrum.\(^{45}\) These shoulders result from two types of transitions. The first type, which provides most of the intensity for the shoulders, is the \( 2^0 \) progression in the \( \text{C}_1 \) bend. The second type is the \( 1^0 \) sequence band progression resulting from the 149 cm\(^{-1}\) frequency difference for \( v_1 \) between \( \text{C}_3 \) and \( \text{C}_3^- \).
The C\textsubscript{3} bending mode has a fundamental frequency\textsuperscript{9,46} of 63 cm\textsuperscript{-1}, which is significantly different from the calculated anion bending frequency (v\textsubscript{2} = 300 cm\textsuperscript{-1})\textsuperscript{42}. In addition, the neutral bending mode is very anharmonic and couples to both of the other C\textsubscript{3} vibrational modes.\textsuperscript{44} All of these effects can produce excitation of the neutral upon anion photodetachment, and the latter two effects create a vibrational pattern for C\textsubscript{3} which is poorly described by a separable normal mode approximation.\textsuperscript{9,44,47}

The inadequacy of the normal mode approximation for describing the C\textsubscript{3} bend can been seen in Figure 2. This shows the results of a Franck-Condon calculation assuming separable harmonic oscillators for the v\textsubscript{1} symmetric stretch and the v\textsubscript{2} degenerate bend. The anion wavefunction is generated assuming an anion bending frequency of 300 cm\textsuperscript{-1} based upon ab initio predictions,\textsuperscript{42,48} and a symmetric stretch frequency of 1075 cm\textsuperscript{-1} (discussed below). The simulation shows some excitation of the neutral bend due to the large difference between the C\textsubscript{3} and C\textsubscript{3}\textsuperscript{-} bend frequencies. However, the frequency difference alone does yield sufficiently bend excitation in C\textsubscript{3}.

In order to account for this discrepancy, an exact quantum mechanical calculation\textsuperscript{49} of eigenvalues and Franck-Condon intensities, Figure 2, was performed on a two dimensional cross-section (v\textsubscript{2} x v\textsubscript{2}) of the semi-empirical MORBID\textsuperscript{50} potential energy surface.\textsuperscript{51} This potential energy surface, generated by fitting Rohlfing's laser induced fluorescence data,\textsuperscript{44} includes the anharmonicity and vibrational coupling present between all three vibrational modes. The anion wavefunction is the same as that used in the harmonic oscillator simulation. Since the calculation considers only the bend mode, the changes in the simulation from the harmonic oscillator results are due to anharmonicity along the C\textsubscript{3} v\textsubscript{2} coordinate. It is clear from this simulation that the
extreme anharmonicity of the bend mode drastically changes the intensities of the $2\text{v}_2^\text{a}$ transitions. Although the experimental spectra do not resolve all this structure, the simulations demonstrate qualitatively that the excitation of the bending mode is due to two effects: the change in frequency of the bending mode upon photodetachment and, more importantly, the floppiness, or anharmonicity, of the $C_3$ bend mode.

Removal of the $\sigma_a$-electron from the $C_7^-$ anion leaves the neutral with the $\ldots 4\sigma_e^2 3\sigma_1^a 1\pi_3^a 1\pi_4^a$ electronic configuration corresponding to either the $C_3 \bar{a}^3\Pi_u$ or $\bar{A}^1\Pi_u$ states. Peak B in the 4.66 eV photoelectron spectrum of $C_7^-$, Figure 1, is assigned to the 0-0 transition to the $\bar{a}^3\Pi_u$ first excited state placing it $2.118 \pm 0.026$ eV above the ground state. While the $\bar{a}^3\Pi_u$ state has been observed in matrix emission experiments due to an intersystem crossing from the $\bar{A}^1\Pi_u$ state, the term value for $C_3 \bar{a}^3\Pi_u$ had not previously been directly measured in the gas phase because the $\bar{a}^3\Pi_u \leftarrow \bar{X}^1\Sigma_u^+$ transition is optically spin-forbidden. Our $T_o$ for the $\bar{a}^3\Pi_u$ state agrees well with matrix values obtained by Weltner and McLeod\textsuperscript{43} (2.117 eV in Ne, 2.100 eV in Ar) and Bondybey and English\textsuperscript{42} (2.117 eV in Ne) and the calculations of Perić-Radić \textit{et al.} (2.04 eV).\textsuperscript{53}

