Abstract

A methodology based on the concept of variable string length GA (VGA) is developed for determining automatically the number of hyperplanes for modeling the class boundaries in GA-classifier. The genetic operators and fitness function are newly defined to take care of the variability in chromosome length. It is proved that the said method is able to arrive at the optimal number of misclassifications after sufficiently large number of iterations, and will need minimal number of hyperplanes for this purpose. Experimental results on different artificial and real life data sets demonstrate that the classifier, using the concept of variable length chromosome, can automatically evolve an appropriate value of $H$, and also provide performance better than those of the fixed length version. Its comparison with another approach using VGA is provided.

Keywords: Genetic algorithms, optimum hyperplane fitting, speech recognition, variable string length.
1 Introduction

Genetic Algorithms (GAs) (Goldberg, 1989) are randomized search and optimization techniques guided by the principles of evolution and natural genetics. They are efficient, adaptive and robust search processes, producing near optimal solutions and have a large amount of implicit parallelism. Application of GA to various pattern recognition problems is described in (Pal and Wang, 1996; Gelsema, 1995). One such application for designing a classifier is provided in (Bandyopadhyay et. al., 1995) where the searching capability of GA is exploited for the placement of a number of hyperplanes, say $H$, for approximating the decision boundaries. The method involves encoding the parameters of the hyperplanes in binary strings called chromosomes, in the feature space that yields minimum misclassification. It was demonstrated in (Bandyopadhyay et. al., 1995) that the GA based classifier, subsequently referred to as the GA-classifier, can be well applied to a variety of data sets having both non-overlapping, non-convex, and overlapping classes. Its recognition scores were found to be comparable to, sometimes better than, those of k-NN rule (for different values of $k$), Bayes maximum likelihood classifier and multilayer perceptron based classifier.

Note that estimation of a proper value of $H$ is crucial for a good performance of the algorithm. Since this is difficult to achieve, one may frequently use a conservative value of $H$ while designing the classifier. This first of all leads to the problem of an overdependence of the algorithm on the training data, especially for small sample size. In other words, since a large number of hyperplanes can readily and closely fit the classes, this may provide good performance during training but poor generalization capability. Secondly, a large value of $H$ unnecessarily increases the computational effort, and may lead to the presence of redundant hyperplanes in the final decision boundary. (A hyperplane is termed redundant if its removal has no effect on the classification capability of the GA-classifier.)

In order to overcome these limitations a method has been described here to automatically evolve the value of $H$ as a parameter of the problem. For this purpose,
the concept of variable length strings in GA has been adopted. Unlike the conventional GA, here the length of a string is not fixed. Crossover and mutation operators are accordingly defined. A factor has been incorporated into the fitness function that rewards a string with smaller number of misclassified samples as well as smaller number of hyperplanes. Let the classifier so designed utilizing the concept of variable string lengths be called VGA-classifier. Issues of minimum misclassification error and minimum number of required hyperplanes are theoretically analyzed under limiting conditions.

One may note the difference between the proposed classification method and the one described in (Srikanth et al., 1995), also using the similar concept of variable length strings. In the latter method, the decision boundary was modeled by a variable number of ellipsoids which have a higher degree of complexity than hyperplanes. The fitness function of the string was determined from the number of misclassified samples only. Thus there was no incentive for reducing the number of ellipsoids although a factor favouring more compact ellipsoids was introduced.

The experimental results on speech data, Iris data and two artificially generated data sets show that the proposed classifier is able to reduce the number of hyperplanes significantly while retaining the classification performance of the previous fixed length GA-classifier. A comparison with the classifier implemented using the operators of Srikanth et al. (1995) is also provided.

2 Genetic Algorithm with Variable String Length and the Classification Criteria

The concept of variable string lengths in genetic algorithms has been used earlier in (Smith 1980) to encode sets of fixed length rules. Messy genetic algorithm (Goldberg et al., 1989) also uses the concept of variable string lengths for constructing the chromosomes which may be under or over specified. Use of GA with variable string length has been made in (Harp and Samad, 1992) for encoding variable number of fixed length blocks in order to construct layers of a neural
network, and in (Maniezzo, 1994) for the genetic evolution of the topology and weight distribution of neural networks.

