INFLUENCE OF THE CENTRAL ASIATIC MOUNTAINS
ON THE FORMATION OF THE JET STREAM

Following is a translation of an article by
F. Pogosyan and K. F. Ugarova in Meteorologiya
i Gidrologiya (Meteorology and Hydrology), No.

Many studies have been devoted to the investigation
of the influence of mountain ranges, most of all of the Cen-
tral Asiatic Mountain Range, on the formation and the va-
riation of intensity and on the seasonal position of trop-
ospheric jet streams. The majority of investigators belie-
ve that the Himalayas and Tibet exert a substantial influen-
ce on atmospheric circulation at high altitudes and there-
fore also on jet streams.

It is hard to disagree with the conclusions of Tu
Cheng Yeh /4,16/ and other Chinese authors /17,18/ about the
influence of the above-mentioned mountain range on atmos-
pheric circulation in the lower half of the troposphere and
on the weather of China and Northern India.

It is also pointed out that Tibet and the Himalayas
exert influence mainly during the cold part of the year and
that they have very little influence during the warm part of
the year. The latter case is caused by the fact that towards
summer the altitudinal frontal zone and the jet stream are
displaced northward, beyond the limits of this upland.

During the cold half of the year, according to these
notions, the western aerial current (jet stream) branches
out on meeting the mountain range. As a result of the mecha-
nical action of the mountains, two jet streams appear north
and south of the highlands. The northern branch of the stream
possesses greater mobility than does the southern because,
according to the opinion of the abovementioned authors, the
displacement of the southern branch is limited by the Himala-
ayas.

Soviet meteorologists also attach substantial im-
portance to the influence of the mountains on the character
of atmospheric circulation in Central Asia, indicating that
large horizontal gradients of pressure and of wind velocity
at the 5-6 km level south and north of Tibet are due to the
presence of the mountain range /2, 6, 13/.

Aerological observations performed over Tibet in the
course of last two years permit a comparatively more pene-
trating investigation of seasonal variations of the fields of temperature and wind, as well as of altitudinal frontal zones and jet streams. During 1957-59, we constructed several series of individual and mean cross-sections of the atmosphere between the Equator and North Pole along different meridians and in different seasons above Eurasia and North Africa.

Some monthly profiles express not only subtropical but also extratropical jet streams. It appeared that, regardless of orography, during the winter months, the subtropical jet streams in the Northern Hemisphere can be found mostly in the 26-30° N latitudinal zone. This corresponds with their recurrence in winter, determined by the velocity of the wind at the 300 mb level. Only during certain periods of time, with significant meridional transformations of the altitudinal thermobaric field, and the development of a high cold cyclone due to isolation, at the 30-40° latitudes, the axis of the subtropical stream can be located at 20-25° N latitudes.

During the summer, under the influence of the circulation of the atmosphere of extratropical latitudes, a change of location and intensity of the subtropical jet stream is observed.

We shall cite here only two mean monthly profiles (January and July) over Tibet and Eastern Siberia (Figs. 1 and 2), and, as a supplement, data on the geographical position and intensity of jet streams during winter and summer over different longitudes.

These data are given in Table 1 for four longitudes: Western Africa - Greenland, Arabia - North Pole (over the European part of the USSR), India - North Pole (over the Japanese islands). Here are represented data on the latitude of the location of the axis of extratropical and subtropical currents at given longitudes in different seasons. It is easy to determine by comparison that in January the subtropical jet streams everywhere fall at a comparatively narrow latitudinal range, when, however, the physical-geographical conditions in the subtropical zone of the Northern Hemisphere are far from being homogeneous.

At the same time, depending on the character of the prevalent circulation form, extratropical streams can be found over most different latitudes ranging from the sub-tropics to 80° N; that is, in a range of more than 4-5,000 km.

As investigations have demonstrated, intraseasonal displacements, as well as the average monthly position, of the axis of the subtropical jet stream are also determined by the character of the circulation in the hemisphere.
Thus, for instance, the anomalous southern position of the axis of the subtropical stream over Western Africa in 1959 was stipulated by significant meridional transformations of the thermobaric field of the troposphere, accompanied by frequent invasions of cold to the south, and by the development between the Azores and Western Africa of an isolated (blocked) high cold cyclone, at the southern periphery of which the strengthening of the subtropical stream took place. A similar anomaly, however, is comparatively rare. It is not accidental that, with the exception of Western Africa, during 1958-59, the axes of all other subtropical streams were located between 27 and 33° N.