The dominance of the 0-0 transition for the $\bar{a}^3\Pi_u$ state indicates a very small difference in geometry between $C_7^-$ and the first excited state of $C_3$. This agrees with geometry calculations for $C_3$ and $C_7^-$,\textsuperscript{42} as well as intuition, because the detached electron originates from the effectively non-bonding $C_7^- \sigma_a$-orbital.
3) $\text{C}_4$ through $\text{C}_9$

The photoelectron spectra of $\text{C}_4^-$ through $\text{C}_7^-$ show many similarities. Each is dominated by a sharp peak (labelled A in each spectrum) and contains several smaller peaks at lower eKE. Peak A is assigned to the $\text{C}_n^- (v' = 0) \leftarrow \text{C}_n^- (v'' = 0)$ transition in each spectrum. As in $\text{C}_3$, the dominance of this transition indicates only a small change in geometry upon photodetachment.

As discussed earlier, there is experimental and theoretical evidence for the existence of linear neutral carbon molecules with up to 9 atoms. In addition, *ab initio* calculations predict linear ground state structures for all $\text{C}_n^- (n \leq 6)$ anions. Based upon the appearance of our spectra and these other results, the peaks in the $\text{C}_4^-$ through $\text{C}_7^-$ spectra are assigned to transitions between the linear forms of the anion and the neutral. The electron affinities for the linear carbon molecules are then determined from the position of peak A in each spectrum. The observed EA's for linear $\text{C}_2^- - \text{C}_9$ (and $\text{C}_{11}$) are compiled in Table V. Contributions from sequence bands, uneven rotational contours, or spin-orbit splittings have not been assessed and so the EA may deviate slightly from the value presented. These effects are the basis for the error bars reported. The uncertainties vary as a function of the eKE at the origin of the spectrum. Also listed for comparison are the EA's obtained from other experiments and from *ab initio* calculations. The EA's of the even molecules are consistently higher than their neighboring odd-numbered counterparts. In general, the EA's agree with the values obtained by Yang *et al.* at significantly lower resolution and confirm the even-odd alternation of ground state symmetries for small carbon molecules. The EA's calculated by Adamowicz appear to be consistently low by $\approx 0.5$ eV for the $\text{C}_{2n}$ molecules and by $\approx 0.4$ eV for the $\text{C}_{2n+1}$ molecules.
Most of the smaller peaks in the spectra presented here can be assigned to either vibrational progressions of the neutral or 'hot bands'. As discussed above, in photoelectron spectroscopy, excitation is seen principally in totally symmetric vibrational modes upon photodetachment. The combination of this principle and \textit{ab initio} calculations of vibrational frequencies provides much of the basis for the assignments presented.

In addition to the vibrational progression assignments, some of the smaller peaks are assigned to excited electronic states of the linear neutral molecules (see discussion of C\textsubscript{4}, C\textsubscript{6}, and C\textsubscript{8}). In the spectra of C\textsubscript{5}\textsuperscript{−}, C\textsubscript{7}\textsuperscript{−} and C\textsubscript{9}\textsuperscript{−} (3.49 eV spectrum only)\textsuperscript{56} there are long tails extending to high eKE, which are assigned to transitions involving non-linear carbon neutrals and/or anions.

The analysis of the linear C\textsubscript{n}\textsuperscript{−} (n ≤ 9) is divided into two sections: one for molecules with an odd number of carbon atoms (C\textsubscript{2n+1}) and the other for those with an even number of carbon atoms (C\textsubscript{2n}). The linear C\textsubscript{2n+1} molecules are all closed-shell, \textsuperscript{1}Σ\textsuperscript{+} species while the linear C\textsubscript{2n} molecules all have open-shell \textsuperscript{3}Σ\textsuperscript{−} ground states.

