A LOW-SPEED EXPERIMENTAL STUDY OF THE DIRECTIONAL CHARACTERISTICS OF A SHARP-NOSED FUSELAGE THROUGH A LARGE ANGLE-OF-ATTACK RANGE AT ZERO ANGLE OF SIDESLIP

By William Letko

SUMMARY

An investigation was made in the Langley stability tunnel to determine the directional characteristics of a sharp-nosed fuselage model through a large angle-of-attack range at zero angle of sideslip. The results showed that the fuselage experienced a large increase in yawing moment as the angle of attack increased, owing to asymmetrical disposition of the pair of trailing vortices emanating from the nose.

A ring or other roughness used on the nose caused (mainly by altering the vortex disposition) a large decrease in the yawing moment obtained at high angles of attack; in fact, for some angles of attack the yawing moment was of a sense opposite to that obtained with a plain fuselage. Although the reason that the ring altered the vortex disposition has not been established, the use of a ring may be convenient for studying the reversal of vortex disposition, and hence of load, which has been found to be self-induced and to occur aperiodically for some fuselages in other investigations.

INTRODUCTION

The interest in the forces and moments experienced by bodies of revolution inclined to the line of flight arose originally in connection with airships. During the era of the subsonic airplane, interest in the forces and moments experienced by bodies lagged somewhat because of the relatively minor contribution of the airplane fuselage to the aerodynamic characteristics of the total airplane configuration. The advent of missiles and supersonic aircraft where the body is a major component of the configuration has again focused interest on body characteristics, especially bodies of revolution at relatively high angles of attack.
At high angles of attack a wide discrepancy exists, of course, between the potential flow considered in reference 1 and the actual flow as shown by the experimental measurements presented in reference 2. The measurements of reference 2 showed that a pair of symmetrically disposed vortices were present behind the inclined airship model tested, and these might be expected to affect the body and body-and-fin characteristics appreciably at high angles of attack.

A phenomenon which, it was believed, could be attributed to an asymmetrical vortex disposition and to an aperiodic reversal of this vortex disposition occurred in the calibration tests of a conical pitch and yaw tube in the Langley stability tunnel. The pressures measured by the yaw orifices of the tube in pure pitch were unsteady at high angles of attack and reversed aperiodically. The aperiodic reversal of pressure was eliminated when a small modification was made to the nose of the pitch and yaw tube.

As a result of these tests with the pitch and yaw tube, it was believed that a sharp-nosed fuselage would have fluctuating forces and moments, or at least asymmetrical directional characteristics, at high angles of attack. Therefore, in order to determine the directional characteristics in pitch of a sharp-conical-nosed fuselage at high angles of attack and the effect of nose modifications on these characteristics, an investigation of a fuselage with a sharp conical nose was made in the stability tunnel. It was hoped that the results of the tests also might shed some light on the cause of the fluctuating pressures measured with the conical-nosed pitch and yaw tube.

The modifications to the basic model consisted of increasing the roughness of the nose by use of a ring made of \( \frac{1}{16} \) -inch wire located at various stations along the fuselage nose and also by covering a portion of the nose with carborundum grains. The effect of successively cutting off 1 and 3 inches of the nose was also investigated. Force measurements were made with a six-component balance system and the instantaneous yawing moment was also measured with a strain-gage balance. Some circumferential pressure measurements were made at one station on the model and the instantaneous differential pressure of two yaw orifices located in the nose of the model was measured. The results of the investigation are presented herein.

**SYMBOLS**

The forces and moments are referred to the body system of axes. The positive directions of forces, moments, and angular displacements are shown in figure 1.

- \( C_N' \) normal-force coefficient, \( N'/qA \)
- \( C_Y \) lateral-force coefficient, \( Y/qA \)
\(C_n\) yawing-moment coefficient, \(N/qAD\)

\(N'\) normal force, lb

\(Y\) lateral force, lb

\(N\) yawing moment, ft-lb

\(q\) dynamic pressure, \(\rho v^2/2, \text{lb/sq ft}\)

\(\rho\) mass density of air, slugs/cu ft

\(V\) free-stream velocity, ft/sec

\(A\) maximum cross-sectional area of model, 0.0608 sq ft

\(D\) maximum body diameter, 0.2783 ft

\(x\) distance along fuselage axis, measured rearward from fuselage nose, in.

\(r\) fuselage ordinate, measured normal to fuselage axis, in.

