A surface ship subjected to an underwater explosion is exposed to shock waves over a short period of time which can vary in magnitude based on charge type, size, and location. The energy of those waves impinging upon the hull is transmitted throughout the ship’s structure and vital equipment. The dynamics of the shock waves also influence the fluid surrounding the outer hull of the ship, creating an area of cavitating fluid. The combination of the shock waves, bubble pulsations, and cavitating fluid induce shipwide vibrations on hull supports and mission essential equipment which may become inoperative. In view of congressional requirements for new ship designs and systems to be shock tested, this thesis investigates the modeling of a preliminary design (Flight I) of the Arleigh Burke Destroyer (DDG 51) exposed to an underwater explosion. The effects of cavitation on one and two dimensional models is explored to determine if cavitation effects are substantially important to a three dimensional ship model. Validation of modeling underwater explosion effects upon a ship model can provide potential insight and savings in cost for future live fire testing and evaluation of the Flight IIA (DDG 79) design of the Arleigh Burke Destroyer.
FLUID-INTERACTION AND CAVITATION EFFECTS ON A SURFACE SHIP MODEL DUE TO AN UNDERWATER EXPLOSION

ABSTRACT

A surface ship subjected to an underwater explosion is exposed to shock waves over a short period of time which can vary in magnitude based on charge type, size, and location. The energy of those waves impinging upon the hull is transmitted throughout the ship's structure and vital equipment. The dynamics of the shock waves also influence the fluid surrounding the outer hull of the ship, creating an area of cavitating fluid. The combination of the shock waves, bubble pulsations, and cavitating fluid induce shipwide vibrations on hull supports and mission essential equipment which may become inoperative. In view of congressional requirements for new ship designs and systems to be shock tested, this thesis investigates the modeling of a preliminary design (Flight I) of the Arleigh Burke Destroyer (DDG 51) exposed to an underwater explosion. The effects of cavitation on one and two dimensional models is explored to determine if cavitation effects are substantially important to a three dimensional ship model. Validation of modeling underwater explosion effects upon a ship model can provide potential insight and savings in cost for future live fire testing and evaluation of the Flight IIA (DDG 79) design of the Arleigh Burke Destroyer.

ACKNOWLEDGMENTS

I would like to express my deep gratitude and appreciation to Dr. Young S. Shin for his continued guidance and encouragement throughout this research. I would also like to thank Dr. John DeRuntz and LCDR Jim Chisum for their patience, support, and expertise they provided me during my studies in the area of underwater shock research. My gratitude also goes to Mr. Chris Dombkowski and Miss Amy Welbaum at SDRC as well as Mr. Jack Castro at MacNeal-Schwendler Corporation for their quick and efficient support.

Finally, I would like to dedicate this work to my loving wife, Marsha, my beautiful daughter, Danielle Mae, and to my devoted mother-in-law, Gertrude B. Queturas, who have supported and sacrificed for my academic endeavor at the Naval Postgraduate School. Their love and encouragement made it possible.
I. INTRODUCTION

A. BACKGROUND

Today's U.S Navy consisting of technologically advanced ships such as the Ticonderoga class cruiser and the Arleigh Burke class destroyer are being driven to operate in the littoral, close to shore, environment as delineated in the Department of the Navy's strategic planning document [Ref. 1]. These platforms equipped with the Aegis weapon system were designed for open ocean, "blue water" tactical scenarios but due to the end of the cold war, a shift in emphasis is placed on low intensity conflicts which occur near the sea-land interface. This has increased the potential for "cheap kill" opportunities against U.S. warships such as an underwater mine as ships close the shore and the availability of such weapons is high and the cost low for third world country to purchase.

As recently as 1991 during Operation Desert Storm, the USS Princeton (CG-59), a Ticonderoga class guided missile cruiser, struck a floating mine near the bow. Although the rupture to the hull was localized, the subsequent whipping of the hull caused severe hull girder damage near the stern of the ship and weapon systems to go off line. This type of tactical environment now places a greater responsibility on ship designers and engineers to meet requirements as specified in MIL-S-901D [Ref. 2].

A number of studies have been conducted on submerged cylinder type models exposed to an underwater explosion in order to predict the hull response of structures
such as a submerged submarine. These studies did not include the effects of cavitation on the wet surface of the model or of the cavitation which occurs at the free surface. For surface ship type studies, simplified beam models such as that conducted by Hicks [Ref. 3] have concentrated only on the effects of whipping of surface vessels due to gas bubble dynamics. In this age of improving computer hardware, larger memory and software programs such as the USA (Underwater Shock Analysis) code with the CFA (Cavitation Fluid Analyzer) [Ref. 4] to model underwater shock effects and improving CAD programs with built in FEM (Finite Element Model) generators such as IDEAS [Ref. 5] and MSC/NASTRAN [Ref. 6], the engineer has a greater ability to improve ship modeling and predict the vibrational response of ship hulls and internal equipment.

B. SCOPE OF RESEARCH

This thesis studies the methods of modeling one and two dimensional finite element models with and without an external fluid. Two different computational methods are selected in the USA code for each model arrangement in addition to incorporating the CFA module in the solution process. The goal is to determine the cavitation effects on a surface vessel and develop the most simplest and conservative method in modeling the underwater explosion. A one dimensional model is created from Bleich’s paper [Ref. 7] which defines the conditions of a square plate sitting on a fluid surface and a fluid column. In addition, an exponential decaying plane wave models the underwater explosion. A second finite element model is created to represent the cross-sectional area of a simple
ship hull. This two dimensional model includes the surrounding fluid to the waterline of the hull and introduces the effects of a free surface due to an actual charge placed at a distance from the hull. The results from these first two models provides some simplification for the three dimensional notional hull structure of the Flight I of the Arleigh Burke. Although live fire testing and evaluation has already been conducted on a Flight I design, a Flight IIA design starting with DDG-79 possesses hull differences shown in Fig.1 which may require shock testing. Improvements in the area of modeling a surface ship such as the Flight IIA design from existing CAD programs and fluid behavior during an underwater explosion through the USA code, can create potential savings in future Flight IIA shock trial tests.