These facts lead to the conclusion that the position of subtropical jet stream over India and Tibet is not stipulated by the presence of the Central Asiatic mountain range, but by general conditions, specific as well for other subtropical regions.

From the constructed vertical cross-section of the atmosphere along the line Trivandrum - NP-7, passing over India, Tibet and Siberia, it can be seen that the subtropical jet stream is located not only in the Himalayan foothills but also over the mountain ranges (Fig. 1). That is, the displacement of the axis of the subtropical stream is not limited by the foothills. In individual cases, as, for instance, on 6-10 February 1958, with the displacement of the warmth crest northwards, the axis of the subtropical jet stream was located immediately over the mountain range at the 29-30°N latitude. As far as the maximal wind velocities at the jet axis are concerned, their magnitude is substantially dependent upon the prevalent synoptic processes.

Physical-geographical conditions exert an influence on the intensity of the subtropical stream in different seasons. In particular, high wind velocities over the Japanese islands are due to large contrasts of temperature which occur between the condensed air over Asia and the warm air over the ocean /11/. During a west-east transfer, meridional processes occur here almost incessantly, accompanied by advection of cold, causing cold air from Siberia and Mongolia and warm air from the Pacific Ocean to draw together. This process is so predominant that it is reflected on modern AT-500 and OT-700 maps, on which a depression of cold and low pressure is clearly expressed over Yakutia and the Far East during winter /11/.

At the same time over Arabia and India, where physical-geographical conditions and the character of circulation do not cause the formation of such significant temperature contrasts, jet streams are comparatively weaker.
As has been stated earlier, the position of extratropical jet streams is less stable because their formation is directly related to cycloonic activity. During some years therefore, depending upon the prevalent processes, the greatest frequency of jet streams can be observed over various latitudes. At the same time, due to physical-geographical peculiarities, the greatest frequency of extratropical jet streams is observed at the 10° W meridian, predominantly within the limits of 50-60°N latitudes.

This zone of maximal frequency of extratropical jet streams is also detected over the European part of the USSR and Western Siberia, while, however, the intensity of streams decreases with eastward displacement. Further to the east, extratropical jet streams are most often observed somewhat more to the south, in the 40-50°N latitudinal zone (Mongolia, Northern China), and over Japan they usually merge with the subtropical jet.

It follows from the above that the extratropical jet stream observed over Mongolia and Northern China is not in any way connected with the Central Asiatic mountain system. Concurrently, as data of aerological observations shows, extratropical jets develop sporadically also in the foothills of Tien-Shan and Tibet. Their formation, however, is not connected with the branching of the subtropical stream, but with a meridional transformation of a thermobaric stream, accompanied by an invasion of cold masses of air into Kazakhstan and Central Asia. An analysis of one of the examples of the formation of a similar jet stream will be given below.

Thus, the conclusion can be made that jet streams, found to the north and to the south of a mountain range, develop independently of one another and are not branches of the same stream.

The position of the jet streams changes substantially toward the summer. Subtropical jet streams over the entire Northern Hemisphere are displaced on the average 1400-1600 km northward. Concurrently, in connection with the total decrease of temperature contrasts between the Equator and the Pole, jet streams decrease markedly. Instead of 180-220 km/h in wintertime, maximal velocities in summer do not exceed 100-140 km/h on the average. The greatest weakening of jet streams from winter to summer is observed over the Japanese islands; it is due to a warming up of the Asiatic mainland and to a substantial decrease of temperature contrasts between the continent and the ocean.

Changes in the position and intensity of jet streams, which have occurred from winter to summer, can be seen on the example of a region of India, Tibet and Siberia, the mean
vertical profile of the atmosphere for July 1958 of which is represented in Fig. 2.

As the data in Fig. 2 shows, the position of the subtropical jet stream in summer is approximately the same at all studied longitudes in the 42-44°N latitudinal zone. Consequently, the mountain range of Central and Middle Asia does not exert any significant influence on the seasonal position of jet streams.