a) C\textsubscript{5}, C\textsubscript{7} and C\textsubscript{9}

The photoelectron spectrum of C\textsubscript{5}\textsuperscript{−} recorded with a photon energy of 4.66 eV, Figure 1, shows a short vibrational progression of the neutral. At higher resolution (3.49 eV, Figure 3), it is evident that several modes, including symmetric stretch and non-totally symmetric bend modes, are excited upon photodetachment of the anion. The forms of these vibrational modes are shown in Figure 8b. The assignments of the peaks in the C\textsubscript{5} spectra (Table I) are based upon \textit{ab initio} results.\textsuperscript{13,57} Peaks B, C and F are assigned to the \textsuperscript{7}Σ\textsuperscript{0}, \textsuperscript{5}Σ\textsuperscript{0} and \textsuperscript{6}Σ\textsuperscript{0} transitions, respectively. The bend frequencies obtained from these assignments are \(2ν_5/2 = 222 \text{ cm}^{-1}\) and \(2ν_7/2 = 101\)
cm$^{-1}$, in agreement with the tentative assignments proposed by Moazzen-Ahmadi et al.,$^{10}$ and $2v_6$
$/2 = 512$ cm$^{-1}$. The uncertainty in these values is approximately 45 cm$^{-1}$. Peak D corresponds to
the $5_0^0/2$ combination band. Peak E is assigned to the $2_0^0$ transition providing a symmetric stretch
frequency of $v_2 = 798 \pm 45$ cm$^{-1}$. Vala et al.,$^{22}$ using force constants obtained from their $v_3$
measurement in the matrix environment, predict frequencies of 1904 cm$^{-1}$ and 785 cm$^{-1}$ for the
$v_1$ and $v_2$ symmetric stretch modes. Our value for $v_2$ agrees well with their prediction. The \textit{ab
initio} and experimental frequencies for $C_5$ are compiled in Table IV.

In addition to these assigned peaks, there are several other peaks to low eKE which do
not appear in the 4.66 eV spectrum due to the lower resolution there. Although some of these
peaks could potentially be assigned to $C_5$ vibrations based upon agreement with \textit{ab initio} results,
higher resolution (10 cm$^{-1}$) threshold photodetachment results obtained in this laboratory indicate
that these peaks may actually be due to transitions involving another electronic state of $C_5$.\textsuperscript{58}
This assignment is supported by a comparison of the two $C_5^-$ spectra presented here. The peaks
to low eKE are \textit{relatively} more intense in the 3.49 eV spectrum than in the 4.66 eV spectrum.
It is well-documented that the partial cross-sections for different photoionization transitions have
different energy dependences.\textsuperscript{39} It appears that the partial photodetachment cross-section for
the transition to the excited state of $C_5$ decreases relative to the $X'\Sigma_g^+ \leftarrow X^2\Sigma_g^+$ transition with
increasing photodetachment energy. In agreement with this observation, there was little or no
signal observed for this transition in the $C_5^-$ photoelectron spectrum obtained by Yang \textit{et al.}\textsuperscript{18}
using a photodetachment energy of 7.9 eV.

The photoelectron spectrum of $C_7^-$ obtained with a photon energy of 4.66 eV, Figure 1,
is similar to that of $C_5^-$. Resolution limitations at higher eKE combined with additional low
frequency bending vibrations of C\textsubscript{7} result in fewer fully resolved vibrational features, but some of the peaks can be assigned (Table I) using \textit{ab initio} results for the vibrational frequencies.\textsuperscript{57}

Peak B is assigned to the \(3\text{\textsubscript{b}}\) transition, providing a symmetric stretch vibrational frequency of \(v_3 = 548 \pm 90\) cm\(^{-1}\). As in C\textsubscript{7}, bending modes are excited upon photodetachment of C\textsubscript{7}. Peak C, tentatively assigned to the \(7\text{\textsubscript{g}}\) transition, gives the bend frequency of \(v_7 = 496 \pm 110\) cm\(^{-1}\). The spacing of peak D from the origin agrees well with the value obtained for the \(v_4\) antisymmetric stretch mode by Heath and Saykally.\textsuperscript{11} However, as in C\textsubscript{5}, peaks D and E (and structure to lower eKE) may result from transitions involving an excited electronic state of the neutral.

While the C\textsubscript{5}\textsuperscript{-} spectrum, Figure 1, resembles the spectra of C\textsubscript{7} and C\textsubscript{7}, it primarily shows two symmetric stretch vibrational progressions. Peaks B and C are assigned to the \(4\text{\textsubscript{g}}\) and \(3\text{\textsubscript{b}}\) transitions providing symmetric stretch frequencies of \(v_3 = 1258 \pm 50\) cm\(^{-1}\) and \(v_4 = 484 \pm 48\) cm\(^{-1}\).