Figure 1. Major Changes (Flight II to Flight IIA) [Ref. 8]
II. UNDERWATER EXPLOSION

A. FLUID BEHAVIOR

When an underwater explosion occurs, the solid explosive material (such as HBX-1, TNT, etc.) suddenly reacts, leaving behind high temperature and pressure of gaseous products. An initial wave of compression is produced due to a sudden discontinuity of pressure which can reach a peak pressure of $2 \times 10^6$ psi. This steep fronted wave known as a "shock wave" propagates radially outward at a speed several times the speed of sound in water and roughly decays exponentially. The velocity of the shock wave decreases such that at approximately 10 times the explosive charge radius, the disturbance is essentially traveling at the acoustic velocity in water, 5000 ft/sec. [Ref 9:pp 3-7]

The pressure sensed at a specific point in the fluid or at a structure is essentially a step increase to the peak pressure followed by an exponential decay with time until the pressure has dropped to approximately one third of the peak pressure. After falling to approximately one-third of the peak pressure, the pressure level falls off inversely with distance [Ref 9:pp3-7].

The cavity of gaseous products left behind at high pressure forms a bubble which subsequently expands to relieve the difference in pressure, accelerating the surrounding fluid particles. The bubble continues to expand beyond the point of hydrostatic equilibrium (due to the inertia of the surrounding fluid) until a point of dynamic equilibrium is reached. The bubble then reverses its motion, continuing to contract until
dynamic equilibrium is again reached, where it quickly rebounds and again begins to expand as illustrated in Fig. 2. This oscillating bubble expansion and contraction continues until the energy of the reaction is fully dissipated or the bubble finally reaches the surface, venting the gaseous by products of the explosion. As the bubble rebounds, it greatly accelerates the surrounding water, generating a substantial pressure pulse (known as the bubble pulse). This bubble pulse can impart significant loads on structures in the vicinity.

In addition to the initial shock wave and bubble pulse, based on the location of the explosive charge with respect to the surface and sea floor, a surface vessel can also experience a combination of the following pressure waves as illustrated in Fig. 3:

1. Free-surface reflection
2. Bottom reflection
3. Bottom refraction (not shown)

The directions of free-surface and bottom reflection waves can be determined through an application of Snell’s law at the surface and sea bottom, respectively. At the surface of a fluid, a reflected wave of negative pressure known as the “rarefraction wave” is formed with a value such that the sum of the direct and reflected pressures is zero along the boundary condition between air and water defined by the surface. This rarefraction wave travels through the fluid region shortly after the incident shock wave at any point which causes the incident shock wave pressure profile to be truncated at a point in time called “surface cut-off.” Bottom reflected and refracted waves are dependent on the
characteristics of the sea bottom and can contribute significant pressure waves in shallow water environments but are not considered for this study.

Figure 2. Gas Bubble behavior

Figure 3. Pressure Wave Profiles
Figure 4. Combined Pressure Profile of an Underwater Explosion

The oscillating bubble pulse can also introduce a low-frequency forcing function that can resonate a ship girder frequency especially when the period of the bubble pulse is in the vicinity of the natural frequencies of the ship girder. Fig. 4 illustrates a combination of the pressure waves.

A number of empirical relationships have been derived through numerous underwater explosion tests since World War II which provide a means to calculate explosion characteristics such as incident wave pressure ($P_{\text{max}}$) which impinges upon a target, shock wave decay constant ($\theta$), pressure as a function of time ($P(t)$), and bubble period ($T$) with derived constants for each respective explosive material provided:
\[ P(t) = P_{\text{max}} e^{\frac{t-t_1}{\theta}} \]  

(\text{psi})

\[ P_{\text{max}} = K_1 \left( \frac{W^{1/3}}{R} \right)^{A_1} \]  

(\text{psi})

\[ \theta = K_2 W^{1/3} \left( \frac{W^{1/3}}{R} \right)^{A_2} \]  

(msec)

\[ T = K_5 \frac{W^{1/3}}{(D+33)^{5/6}} \]  

(sec)

\( W = \text{Charge weight (lb)} \)
\( R = \text{Standoff distance (ft)} \)
\( D = \text{Charge Depth (ft)} \)
\( t_1 = \text{Arrival time of shock wave (sec)} \)
\( t = \text{Time of interest (sec)} \)
\( K_1,K_2,K_5,A_1,A_2 = \text{Shock wave parameters} \)

**B. STRUCTURAL BEHAVIOR**

The dynamic response of a linear-elastic structure can be defined, based on the number of elements and nodes that define the structure, as

\[ [M] \{\ddot{x}(t)\} + [C] \{\dot{x}(t)\} + [K] \{x(t)\} = \{F(t)\} \]  

(2.1)
where \([M]\) = structural mass matrix, \([C]\)=damping matrix, \([K]\)=stiffness matrix, \({F(t)}\)=applied external force, \({x(t)}\)= general displacement vector and derivatives with respect to time. For a structure in a fluid medium, the applied external force created by an underwater explosion, is defined as

\[
-[G] \, [A_{\text{fluid}}] \, (\{P_i(t)\} + \{P_s(t)\}) = \{F(t)\}
\]  

(2.2)

where \([G]\) = the transformation matrix between structural and fluid nodes, \([A_{\text{fluid}}]\)= diagonal area matrix for the elements in the fluid, \({P_i(t)}\)= incident wave nodal pressure vector and \({P_s(t)}\) = scattered wave nodal pressure vector.

The USA code provides the means to model the pressures involved in an underwater shock as a “forcing function” on a fully or partially submerged model. The code also utilizes variations of the DAA (Doubly Asymptotic Approximation) method [Ref. 10] that models the surrounding acoustic medium as a membrane on the surface of the structure actually in contact with the homogeneous fluid. The effects of cavitation on a structure modeled with a surrounding fluid can be also included through the CFA. The fluid motion and structural response is linked together through a series of compatibility relations that are matrix differential equations that relate the symmetric fluid mass matrix of the model’s wet surface, fluid particle velocities from the scattered wave normal to the structures wet surface, and rates of changing scattered fluid pressures. The USA code creates this matrix by utilizing an infinite, inviscid, incompressible fluid in an irrotational flow created by the structure’s wet surface and then creates a virtual mass matrix which is comprised of the added mass of the fluid on the elements of the structures mass matrix which are wet. Kinematic compatibility is obtained between the fluid motion and
structural motion by an invariance of virtual work and transformation matrices that create the final interaction equations for fluid and structure motion [Ref. 10].

