Previous research

Our research in the past year focused on the design and development of Histogram-Based Morphological Edge Detector (HMED) to extract edges from the infrared images obtained from the Advanced Very High Resolution Radiometer (AVHRR).

The motivation of this research stems from our previous experiences with the edge detectors. For instance, the conventional edge detectors are very sensitive to edge fine structure which makes it difficult to distinguish the weak gradients that are useful in this application from noise.

Image analysis techniques use the histogram for operations such as thresholding and edge extraction in a local neighborhood in the image. The histogram is a popular tool used in image processing and image analysis. It is used for edge detection, thresholding, texture feature extraction and other related problems.

Mathematical morphology has been used in the past to develop efficient and statistically robust edge detectors. Morphological edge detectors are designed to work only in the image domain. Such designs ignore the vital information contained in the histogram of an (sub)image. As a consequence, various weak gradient values pertaining to important features are missed in oceanographic IR images.

This led us to design and develop a morphological edge detector that incorporates information from the image histogram to improve the performance while being conceptually simple and computationally efficient. In doing so, new morphological operations are defined in the domain of the histogram of an image.

We compared our HMED with two other morphological edge detectors, namely Blur-minimization Edge Detector (BMM) and Alph-trimmed Edge Detector (ATM). In the comparison, we concluded that HMED performed better than BMM and ATM.

Current Research

Registration of Synthetic Aperture Radar (SAR) images is performed using the statistical correlation between the two images or minimizing the average fluctuation of the phase difference images.
Images from two satellite passes is registered by computing statistical correlation function between the two images over discrete pixel offsets, then interpolating the correlation function to find its minimum position.

Hybrid Approach: The average fluctuation function is evaluated using values of all pixels at every range and azimuth offsets. We believe that such intensive evaluation is not required.

We are currently investigating an alternative procedure that would select sub-images within the SAR images. The phase difference between the two sub-images is evaluated for each offset. For each sub-image the offsets pertaining to the minimum average fluctuation are selected. The sub-images are in fact marked as control points for registration. For each offsets, the global average fluctuation is computed. The final range and azimuth offsets pertaining to the minimum global average fluctuation is computed.

Abstract—We present a new edge detector for automatic extraction of oceanographic (mesoscale) features present in infrared (IR) images obtained from the Advanced Very High Resolution Radiometer (AVHRR). Conventional edge detectors are very sensitive to edge fine structure, which makes it difficult to distinguish the weak gradients that are useful in this application from noise. Mathematical morphology has been used in the past to develop efficient and statistically robust edge detectors. Image analysis techniques use the histogram for operations such as thresholding and edge extraction in a local neighborhood in the image. An efficient computational framework is discussed for extraction of mesoscale features present in IR images. The technique presented here, the Histogram-Based Morphological Edge detector (HMED), extracts all the weak gradients, yet retains the edges sharpness in the image. We also present new morphological operations defined in the domain of the histogram of an image. We provide interesting experimental results from applying the HMED technique to oceanographic data in which certain features are known to have edge gradients of varying strength.

I. INTRODUCTION

A near infrared (IR) image of the ocean obtained from the Advanced Very High Resolution Radiometer (AVHRR) aboard the NOAA-7 satellite is shown in Fig. 1. Such images are widely used for the study of ocean dynamics. In this image, bright areas represent warmer temperatures and light areas represent colder temperatures. The Gulf Stream, cold eddies, and warm eddies (the former are normally found south of the Gulf Stream and the latter north of the Gulf Stream) are examples of “mesoscale” ocean features with dimensions on the order of 50–300 km.