As mentioned in Section 1, the GA-classifier (Bandyopadhyay et al., 1995) with fixed $H$, and consequently fixed string length is rigid, and therefore has several limitations like overfitting of the training data and presence of redundant hyperplanes in the decision boundary when a conservative value of $H$ is used. To overcome these limitations, the use of variable length strings representing variable number of hyperplanes for modeling optimally the decision boundary therefore seems natural and appropriate. This would eliminate the need for fixing the value of $H$, evolving it adaptively instead; thereby providing an optimal value of $H$.

It is to be noted that in the process, if we aim at reducing the number of misclassified points only, as was the case for fixed length strings, then the algorithm may try to fit as many hyperplanes as possible for this purpose. This, in turn, would obviously be harmful with respect to the generalization capability of the classifier. Thus the fitness function should be defined in such a way, maximization of which ensures primarily the minimization of the number of misclassified samples and also the requisite number of hyperplanes.

While incorporating the concept of variable string lengths, one may note that it is necessary to either modify the existing genetic operators or introduce new ones. In order to utilize the existing operators as much as possible, a new representation scheme involving the consideration of the ternary alphabet set \{0, 1, \#\}, where \# represents the don’t care position, is used. For applying the conventional crossover operator, the two strings, which may now be of unequal lengths, can be made of equal length by appropriately padding one of them with \#s. However, some extra processing steps have to be defined in order to tackle the presence of \#s in the strings. Similarly, the mutation operator needs to be suitably modified such that it has sufficient flexibility to change the string length while retaining the flavour of the conventional operator. (As will be evident in the next section, the genetic operators are defined in such a way that the inclusion of \# in the strings does not affect their binary characteristics for encoding and decoding purposes.) The classifier thus formed using variable
string length GA (or VGA) is referred to as the *VGA-classifier*.

Therefore the objective of the *VGA-classifier* is to place an appropriate number of hyperplanes in the feature space such that it, first of all, minimizes the number of misclassified samples and then attempts to reduce the number of hyperplanes. Using variable length strings enables one to check automatically and efficiently, various decision boundaries consisting of different number of hyperplanes in order to attain the said criterion. The description of such a classifier is given in the next section.

### 3 Description of *VGA-classifier*

As evident from the previous section, although the sequence of the different operations for GA (as shown in Fig. 1) is applicable to VGA too, the operators themselves are newly defined for VGA. They are described here.

#### 3.1 Chromosome Representation and Population Initialization

The chromosomes are represented by strings of 1, 0 and # (don’t care), encoding the parameters of variable number of hyperplanes. In $\mathbb{R}^N$, $N$ parameters are required for representing one hyperplane. These are $N - 1$ angle variables, $angle_1^i, \ldots, angle_{N-1}^i$, indicating the orientation of hyperplane $i$ ($i = 1, 2, \ldots, H$ when $H$ hyperplanes are encoded in the chromosome), and one perpendicular distance variable, $p^i$ indicating its perpendicular distance from the origin. Let $H_{\text{max}}$ represent the maximum number of hyperplanes that may be required to model the decision boundary of a given data set. It is specified *a priori*. Let the angle and perpendicular distance variables be represented by $b_1$ and $b_2$ bits respectively. Then $l_H$, the number of bits required to represent a hyperplane and $l_{\text{max}}$, the maximum length that a string can have are

$$ l_H = (N - 1) \times b_1 + b_2 $$  \hspace{1cm} (1)  

$$ l_{\text{max}} = H_{\text{max}} \times l_H $$  \hspace{1cm} (2)
respectively.

Let string $i$ represent $H_i$ hyperplanes. Then its length $l_i$ is

$$l_i = H_i \cdot l_H.$$ 

Initial population is created in such a way that the first and the second strings encode the parameters of $H_{\text{max}}$ and 1 hyperplane respectively to ensure sufficient diversity in the population. For the remaining strings, the number of hyperplanes, $H_i$, is generated randomly in the range $[1, H_{\text{max}}]$, and the $l_i$ bits are initialized randomly to 1s and 0s.

### 3.2 Fitness Computation

As mentioned in Section 2, the fitness function (which is maximized) is defined in such a way that

1. a string with a smaller value of misclassifications is considered to be fitter than a string with a larger value, irrespective of the number of hyperplanes i.e., it first of all minimizes the number of misclassified points, and then

2. among two strings providing the same number of misclassifications, the one with the smaller number of hyperplanes is considered to be fitter.