Hence, the final equations of structure and changing fluid pressures create a set of “augmented interaction equations” which the USA code solves, given a specified time increment, in an unconditionally stable manner.

C. CAVITATION

Two types of cavitation which can occur during an underwater explosion is that of “local cavitation” which occurs at the fluid-surface interface and “bulk cavitation” which occurs near the free surface that can extend beyond the target of interest by hundreds of feet. Utilizing Taylor flat plate theory, the particular models in this thesis will utilize only air backed plate conditions as illustrated in Fig. 5.

![Diagram of Taylor Plate Subjected to Plane Wave](image)

Figure 5. Taylor Plate Subjected to Plane Wave.
1. **Local Cavitation**

When the pressure pulse from an underwater explosion impinges upon a flexible surface such as the hull of surface ship, a fluid-structure interaction occurs which dynamically excites the ship structure. Looking at an infinite, air backed plate of mass, per unit area (m) subjected to an incident plane shock wave $P_i(t)$, a reflection wave of pressure $P_r(t)$ will come off the plate. Letting $v_p(t)$ be the velocity of the plate and applying Newton’s second law of motion:

$$m \times \frac{dv_p}{dt} = P_r + P_i$$  \hspace{1cm} (2.3)

Letting the fluid particle velocities behind the incident and reflected shock waves be $v_i(t)$ and $v_r(t)$, respectively, the velocity of the plate becomes

$$v_p(t) = v_i(t) - v_r(t)$$  \hspace{1cm} (2.4)

Incident and reflected shock wave pressures are defined, respectively:

$$P_i = \rho Cv_i$$  \hspace{1cm} (2.5)

$$P_r = \rho Cv_r$$  \hspace{1cm} (2.6)

where $\rho$=fluid density and $C$=acoustic velocity. Substituting the pressures (2.5) and(2.6) into (2.4) and utilizing for a high explosive shock wave

$$P_i(t) = P_{max} e^{-\frac{t}{\theta}}$$  \hspace{1cm} (2.7)
where \( t = \) time starting after the shock wave arrives at the target, one can solve for \( P_r \):

\[
P_r = P_i - \rho C v_p = P_{\text{max}} e^{-\frac{t}{\theta}} - \rho C v_p
\]  
\( (2.8) \)

Returning to the basic equation of motion (eq. 2.1) and substituting \( P_i \) gives the following first order linear differential equation:

\[
m \frac{dv}{dt} + \rho C v_p = 2P_{\text{max}} e^{-\frac{t}{\theta}}
\]  
\( (2.9) \)

The above differential equation is solved for \( v_p \),

\[
v_p = \frac{2P_{\text{max}} \theta}{m(1 - \beta)} \left[ e^{-\frac{\beta t}{\theta}} - e^{-\frac{t}{\theta}} \right]
\]  
\( (2.10) \)

where \( \beta = \rho C \theta / m \) and \( t > 0 \). Total pressure on the plate is also found to be

\[
P_i + P_r = P_{\text{max}} \left[ \frac{2}{1 - \beta} e^{-\frac{t}{\theta}} - \frac{2\beta}{1 - \beta} e^{\frac{\beta t}{\theta}} \right]
\]  
\( (2.11) \)

Hence, as \( \beta \) becomes larger, representing a light weight plate becoming more flexible, the total pressure will become negative at a very early time and as the total pressure approaches vapor pressure, local cavitation occurs in front of the plate. At this point, the plate is separating from the fluid and the maximum velocity for the plate is attained [Ref. 11]
2. Bulk Cavitation

The combination of the rarefraction wave and incident shock wave near the free surface creates a region of decreasing fluid pressure that approaches the vapor pressure of water. The rarefraction wave direction is determined by an image charge located an equivalent distance from the surface boundary in the air as the actual charge in the fluid. An upper and lower boundary begins to form which defines the bulk cavitation zone (Fig. 6). The velocity of the water particle near the free surface will have primarily a vertical velocity at cavitation. As the reflected shock wave passes, the fluid is then acted upon by gravity and atmospheric pressure.

Figure 6. Bulk Cavitation Zone [Ref. 11]
The upper cavitation boundary of Fig. 6 is the set of location points where the rarefraction wave arrives and the absolute pressure drops to the cavitation pressure. The total pressure which determines the upper boundary is the summation atmospheric, hydrostatic, incident shock, and rarefaction which can be defined as

\[ F(x,y) = K_1\left(\frac{W^{1/3}}{r_1}\right)^{A_1} e^{-\frac{r_2-r_1}{\theta}} + P_A + \gamma y - K_1\left(\frac{W^{1/3}}{r_2}\right)^{A_1} = 0 \]

\[ r_1 = \sqrt{(D-y)^2 + x^2} \]

\[ r_2 = \sqrt{(D+y)^2 + x^2} \]

where

- \( x,y \) = horizontal range and vertical depth of point
- \( r_1 \) = standoff distance from charge to point
- \( r_2 \) = standoff distance from image charge to point
- \( C \) = speed of sound in water
- \( D \) = charge depth
- \( \theta \) = decay constant
- \( P_A \) = atmospheric pressure
- \( \gamma \) = weight density of water
- \( W \) = charge weight
- \( K_1, A_1 \) = shock wave parameters

The lower cavitation boundary is determined by equating the decay rate of the breaking pressure which is the rarefaction wave pressure that reduces a particular location of fluid to the point of cavitation pressure, approximately zero, to the decay rate of the
total absolute pressure of the fluid as illustrated in Fig. 6. This boundary can be defined as [Ref. 12]

\[ G(x, y) = \frac{P_1}{C_0} \left[ 1 + \left( \frac{r_2 - 2D(D+y)}{r_1} \right) \left( \frac{A_2 r_2}{r_1} - A_2 - 1 \right) \right] - \frac{A_1 A_1 r_2}{r_1^2} \left( r_2 - 2D \left( \frac{D+y}{r_2} \right) \right) + \gamma \left( \frac{D+y}{r_2} \right) + \frac{A_1}{r_2} (P_1 + P_2 + \gamma y) = 0 \]

where

\[ P_1 = K_1 \left( \frac{W^{1/3}}{R} \right)^{A_1} e^{-\frac{(x_2-x_1)}{c_0}} \]

\[ \theta = K_2 W^{1/3} \left( \frac{W^{1/3}}{R} \right)^{A_2} \]