The Gulf Stream is warmer than the Surgasso Sea to its south, and much warmer than the waters to its north. Thus, its northern boundaries are more easily detectable than its southern boundaries in satellite IR images. Sometimes, clouds obscure oceanographic features, making their detection difficult. The movement of these features compounds the problems associated with the detection. For instance, the Gulf Stream can meander 30 km in one day. Sometimes, these meanders lead to the “birth” of a Gulf Stream ring, which is a special type of eddy that forms from a cutoff Gulf Stream meander [1]–[3]. When the Gulf Stream closes on itself, surrounding a mass of cold water at its southern boundary, a counterclockwise-rotating cold ring forms. Similarly, when the Gulf Stream surrounds a mass of warm water at its northern boundary, a clockwise-rotating warm ring originates [4].

Since satellite IR images of the ocean often depict the mesoscale features clearly, AVHRR imagery is used extensively to study them. In Section II, we discuss some techniques developed for the detection of edges in oceanographic images. In Section III, we present recently developed morphological edge detectors, and explain some preliminary concepts of morphological operations. We are not aware of any other morphological edge detectors based on the histogram of an image in the field of image analysis and computer vision. The Histogram-Based Morphological Edge detector (HMED) with the new morphological operations is explained in Section IV. Our implementation’s results, when applied to oceanographic images, are given in Section V.

II. EDGE DETECTION IN OCEANOGRAPHIC IMAGES

The Naval Research Laboratory began development of the Semi-Automated Mesoscale Analysis System (SAMAS), a comprehensive set of algorithms that handles the entire automated analysis problem, from low-level segmentation through intermediate-level feature formation...
The current version of SAMAS groups various modules into these three categories. A cloud detection algorithm processes the thermal infrared image of the ocean to classify all pixels either as cloud pixels or noncloud pixels [6]. Considering only noncloud pixels, the system uses the cluster shade texture measure as the low-level operation, and detection of zero crossings in cluster shade as the medium-level operation, leading to a set of edge primitives [7]. SAMAS uses two-step nonlinear relaxation [8] to label edge primitives [9]. In the first relaxation labeling step, a priori probability values of the edge pixels are computed using a priori knowledge of the approximate sizes and positions of the features, based on a previous analysis (typically from one week earlier). In the second step, these probability values are updated using compatibility coefficients in an iterative fashion, until the values stabilize. The relaxation labeling technique reduces uncertainty in the assignment of labels to edge pixels [9].

We developed a topographic-based feature labeling module that uses the surface topology of a pixel and its neighborhood [10]. A rule-based expert system predicts the future position of the mesoscale features [5], [11]. We briefly discuss some edge detection algorithms specifically designed for oceanographic images.

SAMAS currently uses a cluster shade algorithm for the detection of edges [7], [12]. The algorithm works in three stages: 1) computation of cluster shade texture measure from the gray-level cooccurrence (GLC matrix), 2) computations of zero crossings in the cluster shade image to detect the edges, and 3) a cleaning/dilation/thinning step is applied to the edge image. The cluster shade edge detector is characterized by accurate edge localization while rejecting fine structure within the detected edges.

Cayula and Cornillon [13] have developed an edge-detection algorithm for oceanographic satellite images. Their algorithm operates at three levels: picture level, window level, and local/pixel level. At the picture level, most obvious clouds are identified and tagged so that they do not participate at the lower levels. The cloud-finding procedure is based on temperature and shape. At the window level, the temperature distribution in each window is analyzed to determine the statistical relevance of each possible front, using unsupervised learning techniques. Finally, local edge operators are used to complete the contours found by the region-based algorithm. Since the local operations are used along with the window-based algorithm, the qualities of scale invariance and adaptivity associated with the region-based approach are not lost.

Mathematical morphology based on geometric shapes is used in biomedical image processing, robot vision systems, and low-level vision problems for its conceptual simplicity. Many techniques in computer vision use mathematical morphology as a tool for the extraction of features and recognition of objects. Matheron [14] introduced the application of mathematical morphology for analyzing the geometric structure of metallic and geologic samples. Serra [15] applied mathematical morphology for image analysis. Haralick [16] presented a review of mathematical morphology applied to image analysis.

