Accepted for publication in *Chemistry of Materials*

The efficient preparation of a new polymeric gallium imide, \( \{\text{Ga(NH}_3\text{)}_{3/2}\}_n \), from the reaction between \( \text{[Ga(NMe}_2\text{)}_3\text{]}_2 \) and \( \text{NH}_3 \) at ambient temperatures is described. The gallium imide precursor is shown by TEM and XRD studies to yield, upon pyrolysis, a rare cubic/hexagonal variety of gallium nitride, GaN. Some control over the average particle size of GaN in the nanosized region is achieved by application of various pyrolysis schemes.
GALLIUM IMIDE, \{\text{Ga(NH)}_{3/2}\}_n, 
A NEW POLYMERIC PRECURSOR FOR GALLIUM NITRIDE POWDERS

The Group 13 derivatives, \( \text{M(NH}_2\}_3 \), are advantageous precursors for conversion to Group 13 nitrides. They are likely to eliminate \( \text{NH}_3 \) at relatively low temperatures, possibly through a stepwise deamination shown in Equation 1, to afford solid state materials without major separation efforts. Since they do not contain organic groups they should, theoretically, yield pure nitride phases with minimum quantities of a residual hydrogen content, if any. In the relevant scientific literature, the \( \text{M(NH}_2\}_3 \) derivatives are customarily called amides, \( \text{M(NH}_2\)(NH) \) - amide imides, and \( \text{M(NH}_3/2 \) - imides.

\[
\begin{align*}
\text{M(NH}_2\}_3 & \xrightarrow{\Delta \text{-NH}_3} \text{M(NH}_2\)(NH) & \xrightarrow{\Delta \text{-1/2 NH}_3} \text{M(NH}_3/2 & \xrightarrow{\Delta \text{-1/2 NH}_3} \text{MN} \\
\end{align*}
\]

For \( \text{M = B}, \) the ammonolysis of \( \text{BX}_3 \ (X = \text{Cl, Br}) \) was reported to yield \( \text{B(NH}_2\}_3 \), and \( \text{NH}_4\text{Cl} \);\(^1\) however, a subsequent reinvestigation of this reaction both in the gas phase and in liquid \( \text{NH}_3 \) showed a polymeric solid with the approximate formula \( \text{B(NH}_3/2 \).\(^2\) Boron imide was also claimed in the ammonolysis of \( \text{Bi}_3 \).\(^3\) Also, the ammonolysis of the \( \text{B-X bonds on the borazine ring resulted in the (polyborazinylamine) polymer of the formulation identical to that of boron imide.}\(^2,4\) On the other hand, transamination of 2,4,6-tris-(dimethylamine)borazine with ammonia lead to the formation of the postulated dimeric \( \{(\text{NH}_2\text{B(NH}_3)\}_2 \).\(^5\) For \( \text{M = Al}, \) the attempted synthesis of \( \text{Al(NH}_2\}_3 \) through the metathetical reaction between \( \text{AlBr}_3 \) and \( \text{KNH}_2 \) or ammonolysis of \( \text{H}_3\text{Al-NMe}_3 \) resulted at room temperature, in both cases, in the polymeric \( \{\text{Al(NH}_2\)(NH)\}_n \).\(^6\) In the case of \( \text{M = In}, \) crystalline \( \text{In(NH}_3/2 \), obtained from the metathetical reaction between \( \text{InI}_3 \) and \( \text{KNH}_2 \) in liquid \( \text{NH}_3 \), was claimed to be stable at ambient.\(^7\) In the relevant case of \( \text{M = Ga}, \) it was stated that the reactions between \( \text{MGa(NH}_2\)_4 \) and \( \text{NH}_4\text{Cl} \ (\text{M = K, Na}) \) gave \( \text{Ga(NH}_3\}_3 \) as an amorphous product, which was thermally unstable with regard to \( \text{NH}_3 \) evolution.\(^8\) However, the preparations of \( \text{MGa(NH}_2\)_4 \) in liquid \( \text{NH}_3 \) required rather impractical reaction times.
One of the feasible routes to Group 13 amide imides and imides is transamination of the homoleptic compounds $[\text{M(NR}_2]_3n$ (n = 1, 2) with NH$_3$. In this regard, the volatile early transition metal and main group dialkylamide derivatives in combination with gaseous ammonia were demonstrated in vapor deposition techniques to yield nitride films.$^9$ Particularly, GaN and AlN were obtained from their dimethylamide derivatives via this route at 200-250 °C.$^{10}$ Based on both solution and gas phase studies, the presence of various amide and imide intermediate species was postulated in these reaction systems.$^{11}$ However, an ambient temperature stable form of an appropriate gallium derivative has not been reported to date. Described herein is a successful preparation of a new polymeric precursor with a formula corresponding to gallium imide, $\{\text{Ga(NH}_3/2\}_n$, which, upon pyrolysis, yields nanosized cubic/hexagonal GaN solids.