Hence, any point that satisfies \( F(x, y) = 0 \) and \( G(x, y) = 0 \) determines the upper and lower boundary points. Fig. 7 and Appendix A provides a MATLAB code [Ref. 13] for bulk cavitation zones for various depths and charge weights for TNT explosive material. This particular tool was useful in modeling the 2D cross sectional hull and placing the charge in location that would minimize the effects of bulk cavitation and aid in concentrating effects of local cavitation. Fig. 7 illustrates the region of the bulk cavitation zone above the charge does not vary much with changing depth. However, the bulk cavitation zone increases in depth with appreciable increases in charge size. 30 feet below the keel (total depth of 50 feet) was used for the two dimensional study.
Figure 7. Bulk Cavitation Zones for a TNT charge located at the following depths:
   --50ft, -100ft, -150ft
III. COMPUTATIONAL FLOW

Model preparation, translation, calculation, and post-processing involved a number of programs which is depicted in Fig. 8. Each process involves a number of output files which are input to the next step in the process or provides the user a means to verify results from each step before proceeding.

Figure 8. Computer Program Flow
A. MODELING

1. ASSET

ASSET/MONOSC (Advanced Surface Ship Evaluation Tool/Monohull Surface Combatant) [Ref.14] program is an interactive program which created the original ship dimensions for the three dimensional study. It provides a naval architectural tool to address ship design, which includes geometric definition of the hull and superstructure, hull subdivision, hull structure, resistance, appendages, equipment, and costs [Ref. 14]. An early design of the DDG 51 class destroyer with general weights of equipment groups and hull structure requirements based on inputs from designer imposed needs or mission requirements was exported out of ASSET in an IGES (Initial Graphics Exchange System) file format which included general ship offsets which can be imported into IDEAS through the IGES translator. Although general bulkhead, deck, superstructure design was provided, no further details to subcompartmentized spaces, specific weights and locations of internal equipment, sonar dome offsets, and any other explicit details of the notional ship design was available. Appendix B provides a summary of the DDG 51 notional model.

2. IDEAS

IDEAS, Master Series 2.0, [Ref. 5] was utilized to model all three cases of study. The IDEAS program is comprised of a large number of applications such as design,
modeling, testing, manufacturing, and simulation, each with a large group of subtasks for the user to utilize in icon panel form or menu driven selection. The program is also a "team concept" software which allows a number of users in a design or analysis team to take individual parts of the whole model to be designed, modified, or analyzed. For each model, the Simulation Application and all its respective subtasks were utilized to create (e.g. surfacing) and mesh the finite element model for export.

a. One and Two Dimensional Models

For the one dimensional and two dimensional cavitation study, one model was required to be created which included the structure and surrounding fluid. Fluid mesh thickness could not exceed the following requirement due to numerical stability of the CFA code:

\[
\frac{2 \rho_w D}{\rho_s t_s} \leq 5
\]

where \(\rho_w\) = density of water, \(\rho_s\) = density of steel, \(t_s\) = thickness of steel plate, and \(D\) = width of fluid elements. For example, utilizing \(\rho_s/\rho_w \approx 8\), if the thickness of the plate or hull \(t_s\) = 0.5 in, \(D \leq 10\) in. After creating all structure and fluid model regions, the following order for meshing was conducted due to the order that the CFATRAN and CFAGAL program organizes particular fluid nodes and elements:

1. Fluid volume elements (brick elements)
2. DAA boundary (thin shell elements)
3. Hydrostatic boundary (thin shell elements)
4. Specified Pressure regions (not utilized for this study, thin shell elements)

5. Wet structural surfaces (thin shell elements)

6. Remaining structural surfaces

The thin shell elements for the DAA boundary, hydrostatic boundary, as well as for the specified pressure regions if used, provide a means to select the nodes in these particular regions that the CFA requires for numerical solution. The thin shell elements do not become a part of the solution process but act as “markers” in the CFATRAN program for the boundary element nodes which are specifically associated by the MAT field in the NASTRAN ASCII input file. Because of the numerical processing in the USA code, node numbering needs to be described in a counter-clockwise manner looking from the fluid towards the structure. Color coding particular surfaces and their respective elements or by creating specific groups of surfaces or elements in the meshing subtask-grouping icon greatly aids in changing particular characteristics such as the node numbering.

A one psi pressure vector outward from the structure into the fluid is applied to all structural wet elements to act as a marker for the USA code fluid matrix development and restraint set conditions set for symmetric boundaries are created in the BOUNDARY CONDITION subtask.

After meshing, two copies of the global mesh are made. One FEM model will be structure only with the one psi pressure, deleting fluid elements and nodes and one FEM model will be the fluid volume elements with the DAA, hydrostatic, and wet structure thin shell elements, deleting the other dry structural nodes and elements. These two FEM models are then exported out of IDEAS and import to MSC/NASTRAN.
b. Three Dimensional Ship Model

Prior to the IGES translator task, modifications needed to be made to the actual IGES ASCII file for the correct unit system, ensuring IDEAS was preset to the same units (feet, inches, meters, etc.).

Offset points and lines were utilized as “wire guides” to recreate the model in IDEAS for creating all surfaces through lofting, mesh of curves, or planar creation shown in Fig. 9. The following sequence proved to be the best option in creating a complete three dimensional ship model in IDEAS, Simulation, Master surfacing task:

1. HULL
2. BULKHEADS
3. DECKS
4. SUPERSTRUCTURE:

After all the surfaces have been created, all the edges must be connected or STITCHED in order for meshing to be successful and a check for free edges is performed in preparation for meshing. Any new surfaces that need to be created, such as internal bulkheads or connecting the superstructure to the hull, can be done through a surface bound by a combination of edges and three dimensional lines connecting those opposing edges.

The required thin shell element properties are applied and a one psi pressure vector must be applied to all the wet surfaces through the BOUNDARY CONDITION subtask as well as any symmetry condition through the RESTRAINT SET
icon. IDEAS provides a full series of element checks (warping, distortion, interior angles, and normal directions) which must be done for proper solution processing. Only one FEM model was required for export since the CFA program was not applied to this particular model.
Figure 9. Imported ASSET DDG 51 Model
B. TRANSLATION

Each of the following steps allows for output files to be viewed, verifying that information (number of nodes, eigenvalues, etc.) is being properly computed and created in the unformatted fortran files for the next step.