The number of misclassified points for a string $i$ encoding $H_i$ hyperplanes is found as follows: Let the $H_i$ hyperplanes provide $M_i$ distinct regions which contain at least one training data point. (Note that although $M_i \leq 2^{H_i}$, in reality it is upper bounded by the size of the training data set.) For each such region and from the training data points that lie in this region, the class of the majority is determined, and the region is considered to represent (or be labeled by) the said class. Points of other classes that lie in this region are considered to be misclassified. The sum of the misclassifications for all the $M_i$ regions constitutes the total misclassification $miss_i$ associated with the string. Accordingly, the fitness of string $i$ may be defined as

$$fit_i = (n - miss_i) - \alpha H_i \quad 1 \leq H_i \leq H_{\text{max}}$$

$$= 0, \quad \text{otherwise},$$
where $n =$ size of the training data set and $\alpha = \frac{1}{H_{\text{max}}}.$

Let us now explain how the first criterion is satisfied. Let two strings $i$ and $j$ have number of misclassifications $\text{miss}_i$ and $\text{miss}_j$ respectively, and number of hyperplanes encoded in them be $H_i$ and $H_j$ respectively. Let $\text{miss}_i < \text{miss}_j$ and $H_i > H_j.$ (Note that since the number of misclassified points can only be integers, $\text{miss}_j \geq \text{miss}_i + 1.$) Then,

$$
\begin{align*}
\text{fit}_i &= (n - \text{miss}_i) - \alpha H_i, \\
\text{fit}_j &= (n - \text{miss}_j) - \alpha H_j.
\end{align*}
$$

The aim now is to prove that $\text{fit}_i > \text{fit}_j,$ or that $\text{fit}_i - \text{fit}_j > 0.$ From the above equations,

$$
\text{fit}_i - \text{fit}_j = \text{miss}_j - \text{miss}_i - \alpha (H_i - H_j).
$$

If $H_j = 0,$ then $\text{fit}_j = 0$ (from Eq. 4) and therefore $\text{fit}_i > \text{fit}_j.$ When $1 \leq H_j \leq H_{\text{max}},$ we have $\alpha (H_i - H_j) < 1$ since $(H_i - H_j) < H_{\text{max}}.$ Obviously, $\text{miss}_j - \text{miss}_i \geq 1.$ Therefore $\text{fit}_i - \text{fit}_j > 0,$ or, $\text{fit}_i > \text{fit}_j.$

The second criterion is also fulfilled since $\text{fit}_i < \text{fit}_j$ when $\text{miss}_i = \text{miss}_j$ and $H_i > H_j.$

### 3.3 Genetic Operators

Among the operations of selection, crossover and mutation, the selection operation used here may be one of those used in conventional GA, while crossover and mutation need to be newly defined for VGA. These are now described in detail.

**Crossover:** Two strings, $i$ and $j,$ having lengths $l_i$ and $l_j$ respectively are selected from the mating pool. Let $l_i \leq l_j.$ Then string $i$ is padded with #s so as to make the two lengths equal. Conventional crossover like single point crossover, two point crossover (Goldberg, 1989) is now performed over these two strings with probability $\mu_c.$ The following two cases may now arise:
• All the hyperplanes in the offspring are complete. (A hyperplane in a string is called complete if all the bits corresponding to it are either defined (i.e., 0s and 1s) or #s. Otherwise it is incomplete.)

• Some hyperplanes are incomplete.

In the second case let \( u = \) number of defined bits (either 0 or 1) and \( t = \) total number of bits per hyperplane = \((N - 1) * b_1 + b_2\) (from Eq. 1). Then, for each incomplete hyperplane, all the #s are set to defined bits (either 0 or 1 randomly) with probability \( \frac{\mu}{t} \). In case this is not permitted, all the defined bits are set to #. Thus each hyperplane in the string becomes complete. Subsequently, the string is rearranged so that all the #s are pushed to the end, or in other words all the hyperplanes are transposed to the beginning of the strings. The information about the number of hyperplanes in the strings is updated accordingly.

Mutation: In order to introduce greater flexibility in the method, the mutation operator is defined in such a way that it can both increase and decrease the string length. For this, the strings are padded with #s such that the resultant length becomes equal to \( l_{\text{max}} \). Now for each defined bit position, it is determined whether conventional mutation (Goldberg, 1989) can be applied or not with probability \( \mu_m \). Otherwise, the position is set to # with probability \( \mu_{m_1} \). Each undefined position is set to a defined bit (randomly chosen) according to another mutation probability \( \mu_{m_2} \). These are described in Fig. 2.