Peleg and Rosenfeld [17] use gray-scale morphology to generalize the medial axis transform to grayscale imaging. Pelag et al. [18] measure changes in texture properties as a function of resolution using gray-scale morphology. Werman and Pelag [19] use gray-scale morphology for texture feature extraction. We will study the use of gray-scale morphology and texture information for edge detection in oceanographic images.

Recently, mathematical morphology has been applied for the extraction of edges. Most of the template-based edge detectors are known to perform satisfactorily under high signal-to-noise ratio, but degrade significantly when noise is introduced into the system. Some of the template-based edge detectors are the Prewitt operators and the Kirsh operator. A number of edge detectors fit a polynomial function on the data. Then, the first and second directional derivatives are computed, from which the edges are extracted. Mathematical morphology-based edge detectors have been shown to outperform most spatial and differentiation-based edge detectors [20]. Morphological edge detectors are local neighborhood nonlinear operators. Appropriately used, morphological techniques tend to simplify image data while preserving the shape characteristics and eliminating irrelevancies. These algorithms often generate useful and surprising results. We briefly present preliminary concepts of mathematical morphology.

### A. Preliminary Concepts

An image "$f$" is a set of pixels in a rectangular array (mesh). $f(i, j)$ is a pixel at coordinate $(i, j)$ in the image $f$. A structuring element is analogous to the kernel/template of a convolution operation, and it is associated with a predesigned shape. A structuring element may have any shape. Morphologic operators can be visualized as working with two images, the original image and the structuring element. The structuring element is used as a tool to manipulate the image using various operations, namely, dilation, erosion, opening, and closing. The dilation of a binary image $f$ by a structuring element $S$ is defined as

$$f \circ S = \{a + b|a \in f \land b \in S\}.$$  

The erosion of a binary image $f$ by a structuring element $S$ is defined as

$$f \cap S = \{a - b|a \in f \land b \in S\}.$$  

The "dilation" $d$ of a grayscale image $f$ by a structuring element $S$ is defined as

$$d(i, j) = \max (f(i + x, j + y) \bullet S(x, y))$$

III. MORPHOLOGICAL EDGE DETECTORS

Mathematical morphology based on geometric shapes is used in biomedical image processing, robot vision systems, and low-level vision problems for its conceptual simplicity. Many techniques in computer vision use mathematical morphology as a tool for the extraction of features and recognition of objects. Matheron [14] introduced the application of mathematical morphology for analyzing the geometric structure of metallic and geologic samples. Serra [15] applied mathematical morphology for image analysis. Haralick [16] presented a review of mathematical morphology applied to image analysis.

Peleg and Rosenfeld [17] use gray-scale morphology to generalize the medial axis transform to grayscale imaging. Pelag et al. [18] measure changes in texture properties as a function of resolution using gray-scale morphology. Werman and Pelag [19] use gray-scale morphology for texture feature extraction. We will study the use of gray-scale morphology and texture information for edge detection in oceanographic images.

Recently, mathematical morphology has been applied for the extraction of edges. Recently, mathematical morphology has been applied for the extraction of edges. Most of the template-based edge detectors are known to perform satisfactorily under high signal-to-noise ratio, but degrade significantly when noise is introduced into the system. Some of the template-based edge detectors are the Prewitt operators and the Kirsh operator. A number of edge detectors fit a polynomial function on the data. Then, the first and second directional derivatives are computed, from which the edges are extracted. Mathematical morphology-based edge detectors have been shown to outperform most spatial and differentiation-based edge detectors [20]. Morphological edge detectors are local neighborhood nonlinear operators. Appropriately used, morphological techniques tend to simplify image data while preserving the shape characteristics and eliminating irrelevancies. These algorithms often generate useful and surprising results. We briefly present preliminary concepts of mathematical morphology.
Thus, closing is defined as

\[ e(i, j) = \min (f(i + x, j + y) \ominus S(x, y)) \]