1. MSC/NASTRAN 67.5

The MSC/NASTRAN structure database is the required format for this particular version of the USA code during the initial start and restart. The USA code itself is conducting the solution process which would normally be a SOL 109 transient analysis process in MSC/NASTRAN. Appendix B provides the DMAP alters for IDEAS post processing which is attached to the beginning of the exported file out of IDEAS and for the MSC/NASTRAN restart, deleting unnecessary and unneeded lines up the bulk data section. This process generates the geometry information and the structure’s M, C, and K matrices

2. CFATRAN/CFAGAL

CFATRAN is a program modified from [Ref. 15] that takes the MSC/NASTRAN file of the fluid mesh model and groups the elements, nodes, and nodal connectivity in the required format for the CFAGAL program. CFAGAL will read the CFATRAN output and create a global access library of the fluid model and its
boundaries, just as the program FORGAL does for the structure model. This library will then be accessed during the FLUMAS process.

3. **NASSKY/FORGAL**

Nassky prepares the NASTRAN UT1 output file which contains the geometry and matrix data of the structure into "skyline" matrix format, a generic Fortran unformatted file. FORGAL then converts this generic file data into a GAL file (Global Access Library) database which the USA code will access for structure related data.

C. **UNDERWATER SHOCK APPLICATION AND SOLUTION**

Appendix B provides sample inputs for the following programs which were utilized for the two-dimensional study.

1. **FLUMAS**

This is the first step in the USA code which creates the fluid mass matrix of a structure wet surface in an infinite, inviscid, incompressible fluid by the boundary element technique. The key inputs here are the following [Ref. 16,17]:

1. Mesh Geometry: fluid wet-surface and structure wet-surface mesh
2. Element definitions: general curved surface or surface of revolution
3. Material Property: mass density, speed of sound, DAA2 parameter
4. Constraint options: location of free surface, half model, quarter model, long
cylinder, node reassignment in fluid-structure transformation if needed.

For cavitation studies, the CFA is activated and the fluid volume database created by CFAGAL is incorporated with the FLUMAS output. Care should be exercised here during CFA solutions. The NCAV field refers to the number of elements on the wet structure plus the DAA boundary. During non-CFA runs, the NCAV field refers only to the wet elements on the structure since this defines the DAA boundary.

2. AUGMAT

This process in the USA code utilizes the equations specified earlier as the “augmented equations” by utilizing the data in the GAL file and FLUMAS output to construct the specific matrices. The key inputs are the following [Ref. 16,18].

1. Fluid and Structure mass matrices
2. Structural DOF correspondance table
3. Fluid mesh geometry
4. Fluid/Structure DOF transformation coefficients
5. Type of solution to be conducted: plane wave, DAA2 options

3. TIMINT

This step constitutes the most time consuming step depending upon on the number of nodes, elements, and requested length of time to be studied. The
unconditionally stable staggered solution technique is utilized which basically involves the following [Ref. 16,19]:

1. Estimating the unknown structural restoring force \( K_s \{x(t)\} \) at \( t + \Delta t \) from the extrapolation of current and passed values.

2. Solve the fluid equation and obtain a preliminary estimate of the total pressure vector at \( t + \Delta t \).

3. Solve the structural equation for the displacement and velocity vectors at \( t + \Delta t \).

Other steps are involved between these particular steps for matrix transformations and improved accuracy. General inputs from the user involve the following:

1. Incident wave characteristics: location and type of charge source, standoff, specified pressure profile, exponentially decaying wave.

2. Time step information: start and finish times, increments.

3. Display data of particular nodes for checking output results in the solution file: desired node number and freedoms for displacement, velocities, or pressures on the DAA boundary.

Although unconditionally stable, the user should utilize small enough time steps to capture accurate model behavior. Solution time history responses of all structural nodes and fluid nodes for all runs are stored in the file designated POSNAM in the TIMINT input.
D. POST-PROCESSING

Two methods of post processing was done due to the growing amounts of required memory for larger models such as the three dimensional ship hull.

1. XUDVT

This second interface program converts the USA solution history in the corresponding MSC/NASTRAN data block, UDVT, a file format readable by MSC/NASTRAN. The initial MSC/NASTRAN job is restarted at the point just before the NASSKY translation, allowing MSC/NASTRAN to continue to a normal conclusion. The USA solution replaces that which would normally be generated by MSC/NASTRAN in a transient analysis.

During CFA studies, the number of wet points required to be entered are those wet points totals generated by NASSKY which can be found in the nassky.out file. However, during non-CFA studies, the wet points refer to the total number of wet element faces. If the incorrect number of wet points or wet elements are entered, translation will fail or data history for some nodes will not be translated. XUDVT also allows displacement, velocity, acceleration, and pressure histories to be extracted in ASCII table format and placed in the PLT file for X-Y plotting by other programs (e.g. MATLAB).
2. POSTPR

This is a USA postprocessing program which allows extraction of particular node displacement, velocity, or pressure histories. Although not needed for non-CFA studies, this is the only current method which one can extract pressure history profile of fluid nodes during a CFA study. The data is placed in ASCII column tables which can be plotted by other programs such as Matlab. Due to the large solution files generated by the three dimensional ship model and the growing size of files during the XUDVT-MSC/NASTRAN-IDEAS translation and final post-processing, POSTPR proved to be a memory saving tool. The user must ensure the original UT1 file name is either deleted or changed in order to prevent a XUDVT failure since this process produces a UT1 file for the MSC/NASTRAN restart.