All of the odd-numbered molecules discussed thus far show excitation in the breathing-type symmetric stretch (e.g. \(v_2\) for C\textsubscript{5}, Figure 8b), which is the lowest frequency symmetric stretch in all cases. This suggests that all the C-C bonds for these systems change in the same manner upon photodetachment, whether it be to lengthen or shorten. The \textit{ab initio} results for the C\textsubscript{2}/C\textsubscript{3} and C\textsubscript{2}/C\textsubscript{5} systems indicate that all the neutral bond lengths are shorter than those of the ions, in agreement with these results. In addition, as the chain grows in length, the frequency of this mode decreases: \(v_1(C_3) = 1200\) cm\(^{-1}\); \(v_2(C_5) = 798\) cm\(^{-1}\); \(v_3(C_7) = 548\) cm\(^{-1}\); and \(v_4(C_9) = 484\) cm\(^{-1}\). Since the electronic structure is expected to be very similar for these molecules, one might expect comparable force constants for similar types of vibrational modes.
As a result, the decrease in frequency as a function of chain length results mainly from the increase in reduced mass of the longer chains.

b) $C_4$, $C_5$, and $C_6$

The 4.66 eV photoelectron spectrum of $C_7^-$ shown in Figure 4 has four resolved peaks to the low eKE side of the origin. Theoretical calculations for $C_4$ predict two nearly isoenergetic isomers which have been considered for the ground state: a $^3\Sigma_g^-$ $D_{2h}$ linear structure and a $^1\Lambda_g$ $D_{2h}$ rhombic structure. At the highest levels of theory, the two are separated by as little as 1 kcal/mole.\textsuperscript{61,62} The electron affinity of $C_4$ determined from the $C_7^-$ spectra, $3.882 \pm 0.010$ eV, agrees reasonably well with Yang \textit{et al.}'s value of $3.7 \pm 0.1$ eV. From their CEI results, Algranati \textit{et al.}\textsuperscript{26} report an electron affinity of the rhombic isomer of $C_4$ as $2.1 \pm 0.1$ eV. Comparison with Watts \textit{et al.}'s calculated EA for $C_4$ of $3.39$ eV\textsuperscript{63} and Adamowicz's\textsuperscript{55} EA's for the linear and rhombic isomers of $C_4$ ($3.45$ eV and $2.03$ eV, respectively) further supports the assignment of the $C_7^-$ photoelectron spectral features to a linear anion $\rightarrow$ linear neutral photodetachment process.

Peak C is assigned to the $1_b$ transition, providing a symmetric stretch vibrational frequency of $\nu_1 = 2032 \pm 50$ cm$^{-1}$ ($\textit{ab initio}$ value\textsuperscript{57} for $\nu_1 = 2150$ cm$^{-1}$). According to recent geometry calculations for linear $C_4$ and $C_7^-$ at the SDQ-MBPT(4) level of theory,\textsuperscript{63} upon photodetachment of $C_7^-$ the outer bonds will shorten while the inner bond will stretch. The strong resemblance of this geometry change to the $\nu_1$ symmetric stretch normal coordinate, shown in Figure 8a, suggests that excitation of this mode will occur upon photodetachment, in agreement with the present results.
Peaks B and D in the $C_4^-$ spectrum, are located at 0.736 eV and 0.487 eV eKE, respectively. On the basis of *ab initio* frequency calculations alone, peak B could be assigned to either the $5^0_0$ or the $4^1_0$ transition. The latter transition is symmetry forbidden within the Franck-Condon approximation, but can occur in the presence of vibronic coupling to a nearby electronic state. While one might normally exclude this possibility, the strong polarization dependence of peak B and D relative to the other peaks suggests that vibronic coupling may indeed be occurring. The $4^1_0$ transition level can occur if the $v_4 = 1$ level is coupled to the $v_4 = 0$ or 2 levels of a nearby $\Pi$ electronic state. *Ab initio* calculations predict that a $C_4$ excited state of the appropriate symmetry ($^3\Pi_g$) lies just 1.00 eV above the $^3\Sigma_g^-$ ground state. While the assignment of peak B to the $5^0_0$ transition is certainly possible, the polarization dependence of its intensity is difficult to explain. The assignment of peak B to the $4^1_0$ transition provides a bending vibrational frequency of $v_4 = 339 \pm 55$ cm$^{-1}$. Due to its similar polarization dependence and appropriate spacing, peak D is assigned as the $1^0_4 4^1_0$ combination band.