The closing operation is a dilation followed by an erosion, and similarly opening is an erosion followed by a dilation. Thus, closing is defined as

\[ c(i, j) = \min (d(i + x, j + y) \ominus S(x, y)) \]

where \( d \) is the dilated image of original image \( f \). Opening is defined as

\[ o(i, j) = \max (e(i + x, j + y) \ominus S(x, y)) \]

where \( e \) is the eroded image of original image \( f \). A sequence of these gray-scale morphological operations on an image often produces useful results. For instance, a simple morphological edge detector is the dilation residual edge image, defined as

\[ DR(i, j) = d(i, j) - f(i, j) \]

Similarly, the erosion residual edge detector is given by

\[ ER(i, j) = f(i, j) - e(i, j) \]

Even though these edge detectors are simple and robust, they are not reliable for extremely noisy images, and introduce spurious edges.

Lee et al. [20] designed a Blur-Minimization Morphological (BMM) operator for edge detection. The BMM operator blurs the original image by averaging the pixel values spanned by the structuring element. Dilated and eroded images are generated from the blurred image. Dilated residual and eroded residual images are created using these images. The edge strength at coordinate \((i, j)\) is given by the minimum of the dilation residual and erosion residual. Symbolically, we write

\[ BMM(i, j) = \min (f_e(i, j) - e(i, j), d(i, j) - f_d(i, j)) \]

where \( f_e = \sum f(i + x, j + y)/N \) is the blurred image, \( N \) is the number of cells in the structuring element, and \((i + x, j + y)\) is defined in the domain of the image. In spite of being conceptually simple and computationally efficient, the BMM edge detector has been proven to perform better than the spatial- and differential-based edge detectors.

Feehs and Arce [21] showed the importance of blurring the original image for morphological edge detection. They introduced an Alpha-Trimmed Multidimensional Morphological (ATM) edge detector that incorporates the opening and closing operations. They also proved statistically that ATM performs better than BMM. Let us consider the ATM edge detector for two-dimensional images with a structuring element of size \( n \times n \). The original image is initially blurred by \( f_a = \sum f(i - a, j - a)f/k - 2\alpha \)

where \( k = n^2 \) is the number of pixels in the original image spanned by the structuring image, \( f_i \) is the \( i \)th smallest valued pixel in the sorted sequence of pixels in \( f \) spanned by the structuring element, and \( \alpha \) is the trimming factor. If \( \alpha = 0 \), we consider all pixels spanned by the structuring element for blurring. If \( \alpha = i \), we consider all sorted pixels greater than \( f_i \) and less than \( f_{i-1} \) spanned by the structuring element. The edge strength at \((i, j)\) computed by the ATM edge detector is

\[ ATM(i, j) = \min ((o(i, j) - e(i, j)), d(i, j) - c(i, j)) \]

in which the erosion and dilation operations are performed on the \( \alpha \) trimmed blurred image, and the opening and closing operations are performed on the eroded and dilated images of the \( \alpha \) trimmed blurred image.

The ATM edge detector, like the BMM edge detector, is unable to extract the weak gradients associated with certain mesoscale features [22]. This possibly could be because the definition of gray-scale dilation and erosion considers only the maximum and the minimum intensity pixels in a given neighborhood of a pixel. As a result, the dilation and erosion residual values are not sufficient for these edge detectors to pick up the weak gradients. For increased structuring element sizes, weak gradients are extracted, along with other spurious edge pixels which are difficult to isolate.

The cluster shade algorithm [7] presented earlier extracts most of the weak gradient valued pixels, along with the strong gradient valued pixels. This is due to the application of a texture-based algorithm in an application where multiple gradient values are vital for interpretation. The algorithm is very computation intensive [12].

We seek a low-level segmentation module that is simple in design and construction, despite making use of the texture information in the image. We anticipate that such a design would extract all the boundaries of the features irrespective of their gradient values. One of the possible methods of making use of texture information is to compute the first-order histogram in a neighborhood of a pixel.