3. MSC/NASTRAN (restart)

Appendix B illustrates the required fields needed to restart MSC/NASTRAN with a new UT1 file created by the XUDVT process. This process utilizes the original model.MASTER file originally created by the initial MSC/NASTRAN run and creates a solution file for IDEAS to import (model.OP2) which contains all or selected time histories of displacement, velocity, acceleration, and stress. The user should utilize a different .OP2 file name from that of the .OP2 file created in the first MSC/NASTRAN run. Files usually triple in size compared to the POSNAM file output from TIMINT.
4. IDEAS

The final .OP2 file can be imported into IDEAS through the FILE IMPORT-MSC/NASTRAN process. IDEAS will create a universal file (.unv) prior to actually creating a model file database. This universal file is usually three times the memory file size of the .OP2 and model.POS file due to being in ASCII format. Model file database size (file.sf1 and file.sf2) become approximately the same size as the universal file. Hence, a user should ensure plenty of hard drive memory is available during this translation phase, especially for large models (> 2000 elements).
IV. ONE-DIMENSIONAL ANALYSIS

A. PLATE MODEL

A one dimensional study was conducted utilizing the case defined by [Ref. 7] which involved modeling a floating plate on the surface of a bilinear fluid. The goal of this model was to accomplish the same results shown in [Ref. 7] by creating a finite element model and solving with the USA code. Follow-on study was performed by Newton [Ref. 20] in area of cavitation in support of developing a “shock shield,” a gas-filled cushion that was to surround the exterior of a submarine hull and reduce the magnitude of underwater shock loads transmitted through the hull.

Fig. 10 and Table 1 describe the particulars of the Bleich-Sandler case.

| 1 thin shell element, 4 nodes, 1” thick |

Charge depth = 1.0 E7 in, centered on the center of the plate

Table 3. Incident Pressure Characteristics

B. RESULTS

Utilizing a time step size of $1.313 \times 10^{-5}$ sec, 1200 time steps were collected. With the CFA interface turned on with the USA, program Fig. 11 depicts the computed velocity and pressure at the plate. Fig. 12 depicts pressures at specific locations along the column of fluid. Because of the numerical computation scheme within the USA code, time zero noted on each pressure figure refers to the point in time that the incident pressure wave arrives at that particular fluid node and not the global time of plate motion. Total pressures at time zero for each fluid node is the sum of the atmospheric, hydrostatic, and incident pressure wave at that point of arrival from the initial charge location and applied exponential decay. Fig. 11 illustrates that the cavitation region does not touch the interface boundary between the fluid and the plate. Node 401 in Fig 12 confirms the cavitation region is captured by the fluid FEM and does not extend beyond the DAA boundary. Fig. 13 depicts the plate velocity and pressure with CFA OFF.

Calculated time periods of zero pressure or cavitation occurrence grow to a period of .008 sec half-way through the column and stay approximately the same to the end of the fluid column. In addition, the CFA captured the cascading effects of cavitation closure which occurred at similar times following incident pressure wave arrivals at each
fluid node and closure pressures became larger at deeper depths than at the surfaces. This closure phenomenon begins at the point $t = 0.0108$ sec at which the plate experiences an immediate velocity cutoff of the downward direction back to zero by the arrival of this “secondary shock” at the plate. Pressure at this particular time jumps to approximately 14% of the peak pressure and creates an upward velocity of approximately 16% which brings the plate velocity back to zero. Multiplying time by 1004.22 to get it in terms of decay time units of the incident wave and normalizing velocity to $1/1000$ of the speed of sound with a sign change due to the z-axis for vertical displacement being defined downward into the fluid, calculated results match those (Fig. 14) with Bleich and Sandler as shown in Fig. 15 and 16.

Hence, the finite element modeling approach with the USA/CFA code produced identical results as those shown by Bleich and Sandler through the method of characteristics [Ref. 7]. In addition to the pressure history profile of Fig. 15, USA postprocessing was able to display the cavitation closure anywhere in the fluid column.

V. TWO DIMENSIONAL PROBLEM

A. CROSS-SECTIONAL HULL

The mid-section of the imported wireframe hull of the DDG model was utilized for this particular study, assuming structural properties remain linear throughout the process. Previous work conducted by Newton [Ref. 21] in the area of a two dimensional study involved a symmetric cylinder submerged underwater exposed to a plane wave incident shock front, utilizing earlier Fortran finite element programs for meshing, propagation of underwater shock, and transient response calculations.

The goal in this particular model is to study responses, specifically peak velocities, with and without cavitation effects, of a surface ship model with a draft of 20 feet. The time frame was limited to the first 30 msecs, in an attempt to eliminate the effects of the bubble pulse while comparing plane wave modeling and DAA2 spherical.

Utilizing the USA code, Fig. 17 illustrates location of cross section in the global ship wireframe, 1 foot in depth, and Fig.18 to Fig. 20 illustrate the meshed model. In Fig. 18, red donotes the structure mesh while green denotes the fluid mesh. Fig. 20 depicts the outer DAA, hydrostatic, and structural interface elements mentioned previously. Tables 4-6 provide specific model characteristics.

Table 6. Fluid Characteristics

Utilizing the bulk cavitation program to determine the extent of various bulk cavitation zones of a TNT explosion, the smallest region of bulk cavitation takes place directly above the charge at the surface. Therefore, a charge location directly beneath the hull at 100 feet standoff (depth = 120 feet) would minimize effects of the bulk cavitation zone in the general vicinity of the hull model and provide a means for setting the lower edge of the DAA boundary just beyond the cavitating region at a depth of 50 feet, 30 feet under the keel.

B. RESULTS

Fig. 21 to Fig. 30 record the velocities at the locations in the structure and time varying pressures at locations in the fluid volume region for the CFA analysis noted on Fig. 19. Fig. 31 to Fig. 33 provide a comparison of keel velocities and accelerations. The
pressure profiles, like that seen in the one-dimensional analysis, reflect a respective time zero which starts at the point of incident pressure wave arrival at that particular node and not the initial time of structure motion. Structure motion is derived from the cumulative integration of all the pressure profiles in the fluid region superimposing each pressure profile at different spatial locations in time.

The introduction of a fluid mesh beneath the structure and the turning on CFA captured the pressure varying fluid under the hull (Fig. 21 and 24) which significantly effected the velocity response of the hull. The cavitation effects on the hull during plane wave and DAA2 calculations produced almost identical results in the early time phase of hull velocity at the keel (node 42) which was the closest to the charge location. As expected in late time response, the plane wave solution begins to slightly vary from the DAA2 calculations. However, peak velocity response are the same in early time.

Pressure profiles at the keel for both CFA models (Fig. 21 and 24), which are practically identical, indicate the first signs of cavitation closure pressure occurring at a much earlier time compared to the Bleich-Sandler case with an appreciably larger pressure peak, 41% of the initial pressure wave. Numerous other cavitation closure events occur at the keel with decreasing max pressures. This observed behavior was also an event reported in the DDG-53 USS John Paul Jones Live Fire and Testing Shock Post report [Ref. 22] which may have contributed significantly to large accelerations at particular electrical switchboards following the incident pressure wave.