Note that mutation may result in some incomplete hyperplanes, and these are handled in a manner, as done for crossover operation. For example, the operation on the defined bits, i.e., when \( k \leq l \), in Fig. 2, may result in a decrease in the string length, while the operation on #s, i.e., when \( k > l \) in the figure, may result in an increase in the string length. Also, mutation may yield strings having all #s indicating that no hyperplanes are encoded in it. Consequently, this string will have fitness = 0 and will be automatically eliminated during selection.

Note that the operations defined here for designing the VGA-classifier are different from those used in (Smith 1980; Goldberg et al., 1989; Harp and Samad, 1992; Maniezzo 1994, Srikanth et al., 1995).
As in conventional GAs, the operations of selection, crossover and mutation are performed here over a number of generations till a user specified termination condition is attained. Elitism is incorporated such that the best string seen upto the current generations is preserved in the population. The best string of the last generation, thus obtained, along with its associated labeling of regions provides the classification boundary of the \( n \) training samples. After the design is complete, the task of the classifier is to check, for an unknown pattern, the region in which it lies, and to put the label accordingly.

4 Issues of Minimum \( \text{miss} \) and \( H \)

In this section we prove that the above mentioned \( \text{VGA-classifier} \) will provide the minimal misclassification error during training, for infinitely large number of iterations. At the same time it will require minimum number of hyperplanes in doing so.

For proving this we use the result of (Bhandari et al., 1996), where it has been established that for an infinitely large number of iterations, an elitist model of GA will surely provide the optimal string. In order to prove this convergence they assumed that the probability of going from any string to the optimal one is always greater than zero, and the probability of going from a population containing the optimal string to one not containing the optimal one is zero. Since the mutation operation and elitism of the proposed VGA ensure that both these conditions are met, the result of (Bhandari et al., 1996), regarding the convergence to the optimal string is valid for VGA as well.

Let us now consider the fitness function for string \( i \) (Eq. 3). Maximization of the fitness function means minimization of

\[
\text{miss}_i + \alpha H_i = \text{err}_i, \; \text{say}
\]

where \( \alpha = \frac{1}{H_{\text{max}}} \). Let us call this the error function \( (\text{err}_i) \).
Let for any size of the training data set \( n \), the minimum value of the error function as obtained by the VGA-classifier be

\[
\text{err}_{\min} = \text{miss}^o + \alpha H^o
\]

after it has been executed for infinitely large number of iterations. Then according to Bhandari et al. (1996), this corresponds to the optimal string. Therefore we may write

\[
\text{miss}^o + \alpha H^o \leq \text{miss} + \alpha H, \quad \forall \text{miss}, H. \tag{5}
\]

**Theorem 1:** For any value of \( H \), \( 1 \leq H \leq H_{\max} \), the minimal number of misclassified points is \( \text{miss}^o \).

**Proof:** The proof is trivial and follows from the definition of the fitness function (Eq. 3) and the fact that \( \text{miss}^o + \alpha H^o \leq \text{miss} + \alpha H, \quad \forall \text{miss}, H \) (Eq. 5).

**Theorem 2:** \( H^o \) is the minimal number of hyperplanes required for providing \( \text{miss}^o \) number of misclassified points.

**Proof:** Let the converse be true, i.e., there exists some \( H', H' < H^o \), that provides \( \text{miss}^o \) number of misclassified points. In that case, the corresponding fitness value would be \( \text{miss}^o + \alpha H' \). Note that now \( \text{miss}^o + \alpha H' > \text{miss}^o + \alpha H^o \). This violates Eq. 5. Hence \( H' \not\leq H^o \), and therefore \( H^o \) is the minimal number of hyperplanes required for providing \( \text{miss}^o \) misclassified points.

From Theorems 1 and 2, it is proved that for any value of \( n \), the VGA-classifier provides the minimum number of misclassified points for infinitely large number of iterations, and it requires minimum number of hyperplanes in doing so.