B. Motivation and Scope

Previous morphological edge detectors are designed to work only in the image domain. Such designs ignore the vital information contained in the histogram of an (sub-) image. As a consequence, various weak gradient values pertaining to important features are missed in oceanographic IR images. We expect that a morphological edge detector that incorporates information from the histogram will provide improved performance while being conceptually simple and computationally efficient. In Section IV, we propose new morphological operations defined over the histogram of a neighborhood of a pixel. The new morphological operations are limited to erosion and dilation only, and the morphological basis of these new operations is explained in the context of oceanographic images only.
IV. HISTOGRAM-BASED MORPHOLOGICAL EDGE DETECTOR

The histogram is a popular tool used in image processing and analysis. It is used for edge detection, thresholding, feature extraction, and other related problems. Let \( H \) be the histogram of an image or sub-image, let \( g_0, g_1, \ldots, g_{l-1} \) be the gray levels for which the histogram is defined, and let \( h(g_0), h(g_1), \ldots, h(g_{l-1}) \) be the count values for those gray levels. Previously, researchers have designed image segmentation methods from the histogram using either global or local thresholding concepts. For instance, when a light object is present in dark background, the histogram may have twin peaks occurring at the intensities corresponding to the intensities of the object and background. A suitable threshold between the two peaks is selected to segment the object from the background [23]. When multiple objects are present in the background, a global histogram is of little use. However, a local histogram in the neighborhood of a pixel would exhibit twin peaks from which an object can be segmented from the background [24].

It is noted that the gray-scale dilation and erosion are the maximum and minimum of the image pixels spanned by the structuring element, respectively. The definitions of gray-scale morphology, in fact, make use of the histogram indirectly. This is explained using a structuring element \( S \) of height 0 in the following way: gray-scale dilation over the histogram is the maximum of \( g_0, g_1, g_2, \ldots, g_{l-1} \) for which \( h(g) \neq 0 \). Similarly, the gray-scale erosion is the minimum of \( g_0, g_1, g_2, \ldots, g_{l-1} \) for which \( h(g) \neq 0 \). The average of the image pixels is computed from the histogram. It is also noted that the BMM and ATM edge detectors extract edges using the gray-scale dilation and erosion operations. But these definitions consider only the maximum and minimum of the image pixel intensities in a given neighborhood. Thus, we infer that there is a clear distinction in theories between the histogram-based edge detectors and morphology-based edge detectors. The essential ideas in the former methods stem from the fact that the histogram taken near the boundaries exhibits twin peaks, while the latter methods mark a pixel as an edge pixel depending on the maximum and minimum intensity values of the pixels near the boundaries.

We anticipate that morphological edge detectors that use the histogram in an effective way would reduce the gap between these two edge detection theories. In doing so, we will develop extensions to the definitions of morphological operations in the domain of the histogram, but not in the domain of the image. We anticipate that such extensions provide us new directions in the notion of morphological methods (BMM and ATM) search for the extreme intensities that have nonzero histogram heights.

A careful examination of these definitions indicates a strong link between the histogram-based and morphology-based edge detectors. For instance, consider a histogram computed in a neighborhood of a pixel near the boundary having (twin) peaks with the average intensity falling between the peaks. The histogram-based methods search for the valleys and peaks in the histogram, whereas the morphological methods (BMM and ATM) search for the extreme intensities that have nonzero histogram heights.

Fig. 2 is the new edge detector that makes use of the histogrammic dilation and erosion. The edge strength in the edge image at \( (x, y) \) is given by

\[
HMED (x, y) = \min \left( f(x, y) - e_h(x, y), \right.
\]

\[
\cdot d_h(x, y) - f(x, y) \right)
\]

where \( f(x, y) \) is the average intensity \( g_i \) at coordinate \( (x, y) \).