We first explored the GaBr$_3$/3LiNH$_2$ system which, upon LiBr formation and its convenient removal by ether washings, was hoped to afford gallium amide. However, the reactions between GaBr$_3$ and LiNH$_2$ in refluxing aromatic/diglyme solvents yielded solids containing unreacted LiNH$_2$. The pyrolysis of these solids at 450 °C under vacuum resulted in the formation of GaN, as evidenced by XRD and IR spectroscopies, but sublimable NH$_4$Br was also formed, and some lithium and bromine were retained in the final product mixture. Similar results were obtained from combinations of GaBr$_3$ and LiNH$_2$ in liquid NH$_3$ followed by pyrolysis at 450 °C; this path was complicated by sublimation of volatile Br$_3$Ga·nNH$_3$ from the hot zone of the heated set-up. We also used Br$_3$Ga·nNH$_3$, instead of GaBr$_3$, in refluxing solvent systems (as above) and still obtained products containing GaN but contaminated with non-removable lithium and bromine species. Unfortunately, this metathetical reaction system did not yield pure gallium amide or imide precursors and, consequently, pure GaN was not produced under the range of applied conditions.

A successful preparation of the precursor with the formula corresponding to gallium imide, $\{\text{Ga(NH}_3/2\}_n$ (1), was accomplished by reactions of $[\text{Ga(NMe}_2]_3]_2^{12}$ (2) with gaseous NH$_3^{13}$ or liquid NH$_3$. The estimated quantity of the evolved HNMe$_2$ indicated a very efficient transamination of 2 towards an imide type of product and only residual -NMe$_2$ groups remained in the solid. This was further corroborated by IR spectroscopy that showed no discernible C-H bands for both solids. However, the elemental analyses of the solids showed 2.49 to 3.65% carbon content supporting small quantities of these groups. The N/Ga and H/N element ratios of nearly 1.5/1 and 1/1, respectively, were consistent with the imide formulation for precursor 1. The IR spectra for the solids were in agreement with such a formulation and the broadness of the bands suggested a polymeric nature for the imide. The bands at approx. 3150 cm$^{-1}$ and 1515 cm$^{-1}$ could be assigned,
respectively, to the stretching and bending modes of the -N(H)- moieties.\textsuperscript{6b} The very strong band at approx. 570 cm\(^{-1}\) was typical of the Ga-N stretch.\textsuperscript{15a} However, the weak band at approx. 1615 cm\(^{-1}\) suggested the presence of some strongly adsorbed NH\(_3\) molecules\textsuperscript{15b} or -NH\(_2\) groups.\textsuperscript{6b} This band diminished in intensity after a prolonged evacuation of the solid at ambient temperatures, which was consistent with progressing deamination and supported the above assignment. Finally, the observed total weight loss of 4.9\% in the TGA experiment (UHP nitrogen) for solid 1 could be compared with the theoretical value of 9.2\% for: Ga(NH)\(_{3/2}\) = GaN + 1/2 NH\(_3\). In this regard, it was noticed that solid 1 was extremely sensitive to oxidation; an initial fast weight increase was observed beginning at 30 °C to 100 °C even with application of the UHP nitrogen carrier gas. The overlap of the oxidation (weight increase) and deamination (weight loss) could explain the observed low weight loss. However, the magnitude of the weight changes in the TGA experiment compared favorably with the imide formulation for precursor 1.