Although the relative intensity of peak E does not vary significantly as a function of laser polarization, it is assigned as a transition to an excited state of linear $C_4$ ($T_0 = 0.327 \pm 0.006$ eV). This assignment is based upon two major factors: 1) no reasonable vibrational state assignment can be made which agrees the frequencies available from theoretical and experimental results and 2) two excited electronic states are predicted to lie in the vicinity of peak E. From the electronic configuration of linear $C_4$, $\ldots 1\pi^4 4\sigma^5 5\sigma_1^2 1\pi_2^2$, three electronic states can be formed: $^3\Sigma_g^-$, $^1\Sigma_g^+$ and $^1\Delta_g$. *Ab initio* calculations and high resolution gas phase absorption experiments agree that the ground state of linear $C_4$ is $^3\Sigma_g^-$ [24,61]. Therefore, peak E can be assigned to either the $^1\Delta_g$ or the $^1\Sigma_g^+$ electronic states which have been calculated as nearly isoenergetic states lying between 0.25 eV
and 0.75 eV.\textsuperscript{64,65} Based upon Hund's rules and Liang \textit{et al.}'s \textit{ab initio} results,\textsuperscript{66} discussed below, peak E is assigned to the \(^1\Delta_g\) excited state.

The 4.66 eV C\(_6^-\) photoelectron spectrum, Figure 4, contains structure to the low eKE side of the origin, peak A, in the form of partially resolved peaks with shoulders. Peak B, located 194 \(\pm\) 35 cm\(^{-1}\) above the origin, is assigned to the \(9_0^2\) transition (a \(\pi_u\) bending mode) according to agreement with \textit{ab initio} values. Peak C, located \(\approx 850\) cm\(^{-1}\) from the origin can be tentatively assigned as the \(8_0^2\) (\(\pi_u\) bend) on the same grounds.\textsuperscript{57} Peak D, located at 0.312 eV, is 1315 cm\(^{-1}\) above the origin. This peak spacing does not agree with any of the calculated vibrational frequencies for linear C\(_6\). It is better assigned as the \(^1\Delta_g\) excited electronic state, predicted to lie about 1200 cm\(^{-1}\) above the ground state.\textsuperscript{66,67} Peak E, at 0.289 eV, is assigned either to a low frequency bending mode of the \(^1\Delta_g\) excited state (with a frequency of \(\approx 175\) cm\(^{-1}\)) or to the \(2_1^1\) transition to the ground state of linear C\(_6\) (providing a symmetric stretch frequency of 1661 cm\(^{-1}\)).

Due to the high electron affinity of C\(_6^-\) relative to C\(_4^-\) and C\(_6\), the amount of information obtained from the C\(_6^-\) spectrum is not as abundant. The spectrum, Figure 4, contains two peaks (A and B) at very low eKE separated by \(\approx 565\) cm\(^{-1}\). This lies close to the predicted value of the \(v_4\) symmetric stretch vibration in C\(_6\),\textsuperscript{57} so peak B is tentatively assigned to the \(4_0^1\) transition. It is also possible that peak B represents the low-lying \(^1\Delta_g\) excited electronic state of C\(_6\).\textsuperscript{66} Liang \textit{et al.}\textsuperscript{66} predict that the splitting between the \(3\Sigma_g^-\) and \(^1\Delta_g\) states of a linear even carbon cluster decreases with increasing chain length, a reasonable result because the larger MO's available for the two \(\pi\)-electrons allow them to avoid each other more efficiently. However, according to this calculation, the splitting is predicted\textsuperscript{66} to be 1130 cm\(^{-1}\), somewhat larger than the interval between peaks A and B. If this calculation were correct, the transition to the \(^1\Delta_g\) state would occur at an
electron kinetic energy of 0.14 eV in the 4.66 eV photoelectron spectrum, which lies below the transmission limit of our spectrometer. Thus, although we believe we have observed transitions to the first excited $^1\Delta_g$ state in the $C_4^-$ and $C_6^-$ spectra, a higher photodetachment energy may be necessary to observe this transition in the $C_8^-$ spectrum.