Keel velocities in the plane wave (CFA OFF) and DAA2 (CFA OFF) analysis, which places the DAA boundary at the ship's wet hull surface, did not capture the
detailed high frequency response of the structure exposed to identical underwater explosion conditions (Fig. 27 and 29). Peak keel velocities were identical in magnitude and occurrence in time but greatly diverged past reaching the peak velocity of 162 in/sec. Pressures along the keel during both CFA OFF calculations were found to include only the large initial pressure wave arrival and small variations in the pressure later in time along the wet hull, while those in the DAA2 calculation being slightly larger.

Internal deck velocities, however, revealed velocities greater during the plane wave modeling with a surrounding fluid mesh and CFA ON (Fig. 22). The pressure and corresponding variations along the wet surface of the hull caused internal velocities to be greater than those seen in the DAA2 CFA ON solutions (Fig. 25), primarily due to the less accurate calculations late in time for the plane wave equations and higher velocity response calculations. Both CFA OFF runs (Fig. 28 and 30) reveal small variations in velocity, the greatest occurring at the lowest deck. These small velocities could be attributed to the simplified cross sectional hull model which does not include any internal longitudinal or transverse bulkheads. If these particular bulkheads were modeled between decks, the transit velocity responses of the keel could have been transmitted to the upper decks instead of the bending the outer hull only.

Fig. 31 depicts the overlay of velocities of all 4 models (plane wave with and without CFA, DAA2 with and without CFA) at the keel, illustrating the larger velocities of the CFA OFF calculations for both plane wave and DAA2 modeling. Plane wave modeling of the underwater explosion incident pressure wave without a fluid mesh provides for a conservative approach in calculating the peak velocity of the structure at 46
the fluid structure interface. A shift to a higher velocity at an earlier time was more pronounced during this particular CFA study in comparison to the Bleich-Sandler case with a 22% increase in peak velocity. Appreciable differences in acceleration were noted between CFA ON and CFA OFF calculations (Fig. 32 and 33). CFA OFF results reflected initial accelerations 3.5 times larger than CFA ON results but with no following variations.

Peak velocities in each case are provide in Table 7.

Table 7. Maximum Velocities (in/sec)

The responses labeled “increasing” in Table 7 reflect increasing values at the end of the time period studied.

Fluid pressures at nodes 3021, 1600, and 2994 during both plane wave and DAA2 CFA ON calculations (Fig. 23 and 26) show similar relative patterns of growing numbers and durations of cavitation periods as depth decreases. The magnitude of peak pressures following initial cavitation in the DAA2 results tended to be 15-20% larger than the plane wave peak pressures. Node 3021 pressures during both CFA ON calculations at t=.0025 secs captured the largest peak pressure, followed by Node 2994 at t=.0047 secs.
Hence, based on the results, the best conservative approach to modeling a surface ship exposed to an underwater explosion would be to apply the plane wave incident pressure wave in a fluid mesh that surrounds the entire wet surface of the ship.

VI. THREE DIMENSIONAL MODEL

The ideal three dimensional ship analysis would include:

1. A detailed ship model which included specific hull and equipment characteristics (locations, weights, etc.)

2. A fluid mesh model of the surrounding ocean that captures the cavitation region in three dimensions, as seen in the one and two dimensional analysis.

3. A computer hardware that can handle the detailed processing and large solution database.

Due to the complexity of a global ship model and the time integration required, a simplified “notional” ship design was utilized which was part of an earlier model of the Arleigh Burke Destroyer. Based on the results obtained with the two-dimensional model and the requirements for conditions 2 and 3 stated above, a plane wave/CFA OFF analysis was utilized for the three-dimensional ship model which sets the DAA boundary at the wet surface of the hull. Table 8 provides general characteristics of the DDG model [Ref. 23].

Figure 35. Charge Locations Below the Keel (1) and Offset (2).
Figure 36. General Space Locations.
A. 1962 FINITE ELEMENT MODEL

1. Modeling

This initial model utilized a general plate thickness of 0.4 inches of similar material qualities used in the two dimensional model throughout the entire ship. Inner bottom stiffeners and heavy equipment locations were not constructed in the original IGES model out of ASSET but were later created in IDEAS for the 5682 element model study. Fig. 35 illustrates the 1962 element model which includes 348 wet elements. In order to capture peak velocities, damping coefficients were not applied to the model.

Explosive charge conditions were the same as those utilized for the two dimensional analysis:

**Table 9. Charge characteristics**

2. Results

The whipping motion of this particular model exhibited the expected basic motion of a simple free-free beam excited by a forcing function in the middle of the model. The highest velocities and accelerations occurred at the node (Node 42) closest to the charge (Fig. 37 and 38) due to an unsmeared and unstiffened keel and outer hull. The
unsmeared and unstiffened keel also experienced high frequency oscillations in comparison to other areas of the model. The bow and stern experienced the second largest maximum vertical velocities and accelerations (Fig. 39 to 42) which occurred approximately 45 msec and 32 msec, respectively, after the peak keel velocity.

Peak velocities at the bow, stern, and closest point to the charge at the keel indicate the greatest magnitude in velocities to be in the vertical direction, followed by fore and aft motion, and the athwartships direction to be the lowest. However, internal deck locations exhibited the greatest peak velocities in the fore and aft direction, followed by athwartship, and vertical velocities to be the lowest because of their general locations close to the incident shock wave arriving midships in the model. Both MER spaces (Fig. 43 to 46) experienced the largest internal accelerations, specifically in the fore and aft direction followed by CSER 3 (Appendix C) with almost equal velocities and accelerations in the fore and aft and athwartship directions. MER 2 experienced the largest fore and aft motions in comparison to the other internal spaces studied, largely due to its close location to the initial shock wave. Amongst the combat systems spaces, the SPY radar room (Appendix C) had the highest fore and velocity (9 in/sec) but with similar accelerations. The asymmetry of the aft super structure arrangement places a majority of the structure to port. This asymmetric condition in the DDG-51 model contributed to the athwartship velocities and accelerations in all areas of the ship.