5 Implementation and Results

The experimental investigation presented in this section has two parts. In the first part, the effectiveness of VGA in automatically determining the value of \( H \) of the classifier is demonstrated for two sets of artificial data, a speech data and Iris data. The recognition scores of the VGA-classifier are also compared with
those of the fixed length \textit{GA-classifier}. Secondly, we compare our concept of using variable string lengths in GA with another similar approach (Srikanth et al., 1995). For this purpose we have implemented their different operators in our classification algorithm for the above mentioned four data sets.

The 2-dimensional artificial data sets, \textit{ADS 1} (Fig. 3) and \textit{ADS 2} (Fig. 4), consist of 557 and 417 points respectively belonging to two classes. The real life speech data, \textit{Vowel} (Pal and Majumdar, 1977), consists of 871 samples having three feature values (corresponding to the three formant frequencies) and six classes \{\delta, a, i, u, e, o\}. Fig. 5 shows the overlapping class structures in the first and second formant frequency plane. Iris data comprises 150 samples having four features and three classes with 50 points in each class.

A fixed population size of 20 is chosen. \textit{Roulette wheel strategy} (Goldberg, 1989) is used to implement proportional selection. As in an earlier investigation (Bandyopadhyay et al., 1995), \textit{single point crossover} is applied with a fixed crossover probability of 0.8. A variable value of mutation probability $\mu_m$ is selected from the range [0.01, 0.333]. Initially it assumes a high value, gradually decreasing at first, and then increasing again in the later stages of the algorithm. 200 iterations are performed with each mutation probability value. The values of $\mu_{m_1}$ and $\mu_{m_2}$ mentioned in Section 3.3 are set to 0.1. The process is executed for a maximum 3000 iterations. \textit{Elitism} is incorporated by replacing the worst string of the present generation by the best string seen upto the previous generation.

\textit{Performance of the VGA-classifier}

Tables 1 and 2 show the number of hyperplanes $H_{VGA}$ as determined automatically by the \textit{VGA-classifier} for modeling the class boundaries of the aforesaid four data sets when the classifier is trained with 10\% and 50\% samples respectively. Two different values of $H_{max}$ are used for this purpose viz., $H_{max} = 6$ and $H_{max} = 10$. The overall recognition scores obtained during testing of the \textit{VGA-classifier} along with their comparison with those obtained for the fixed length version (i.e., \textit{GA-classifier}) with $H = 6$ and 10 are also shown. (Note that $H = 6$ had been found to provide, on an average, good recognition scores in earlier experiments (Bandyopadhyay et al., 1995) with these data sets.) The scores
provided are the average values obtained over 5 different runs of the algorithms.

</table>

The results demonstrate that in all the cases, the VGA-classifier is able to evolve an appropriate value of $H_{VGA}$ from $H_{\text{max}}$. In addition, its recognition score on the test data set is found, on an average, to be higher than that of the GA-classifier. There is only one exception to this for the Vowel data when 10% of the samples is used for training (Table 2). In this case, $H_{\text{max}} = 6$ does not appear to be a high enough value for modeling the decision boundaries of Vowel classes with VGA-classifier. This is reflected in both the tables, where the scores for VGA-classifier with $H_{\text{max}} = 6$ are less than those with $H_{\text{max}} = 10$. 

12
In all the cases where the number of hyperplanes for modeling the class boundaries is less than 6, the scores of \textit{VGA-classifier} with $H_{\text{max}} = 6$ are found to be superior to those with $H_{\text{max}} = 10$. This is so because with $H_{\text{max}} = 10$, the search space is larger as compared to that for $H_{\text{max}} = 6$, which makes it difficult for the classifier to arrive at the optimum arrangement quickly or within the maximum number of iterations considered here. (Note that it may have been possible to further improve the scores and also reduce the number of hyperplanes, if more iterations of VGA were executed.)

In general, the scores of the \textit{GA-classifier} (fixed length version) with $H = 10$ are seen to be lower than those with $H = 6$ because of two reasons; overfitting of the training data and difficulty of searching a larger space. The only exception is with \textit{Vowel} for training with 50\% data where the score for $H = 10$ is larger than that for $H = 6$. This is expected, in view of the overlapping classes of the data set and the significantly large size of the training data. One must note in this context that the detrimental effect of overfitting on the generalization performance increases with decrease in the size of the training data.

As an illustration, the decision boundary obtained by the \textit{VGA-classifier} for \textit{ADS 1} when 10\% of the data set is chosen for training is shown in Fig. 3.