4) $C_{10}$, $C_{11}$ and Non-linear Anion Photodetachment

The photoelectron spectra of $C_{10}^-$ and $C_{11}^-$, Figure 5, have a different appearance than the other spectra presented. The $C_{10}^-$ spectrum consists of several broad unresolved features. The $C_{11}^-$ spectrum has similar broad features, but also exhibits three sharp peaks (labelled as A, B and C). These three peaks taken alone strongly resemble the linear anion $\rightarrow$ linear neutral transitions seen in the $C_{2n+1}^-$ spectra. We therefore assign peak A to the linear $\rightarrow$ linear origin and peaks B and C, spaced 440 cm$^{-1}$ and 830 cm$^{-1}$, respectively, from peak A to transitions to vibrationally excited levels of linear $C_{11}^-$. The approximately equal spacing of the three peaks suggests that they may belong to a single vibrational progression, most likely in the breathing mode analogous to the $v_4$ symmetric stretch in $C_9$. The electron affinity determined for the linear $C_{11}$ molecule, $3.913 \pm 0.010$ eV, compares well with Yang et al.’s$^{18}$ assignment of the linear $C_{11}$ electron affinity as $4.00 \pm 0.1$ eV. The $C_{10}^-$ spectrum, in contrast, shows no evidence for linear $\rightarrow$ linear transitions.

We next consider the broad structure in the $C_{10}^-$ and $C_{11}^-$ spectra. Every ab initio calculation for $C_{10}$ has predicted a monocyclic ground state with the lowest linear isomer considerably higher in energy; Schaeffer predicts an energy difference of 2.9 eV, for example.$^{64}$ It is therefore reasonable to assign the $C_{10}^-$ spectrum to transitions to one or more electronic states of the cyclic $C_{10}$ isomer. Based upon its similarity to the $C_{10}^-$ spectrum, the broad structure
in the C\textsubscript{11} spectrum is also assigned to a transition to cyclic C\textsubscript{11}. Thus, the C\textsubscript{11} spectrum exhibits transitions to both the linear and cyclic forms of C\textsubscript{11}.

A more difficult question pertains to the structures of the C\textsubscript{10} and C\textsubscript{11} anions which yield the broad features in the two spectra. Specifically, are these features due to linear anion \rightarrow cyclic neutral transitions or cyclic anion \rightarrow cyclic neutral transitions? The C\textsubscript{11} spectrum suggests the latter to be the case. If only the linear C\textsubscript{11} anions were responsible, then it is difficult to understand why the integrated intensity of the three sharp peaks assigned to the linear \rightarrow linear transition is so much smaller than that of the broad features. A more reasonable explanation is that both the cyclic and linear isomers of C\textsubscript{11} are present in the ion beam, and that these are responsible for the broad features and the narrow peaks, respectively, in the spectrum. Yang \textit{et al.}\textsuperscript{18} used similar reasoning to explain how their C\textsubscript{11} photoelectron spectrum changed as a function of ion source conditions.

For C\textsubscript{10} and C\textsubscript{11}, the assignment of the long tails in the spectra to the cyclic anion \rightarrow cyclic neutral transitions allows us to estimate the electron affinities of the cyclic molecules. Based upon the eKE at which these long tails approach baseline, we can approximate the EA's of cyclic C\textsubscript{10} and C\textsubscript{11} to be 2.2 \pm 0.1 eV and 1.5 \pm 0.1 eV, respectively. These values are indicated by arrows in the C\textsubscript{10} and C\textsubscript{11} photoelectron spectra, Figure 5.

One problem with the assignment of the broad features to the cyclic \rightarrow cyclic transitions is that these features extend over at least 2 eV of electron kinetic energy, implying a substantial difference in geometry between the anion and the neutral and/or the presence of overlapping electronic transitions. Both of these possibilities appear reasonable in light of the \textit{ab initio} study by Liang and Schaeffer,\textsuperscript{64} which predicts three close-lying cyclic isomers of C\textsubscript{10}: two cumulenic
forms (one with $D_{2h}$ symmetry and one with $D_{10h}$ symmetry) and one acetylenic form ($D_{2b}$). The bond lengths and angles are quite different among these three isomers. One can therefore envision transitions between cyclic forms of the anion and neutral involving a considerable change in geometry. Whether such a change is sufficient to explain the broad features in the $C_{10}^-$ and $C_{11}^-$ spectra will require calculations of the anion geometries and a multidimensional Franck-Condon simulation of the spectrum.