However, this cannot be said in relation to the intensity of jet streams. Thus, in July 1958, the mean velocity of the jet stream north of Tibet appeared to be somewhat greater than in other regions. This fact might be explained by the radiational conditions of the high plateau /1,3/. Yet, the fact has to be taken into consideration that, due to geographical conditions over the southern Asian mainland, warming up of the air progresses most intensively. In the conditions of Central Asia, the comparatively cold masses of air progressing inland invading the continent from the north and the northwest, are warmed up discontinuously. This occurs not only over the mountain ranges of Central Asia but also to the west of them, in almost mountainless regions. At the time of the general west-east transfer, water vapor in the warming air is eliminated from the state of saturation, fronts are eroded. Even in the system of depressions, moving in from the west or developing in Central Asia, clear weather is observed, which facilitates the radiational warming up of the underlaying surface and air. It is easy to discover on the mean monthly maps of baric topography that, starting from the northwestern coastal areas of Africa and the Pyrenees and on to Central Asia, the structure contours 1000 /12/ are gradually displaced northward; that is, the process of the warming up of air with the eastward movement is expressed on mean OT maps independently of the presence or absence of mountains. It is possible that warming up of air occurs somewhat more intensively over Tibet than over adjacent regions. It is evident, however, that irrespectively of the existence of the mountain range, the altitudinal crest could still be located over these regions as a result of the west-east transfer and the warming up of the air.

In spring and in autumn, the subtropical jet stream occupies a position which is intermediate between the winter (27°N in January) and the summer (43°N in July) positions. On the 90°E meridian as well as in other regions, the jet stream is displaced in the spring from south to north and in autumn from north to south. The disappearance of the stream in May over India /14, 15/ is explainable by the fact that
the planetary altitudinal frontal zone is displaced into more northern regions in accordance with the radiational conditions.

The gradual transfer of the subtropical stream during April, May and June is demonstrated in Fig. 3. A time profile of the direction and velocity of wind for five stations, located approximately along the 90°E meridian in the foothills and over the mountain range, is depicted here.

It follows from the data in Fig. 3 that strong winds are observed in April predominantly over the north of India; that is, the subtropical stream still almost maintains its winter position.

According to the mean cross-section for April along the 90°E meridian, the axis of the subtropical stream is located at the 29°N latitude. The position in May is already different. Strong winds are observed mainly over Lhasa and Khormu; in Calcutta the strong winds completely disappear; that is, the subtropical jet is displaced northwards to the upland.

As an example, a vertical cross-section at 15 h., 14 May 1958, along the line Trivandrum - SP-7 9Fig. 4) can be cited. Here, according to the data of the actual wind, the axis of the jet is located approximately at 35°N latitude, i.e., directly over the mountain range. North and South of the Himalayas and Tibet the wind velocities decrease sharply. The transfer to the summer position occurs in June. Toward the middle of that month, the strong winds over Lhasa have already completely disappeared. A subtropical jet stream is located over the northern periphery of Tibet.

In autumn, a displacement of the subtropical jet from north to south occurs in a similar manner. It can be seen on the time cross-section for September, October, and November (Fig. 5.) that the maximal frequency of strong winds moves gradually from the northern regions to the southern. If in September winds with 100 km/h velocity can be observed only in Zhatsyan and Khormu, in October they are already noticed also in Lhasa. In the middle of October, as mentioned by several investigators /14, 15, 16/, a sudden appearance of a jet stream over the north of India takes place.

Judging from a vertical cross-section of atmosphere along the 90°E meridian for October 1958, the axis of the subtropical jet can be observed on the average at 38°N latitude. Strong winds appear in November over Gauhati and Calcutta. Strong winds in November are also often observed north of Tibet.

Those are, however, already extratropical jet streams, the axis of which are located close to the 300 mb surface level, while maximal velocities at the axis of a subtropical are usually located close to the 200 mb surface level.
Thus, the sudden development of a subtropical jet stream over Northern India in October, as well as its disappearance in May, is related to seasonal displacements of a jet stream which here, as well as in other regions of the subtropical zone, is determined by general radiational conditions.

We would like to dwell longer on a single example of the evolution of a jet stream in a region of Central and Middle Asia in the period of 2–12 January 1959. Maps of equal velocity lines of the isobaric 300 mb surface, maps of diurnal variations of the temperature of the troposphere, and vertical cross-sections for that period were prepared.

According to the analyzed material, in the beginning of the period investigated, three jet streams were observed over the territory of Asia; two extratropical and one subtropical, which merged over the Far East, forming a wide zone of strong winds. The extratropical jet streams were branches of a jet which passed over the European territory of the USSR. One of the branches was located over the north of Western Siberia and later over Eastern Siberia in more southern latitudes. The second, more intensive, branch passed over the Caucasus, south of Middle Asia, and further along the northern frontier of the mountain range.

The equal-velocity maps demonstrate clearly that the presence of two jet streams north and south of the Himalayas and Tibet was not caused by a branching of the jet under the influence of the mountain range: a subtropical jet passed in the south and one of the branches of the extratropical jet did so in the north.