Modeling the ship globally without a fluid volume mesh and exposing it to a plane wave underwater explosion captured the high frequency vibration or “ringing” in
the hull which was not observed in the plane wave/CFA OFF two dimensional cross-
sectional hull model. Table 10 summarizes maximum velocities and accelerations:

B. 5682 FINITE ELEMENT MODEL

1. Modeling

In order to provide a detailed mesh for the wet surface of the hull and improve equipment locations, a finer mesh was created of the same model which included inner bottom stiffeners and 955 wet elements, Fig. 47. Utilizing the available ASSET data on main engineering equipment [Ref. 23], early Flight II/IIA study drawings [Ref. 24], and DDG combat system equipment data [Ref. 25], large groups of heavy equipment were lump massed in their respective areas.

The detailed requirement for longitudinal and transverse stiffners was simplified by the smearing technique utilized in ASSET (APPENDIX D). Although previous work by Cunningham [Ref. 26] revealed the limitations in local and global smearing, the ASSET technique sizes stiffeners to provide a T-section with reasonable proportions that meet strength and geometric constraints. The stiffener cross-sectional area is smeared into the plate cross sectional area, creating a smeared plate thick than the standard plate by a factor of \((1 + \text{smear ratio}(S))\). Based on the data for the notional DDG design which included initial plate thickness and stiffener smearing ratios, the following plate thicknesses were used in this particular model:
<table>
<thead>
<tr>

</tbody>
</table>

Table 12. Engineering Equipment Total Weights (LTON) [Ref. 23]

The net weight of the entire model was 3598 Lton, 43% lighter than the original “light weight” DDG ASSET model.

Charge location was placed in an offset position utilizing only 120 lbs TNT at a standoff distance of 107 feet and a depth of 50 feet.
Figure 47. DDG 5682 Finite Element Model
2. Results

Due to the increased complexity of the meshed model, post processing of this particular model became quite difficult during the MSC/NASTRAN restart which prevented further post-processing into IDEAS. Fig. 48 to 51 depict the greatest velocities and accelerations occurring midships of this model, specifically at the point along the hull closest to the charge (Node 393) and at the node along the keel with the same axial distance from the bow (Node 397). These two locations coincide with those same points on the hull noted previously in Fig. 35 with charge 1 for node 397 and charge 2 for node 393.

Bow and stern reactions (Fig. 52 to 55) were noted higher than those seen in the 1962 element model due to the majority of concentrated masses being located in central locations of the ship (i.e. aft of the forward VLS and forward of CSER3) as well as the spaces of interest (Fig. 36) and the lack of masses in the general area of the bow and stern. Peak bow and stern vertical reactions occurred 40 msec and 30 msec, respectively, later relative to midships reactions (Node 393 and 397) with high frequency oscillations. MER 1 (Fig. 56 and 57) exhibited lower velocities and accelerations relative to MER2 (Fig. 58 and 59) which can be contributed by the asymmetry between the two engineering rooms. The gas turbine modules and reduction gear masses were located on the port side of the engine room of MER 2 which was the same side as the charge location and, as seen in the 1962 element model, MER 2’s location was closer to the incident shock wave arrival point along the hull. Bow, stern, and both MER spaces tended
to have reactions in the following order of highest to lowest magnitude: vertical, fore/aft, and athwartships. Combat system equipment rooms (CSER 1, 2, and 3) and the SPY radar room (Appendix F) showed very little motion in the fore/aft and athwartships direction with practically zero vertical motion.

For this particular tactical scenario and model, the only shipboard internal space which experienced the highest acceleration was MER 2 with large magnitudes of oscillations in the fore and aft direction as well as athwartship (Fig. 58 and 59). All other internal spaces encountered low accelerations which did not seriously introduce severe shock loadings upon their respective equipment. The effect of smearing and lump massing groups of large pieces of internal equipment created dramatically different results compared to the 1962 unsmeared, unlumped element model. In addition to these structural differences, the low charge weight and offset distance of the underwater explosion did not produce appreciable effects on internal ship behavior. Table 12 provides a summary of the maximum velocities and accelerations in each area:

VII. CONCLUSIONS AND RECOMMENDATIONS

The introduction of a fluid volume model with a structure and utilizing the USA/CFA interface provides a means to capture the effects of cavitation upon a surface vessel in the early time frames of an underwater explosion. The effects of cavitation closure as seen in the two dimensional model can be quite significant and inflict another impulsive force upon the ship as reported in the DDG 53 shock trial reports [Ref. 22] in addition to the incident wave, bubble pulsations, bottom reflection, or bottom refraction. This increases the complicated task of predicting surface ship behavior when exposed to an underwater explosion. CFA OFF modeling may provide a conservative approach in predicting ship response to an underwater explosion in early time. Finite element modeling, time integration calculations, and tactical placement of an explosive device must be carefully done to accurately model surface ship behavior. Plane wave modeling with a surface ship model and a fluid mesh may provide more accurate overall ship and internal equipment responses.

With improving systems and capacity, the testing of new ship models with specific interior designs from the ship designer with the underwater shock analyst utilizing the USA/CFA code can prove to be a formidable method in predicting forcing functions on internal equipment of a surface vessel. In view of the changes of the DDG Flight IIA designed compared to the present DDG Flight II, this particular method may provide some cost benefits in future ship shock trials.
Recommend continuing studies in the following areas:

1. Improve on the two and three dimensional model with internal masses or fluids.

2. Obtain actual DDG-51 Flight IIA DDG designs from NAVSEA which can be imported into an FEM program such as IDEAS or MSC/PATRAN which can be tested with the USA code for both linear and non-linear responses.

3. Introduce other surface ship model types such as the slice hull.

4. Model the underwater tactical scenario with significant shallow water bottoms in order to study "littoral" responses of a surface ship close to the shore.
APPENDIX A. BULK CAVITATION PROGRAM

The following program calculates the bulk cavitation zone for various weights and depths of TNT. The program can be easily modified for other explosive material.
% The following program will compute the bulk cavitation zone of an underwater explosion of TNT explosive with depth and weight of charge as inputs.

% TNT characteristics
Al=1.18;A2=-.185;K1=22505;K2=.058;

%=input('Enter depth of your charge '); % speed of sound in water (ft/sec)
W=input('Enter the weight of TNT explosive '); % atmospheric pressure
Co=4967;
Pa=14.7;

x=[0:5:1200]';