As noted previously, the $C_5^-$, $C_6^-$ and $C_7^-$ photoelectron spectra show low-intensity 'tails' on the high eKE side of the sharp structure of the spectra (for $C_7^-$, the tail is only visible in the 3.49 eV spectrum). These tails extend for nearly 1 eV, suggesting that they are not simply 'hot bands'. Based on our interpretation of the $C_{10}^-$ and $C_{11}^-$ spectra, we believe that the tails are due to transitions involving cyclic forms of the anion and/or neutral molecules. *Ab initio* calculations indicate that while the cyclic and linear forms of neutral $C_6$ are nearly degenerate, the cyclic form of the anion lies 1.4 eV above the linear ground state.\(^{34}\) This suggests that the tail in the $C_6^-$ spectrum results from the presence of cyclic $C_6^-$ in the ion beam, and that either cyclic $\rightarrow$ cyclic or cyclic $\rightarrow$ linear transitions are occurring. Similar explanations account for the tails in the $C_5^-$ and $C_6^-$ spectra.

Note that Feldman *et al.*\(^{26}\) claim to observe the cyclic forms of $C_5^-$ and $C_6^-$ with relatively low electron binding energies in their Coulomb Explosion Imaging experiments. Their Cs\(^+\) bombardment ion source lacked the cooling provided by a supersonic jet, so one might expect considerably higher percentage of vibrationally excited cyclic anions in their experiment as compared to ours. In any case, our explanation of the tails in our photoelectron spectra is consistent with their earlier work.
The most controversial 'cyclic vs. linear' debate concerns the structure of $C_4$, as evidenced by the number of recent theoretical results cited in the discussion of the $C_4^-$ photoelectron spectrum. As discussed above, the photoelectron spectral features correspond to the neutral which results from vertical detachment stable anions. Unlike the spectra of the other even-numbered carbon molecules, there is no evidence in the $C_4^-$ spectra that a detectable number of cyclic anions are photodetached in our experiment.

Conclusions

Vibrationally resolved spectra of the carbon molecules $C_2$ through $C_{11}$ have been obtained using anion photoelectron spectroscopy. The spectra of $C_2^-$ through $C_9^-$ are dominated by transitions between the linear forms of the anions and neutrals. Electron affinities are determined for the linear isomers of $C_2$ - $C_9$ and $C_{11}$ with a typical uncertainty of approximately 0.010 eV. The spectra confirm the even-odd alternation of electronic structure seen by Yang et al.\textsuperscript{18} In addition, several vibrational frequencies (including symmetric stretch, antisymmetric stretch and bending modes) are determined for these linear species. All the odd-numbered spectra show excitation of the breathing mode symmetric stretch upon photodetachment and there is a decrease in the frequency of this mode as the carbon chain length increases. In addition to vibrational frequencies, the even-numbered carbon chains show transitions to the low-lying excited states of these open-shell systems. Tentative assignments are made for the $^1\Delta_e$ excited state term values of linear $C_4$ and $C_6$.

Several of the spectra show evidence for photodetachment transitions involving non-linear isomers of the anion and/or neutral. The spectra of $C_{10}^-$ and $C_{11}^-$ appear to result from transitions
involving cyclic neutrals and most likely cyclic anions. For C_5^-, C_6^- and C_7^-, evidence indicates that cyclic anions are detached to form either cyclic or linear neutrals.

It is clear from these results that anion photoelectron spectroscopy can provide a wealth of information about these intriguing molecules. Higher resolution experiments employing both anion photoelectron spectroscopy and threshold photodetachment techniques\textsuperscript{69} are underway to expand our knowledge of the linear molecules observed. These results also show that this method may be used to observe non-linear or cyclic carbon molecules. Further new techniques will be employed to enhance production of the non-linear species so that they may be studied in greater detail. With the aid of high level \textit{ab initio} calculations, the structures of these species may be more easily understood.

a) The v_2 mode is a symmetric stretch and the v_5, v_6, and v_7 modes are bending modes, see Fig 8b.

| C_7 | A | 1.302 | 0 | Origin |
|     | B | 1.234 | 548 | 3_0 |
|     | C | 1.179 | 992 | 7_0 |
|     | D | 0.773 | 4267 | 4_0 |

b) The v_3 mode is a symmetric stretch, v_4 is an antisymmetric stretch and v_7 is a bending mode.

| C_9\textsuperscript{-} | A | 0.978 | 0 | Origin |
|                         | B | 0.918 | 484 | 4_0 |
|                         | C | 0.822 | 1258 | 3_0 |

c) The v_3 and v_4 modes are symmetric stretches.
### Table II: Peak positions and assignments for the $C_7^-$ photoelectron spectrum.