Invasions of cold in Middle Asiatic territory have periodically led to the strengthening of the extratropical jet stream on the northern periphery of the mountain ridges. Concurrently with very strong advection, the subtropical jet grew stronger as, for instance, from 2 January to 4 January, when the invasion of cold to the north of India here caused a significant increase of maximal velocities, from 140 to 250 km/h in the center of the jet and from 60–90 to 110–160 km/h at the 500 mb surface level. 24 hours later, after the air warmed up, the contrasts of temperature and the wind velocities correspondingly decreased over India.

During this period the southernmost branch of the extratropical jet stream has, as a result of displacement of the altitudinal trough and of the focus of cold to the east, also been displaced eastward; in the morning of 4 January it could not be detected any more over the Caucasus and toward 6 January strong winds disappeared completely over the territory of Middle Asia and Pamir. Two branches of the
extratropical jet stream still existed on 6-7 January in the noro eastern regions. In the following days, the southern branch of the extratropical jet was displaced in accordance with synoptic processes into the region of Tibet and Southeastern China and toward 10 January it merged with the subtropical jet at the 25-30ºN latitudes.

Besides the subtropical jet, during 10-14 January over Asia an extratropical jet stream was observed which passed markedly to the north of the upland. Only weak winds were detected over Middle Asia and the foothills of the Central Asiatic range. Only beginning with 15 January did a new extratropical jet begin to develop over the northern foothills of Tien-Shan as a result of synoptic processes.

Thus it also follows from the cited example that the Central Asiatic mountain range does not present an obstacle, dividing the jet stream into two parts - a northern and a southern one. The origins and development of extratropical and subtropical jet streams occur absolutely independently and are due mainly to the general seasonal radiational conditions and circulatory processes /7/.

The position of the subtropical jet during transitional seasons directly over the mountain range once more demonstrates convincingly that Tibet and the Himalayas are not obstacle that limit the passage of jet streams over them.

The process of merging of jet streams over the east of Asia originates under definite forms of meridional circulation and can take place in any other region of the subtropical zone. Due to physical-geographical conditions, however, the merging of extratropical and sub-tropical jet streams most frequently takes place over Eastern China and the Japanese islands.

As far as the influence of radiational warming up and cooling of air over Tibet on the seasonal position and intensity of the subtropical jet stream is concerned, according to our view this problem is not of a decisive nature. As we have seen, independently of the presence or the absence of mountain ranges, formation and seasonal displacements of subtropical jet streams take place in all regions of the earth almost identically.

In conclusion, we consider it necessary to dwell on a report, published recently by a group of authors /5/, dealing with the influence of mountain systems on the formation of a jet stream.

It contains mean monthly vertical cross-sections, drawn over lowlands (along the 64ºE meridian) and over the mountain systems of Middle Asia (along the 73ºE meridian)
for August 1956 and September 1957. On the basis of an anal-
ysis of the cross-section, the authors maintain that "an
crographically-conditioned jet stream corresponds to each
large mountain system: a maximum over Dzhambul – Arkit cor-
responds to the Tien-Shan mountain system, a maximum over
Osh – Sary-Tash corresponds to the Pamir-Altai system."

Through a thorough study of investigation data, par-
ticularly of the daily maps of baric topography of upper le-
vels, we have established that in August 1956 the axis of
the jet stream was displaced several times, together with
the cold invasions far to the south so far as a contrast of
temperature existed, independently of the presence or ab-
sence of a mountain range. The same can be ascertained
from the figures which accompany this report /5/. Over moun-
tains as well as over lowland, there can be observed a wide
zone, elongated southward, of great wind velocities, in which
displacement of individual jet streams took place during the
month, on both cross-sections for August 1956 (/5/, Figures
1 and 2).

Two closed equal-velocity lines of 20 and 25 m/sec
are represented over the mountain systems (Fig. 2); at the
40-42° latitude a closed center with 19 m/sec velocity can
be found; consequently, the presence of an independent ma-
ximum of the velocity of wind over the mountain crests is
stipulated not so much by the mountain range as by general
circulatory conditions, characteristic also for adjacent
lowland areas.

We do not tend to deny completely the influence of
large mountain systems on the character of wind in the tro-
posphere. It is obvious that the encounter of cold aerial
masses with mountainous obstacles of 4-5 km average height
and the development of large temperature contrasts is ac-
companied by some acceleration of wind at altitudes, parti-
cularly on the surface of the axis of a jet stream. It is
difficult to state at this time the order of magnitudes
of this additional acceleration of wind velocity. More com-
plete data are necessary for its determination. Yet, as
was demonstrated above the formation and evolution of a
jet stream is determined mainly by general radiational and
circulatory conditions.