\textit{Comparison with the Method in (Srikanth et al., 1995)}

In this section an investigation is made to compare the performance of our concept of using variable string length in GA with that of another similar approach (Srikanth et al., 1995). For this purpose the operators used in (Srikanth et al., 1995) are implemented here for the same problem of pattern classification using hyperplanes, and the resulting performance is compared to those of our \textit{VGA-classifier} for the four data sets. Before providing the results, let us describe in brief the method of incorporating variable string lengths in GAs as proposed in (Srikanth et al., 1995).

The initial population is created randomly such that each string encodes the parameters of only one hyperplane. The fitness of a string is characterized by just the number of training points it classifies correctly, irrespective of the number of hyperplanes encoded in it. Among the genetic operators, traditional selection
and mutation are used. A new form of crossover, called *modulo crossover* is used which keeps the sum of the lengths of the two chromosomes constant both before and after crossover.

Two other operators are used in conjunction with the *modulo crossover* for the purpose of faster recombination and juxtaposition. These are the *insertion* and *deletion* operators. During *insertion*, a portion of the genetic material from one chromosome is inserted at a random *insert-location* in the other chromosome. Conversely, during *deletion*, a portion of a chromosome is deleted to result in a shorter chromosome.

Tables 3 and 4 show the comparative overall recognition scores during both training and testing of the *VGA-classifier* for the above mentioned four data sets when our approach of incorporating variable string length is compared with that adopted in (Srikanth et al., 1995) for 10% and 50% training data respectively. Other parameters are kept the same as before. Results shown are the average values taken over five different runs. For keeping parity, the VGA of Srikanth et al. is implemented such that no more than 10 hyperplanes are used for modeling the decision boundary of the data sets. The table also shows the number of hyperplanes, $H_{VGA}$, generated by the two methods for one particular run. Since the VGA of Srikanth et al. does not take care of the minimization of the number of hyperplanes while maximizing the fitness function, the $H_{VGA}$ is usually higher than that of our method.

As is evident from the tables, the performance of the classifier during training is better for the VGA of (Srikanth et al.) than the proposed one for all the data sets. The former, in general, uses more hyperplanes (of which many were found to be redundant on investigation), which results in an increase in the execution time. From the training performance, it appears that the operators used by Srikanth et al., are better able to recombine the subsolution blocks into larger blocks. However this is seen, in general, to result in comparatively poorer scores during testing. To consider a typical example in one of the cases for the *Vowel* data set when 10% data is used for training, 10 hyperplanes were used to provide a training recognition score of 97.47%, while the recognition score during testing fell to 68.95%.
It is also found that with increase in the size of the training data, the number of hyperplanes for modeling the class boundaries increase for the algorithm of Srikanth et al. Furthermore, as expected, the performance of all the classifiers is improved with increase in the size of the training data from 10% to 50%.

6 Conclusions

The problem of fixing the appropriate value of $H$ \textit{a priori} of the \textit{GA-classifier}
(Bandyopadhyay et al., 1995) has been resolved by using the concept of variable string lengths in genetic algorithm. New genetic operators are defined to deal with the concept of variable string lengths for formulating the classifier. The fitness function has been defined so that its maximization indicates minimization of the number of misclassified samples as well as the required number of hyperplanes. It is proved that for infinitely large number of iterations the method is able to arrive at the optimal number of misclassified samples and will need optimal number of hyperplanes for this purpose.

Experimental evidence for different percentages of training and test data indicates that given a value of $H_{\text{max}}$, the algorithm can not only be able to automatically evolve an appropriate value of $H$ for a given data set, but also result in improved performance of the classifier. The method of using variable string length in the algorithm of Srikanth et al. is also implemented in our VGA-classifier for comparison. Since the former method does not include a factor for reducing the number of surfaces, it is found to use more hyperplanes for constituting the decision boundary. This results in better training performance, mostly at the cost of reduced generalization capability. Additionally, the execution time is also more since no explicit effort is made to decrease the number of hyperplanes.

In this connection one may also note that the genetic operators and processing steps of the VGA described in this article entail very little disruption of those in the conventional GA. On the other hand this is not true for the method of Srikanth et al. which introduces two new processing steps viz., insertion and deletion, besides using a significantly different crossover operator. Further, the former method requires the specification of $H_{\text{max}}$, whereas such a constraint is not required for the latter one.