Thus, the edge magnitude values in the output image are computed in a similar fashion to that of the BMM and
ATM edge detectors. Normally, an edge detector should generate edge pixels of width two in case of ideal step edges. However, this is not true for edge detectors that take input images which are blurred or smoothed versions of the original image. The HMED technique, when used with large structuring elements, produces significant non-zero edge strength of width more than one pixel. This is consistent with the fact that HMED blurs the original image. Usually, the true edge pixels get assigned higher edge strength than their neighbors. Normally, a suitable threshold is selected to extract the true edge pixels. However, HMED extracts the true edge pixels using a nonmaxima suppression technique.

Thus, we establish a computational framework that adapts the advantages of two edge detection theories. With such a computational framework, we show that HMED performs better than the BMM and ATM edge detectors.

A. Comments on HMED

The procedure HMED given in Fig. 2 takes a blurred image as input and produces an edge strength image in which nonmaxima suppression has to be performed.

It is noted that a new histogram is not computed from scratch at every pixel’s neighborhood. The histogram of the adjacent neighborhood \((x, y + 1)\) is computed by using the histogram computed at pixel \((x, y)\) as described in version 6 in [12].

The HMED algorithm presented here involves only parameters such as the size of the structuring element and nonmaxima suppression. No strict rules can be stated in this regard. For the images considered here, we present results that are produced with structuring element sizes 5 x 5, 7 x 7, 9 x 9, 11 x 11, and 13 x 13, while we used structuring element sizes of 13 x 13, 15 x 15, 17 x 17, 19 x 19, and 21 x 21 with the HMED detector. The ATM edge detector’s \(\alpha\) parameter was 3 in all cases. We do not know of any strict rules to govern the choice of the structuring element’s size or the value of \(\alpha\).

Figs. 3 and 4 all show the results obtained with Fig. 1. Fig. 3 shows the results of applying the BMM edge detector with structuring elements of sizes 5 x 5, 7 x 7, 11 x 11, and 13 x 13. Increasing the structuring element’s size results in finding more edges. Fig. 4 shows the results of applying the ATM detector with structuring elements of sizes 5 x 5, 9 x 9, 11 x 11, and 13 x 13. The results are slightly different, but again increasing the structuring element’s size finds more edges. Figs. 5 and 6 are the \(h\)-dilated and \(h\)-eroded images of Fig. 1. Fig. 7 is the gradient image created by taking the minimum of the residuals. Fig. 8 shows the results of applying the HMED detector with window sizes 13 x 13, 15 x 15, 17 x 17, and 19 x 19. The HMED detector finds far fewer spurious edges, and increasing the window size seems to increase the continuity of the edges without finding many more.

Figs. 9 and 10 are also satellite images of the North Atlantic. Figs. 11, 12, and 13 show a comparative analysis of the three methods applied to the three images. In each case, the result with the structuring element judged to give the best performance is shown.

All three methods find the Gulf Stream’s North Wall and boundaries of warm eddies for all structuring elements. These edges have high gradient values, so detection is relatively easy. The South Wall and boundaries of
cold eddies are spatially distributed over 6-7 pixels with low gradient values. None of the detectors does as well in extracting these weak gradients as in finding the stronger ones when using small structuring elements. Increasing the size causes the BMM and ATM detectors to introduce many spurious edges. However, the HMED detector is able to extract these weak gradient values without introducing many spurious edge pixels.
Fig. 7. Gradient image using Figs. 5 and 6.

Fig. 8. Results of applying HMED with various structuring elements on Fig. 1. (a) 13 × 13 structuring element, (b) 15 × 15 structuring element, (c) 17 × 17 structuring element, (d) 19 × 19 structuring element.

Fig. 9. North Atlantic image obtained on April 10.

Fig. 10. North Atlantic image obtained on April 21.
Again, HMED is able to extract the boundaries of the mesoscale features without introducing spurious edge pixels. We conclude that the HMED’s better performance is due to the use of $h$ dilation and $h$ erosion.