The pyrolysis studies (450-500 °C, vacuum or NH\(_3\) flow) were performed for precursor 1 obtained both from the reaction of compound 2 with NH\(_3\) in the liquid phase\textsuperscript{16} and in the gas phase to yield similar results. The former case will be discussed below in more detail. Thus, the elemental analyses of the solids from pyrolysis of 1 under vacuum and under NH\(_3\) showed the N/Ga atomic ratios were very close to 1/1, consistent with the formation of stoichiometric GaN and only small quantities of retained carbon (e.g. 0.22\%, pyrolysis under NH\(_3\)). Interestingly, for pyrolysis of 1 under vacuum, the analysis of collected volatiles showed a small amount of CH\(_4\) (and, possibly, H\(_2\)) and HNMe\(_2\) in addition to the major NH\(_3\) component. The IR spectroscopy supported the formation of GaN in all investigated materials (strong Ga-N band at 570 cm\(^{-1}\)).\textsuperscript{15a} The presence of the weak bands at 3200 cm\(^{-1}\) and 980 cm\(^{-1}\), especially for the pyrolysis product under vacuum, could be due to remaining -N(H)- and -Ga(NH)- species; however, some N-C species from the cracking of the residual -NMe\(_2\) groups (evidenced by CH\(_4\) evolution) could contribute to the latter band.

The gray-yellowish (pyrolysis under vacuum) and yellow-grayish (pyrolysis under NH\(_3\)) products were shown by XRD spectroscopy (Fig. 1) to be, remarkably, the same mixture of cubic and hexagonal close-packed layers of GaN that was reported earlier by Gladfelter et al.\textsuperscript{17} from thermal decomposition of [H\(_2\)GaNH\(_2\)]\(_3\). The relatively sharp XRD powder pattern obtained for the solid from the pyrolysis at 500 °C under NH\(_3\) (Fig. 1A) matched the pattern reported in the above reference. The TEM micrograph and the electron diffraction pattern for this solid supported the presence of relatively large particles of cubic GaN (Fig. 2A). The observed cross-fringes (approx. 71° angle of the (111) planes viewed along the [110] direction) were consistent with the cubic form of GaN. Based on the
relative broadness of the XRD powder patterns (Scherrer's equation) and the TEM results (Fig. 2), the solid from the pyrolysis at 500 °C under NH₃ consisted of bigger and less disordered GaN crystallites (av. 7 nm) than the solid from the pyrolysis at 450 °C under vacuum (av. 2 nm). A topotactic relationship between the precursor [H₂GaNH₂]₃ and the final product was proposed to play a role in the formation of the kinetically favored cubic GaN as compared with the nitride's thermodynamically stable and common hexagonal form. However, in the case of gallium imide this premise could not be ascertained due to the lack of detailed knowledge of the polymeric imide's structure.

In addition to the discussed pyrolysis schemes, refluxing precursor 1 in N,N,N',N'-tetramethyl-1,6-hexanediamine (b.p. 210 °C) for 40 h and removing the solvent afforded a pale yellow solid that displayed an XRD powder pattern similar to the pattern for the solid heated at 450 °C under vacuum. The TEM images showed this solid to consist of very small crystallites, <1nm (Fig. 2C). Also, heating pure compound 2 under NH₃ using a specially designed temperature program resulted in a yellow material that gave an XRD powder pattern identical with the ones discussed above.

We also report preliminary results on the preparation and utilization of yet another imide-type precursor to GaN. It was obtained from an oily product synthesized in the reaction between GaCl₃ and LiNEt₂, which was aimed at the synthesis of \{Ga(NEt₂)₃\}. This oily product reacted with NH₃ to afford a yellow solid that showed similar IR and TGA characteristics as precursor 1. This solid was also converted by pyrolysis under ammonia to the same type of the cubic/hexagonal GaN as discussed above.

In summary, an efficient preparation of the new polymeric gallium imide, \{Ga(NH)₃/2\}ₙ, from the reactions between [Ga(NMe₂)₃]₂ and NH₃ at ambient temperatures was described. The gallium imide precursor was shown to yield upon pyrolysis a rare cubic/hexagonal variety of GaN. Some control of the average particle size of GaN in the nanosized region was achieved by application of various pyrolysis schemes.