\((\text{fig. 2})\)

\(p\) local orifice pressure, \(\text{lb/sq ft}\)

\(\Delta p\) pressure difference between two yaw orifices located in fuselage nose, \(\text{lb/sq ft}\)

\(H\) total pressure of free stream, \(\text{lb/sq ft}\)

\(\alpha\) angle of attack of fuselage center line, deg

\(\beta\) angle of sideslip of fuselage center line, deg

**MODEL AND APPARATUS**

The fuselage used in the investigation was a body of revolution which was made of mahogany with a nose of brass. The fineness ratio of the fuselage was about 10.4. The nose portion of the fuselage was a cone of 15° apex angle. The coordinates of the fuselage are given in figure 2 and a photograph of the fuselage mounted in the tunnel is given as figure 3. Twelve equally spaced orifices were located on the circumference of the fuselage at a station 17.675 inches from the nose. The pressures at these orifices were measured with an alcohol manometer. An electrical pressure pickup was built into the brass nose portion of
the fuselage to determine the pressure difference between two yaw orifices located on the sides of the cone 2.125 inches from the apex. The fuselage was mounted through a strain gage to a strut which, in turn, was mounted on a six-component balance system. The strain gage was so arranged that it measured the instantaneous yawing moment of the fuselage about the fuselage axis. The forces and moments were measured with the balance system about the wind axes and then converted to the body-axes system.

The instantaneous pressure difference between the yaw orifices and the instantaneous yawing moment measured by the strain gage were photographically recorded by means of an oscillograph.

A small rectangular tail (6 inches by 3 inches) of aspect ratio 2 was used in conjunction with the fuselage for some of the tests. (See fig. 2.)

TESTS

The tests were made in the 6- by 6-foot test section of the Langley stability tunnel. Most of the tests were made at a dynamic pressure of 98.3 pounds per square foot, but some configurations were tested also at dynamic pressures of 64.3, 39.7, and 24.9 pounds per square foot. The maximum Reynolds number based on free-stream velocity and maximum fuselage diameter was approximately 500,000. The maximum Mach number was 0.26.

All tests were made with a dummy support strut and fairing in order to maintain symmetrical conditions near the body. Angles of attack were obtained by yawing the model in the tunnel. The angle-of-attack range was from 0° to 40° and, for most of the tests, the angle of sidlip was 0°. A few tests were made at -6° angle of sideslip for the same angle-of-attack range.

No wind-tunnel-wall or strut-tare corrections were applied to the data.

RESULTS AND DISCUSSION

The results of the investigation are presented in figures 4 to 16. Although both the static and the instantaneous yawing moments of the model were measured, most of the data presented are from the static measurements obtained with the balance system.
The variation of normal-force and yawing-moment coefficients (determined from balance-system readings) of the fuselage with angle of attack for zero sideslip angle is shown in figures 4 and 5, respectively, for several values of dynamic pressure. The normal-force coefficient shown in figure 4 increases with angle of attack as expected and, in general, increases with an increase in dynamic pressure for all the angles of attack tested. The yawing moment (fig. 5) is small and fairly constant up to about 15° angle of attack but increases rapidly above 15° and reaches a rather high maximum positive value at about 35° angle of attack. Repeat tests of the fuselage, which was a body of revolution, resulted in a yawing moment which consistently showed the same variation with angle of attack. With a perfectly symmetrical fuselage the variation would be expected to differ from test to test; that is, for one test the yawing moment might become more positive with angle of attack, whereas for the next test it might become negative, depending on initial trends. The tendency of the yawing moment of the fuselage to become more positive with angle of attack in the present tests was found to be associated with model characteristics rather than tunnel test setup because a test (data not presented) with the model inverted showed the yawing moment to be in the same direction relative to the fuselage. An increase in dynamic pressure generally decreased the values of yawing moment in the angle-of-attack range near the angle for maximum positive yawing moment; however, the effect is not consistent for all angles of attack. (See fig. 5.)

The cross Reynolds numbers corresponding to the dynamic pressures of these tests were fairly low so that the critical cross Reynolds number for a cylinder, based on maximum fuselage diameter, was attained at the highest dynamic pressure of the tests at about 25° angle of attack of the fuselage. It is believed, however, that even if the critical cross Reynolds number were reached at lower angles of attack, the general variations of the forces and moments with angle of attack would not be altered appreciably for the body tested.

Studies of records such as figure 10, which will be discussed later, showed that a reversal of lateral load with time, expected on the basis of previous tests, was not obtained in the present tests. The loading on the fuselage tended to reverse, however, when the angle of attack was increased above 35°. This tendency is indicated by the large decrease in yawing moment and an actual change in sign of the yawing moment at a dynamic pressure of 24.9 pounds per square foot and an angle of attack of 38°. (See fig. 5.) A change in direction of the lateral load and yawing moment relative to that obtained for the plain model was obtained, however, even at angles of attack as low as 20°, when a \( \frac{1}{16} \) -inch-diameter wire was wrapped around the nose portion of the fuselage to form a ring 1 inch from the apex. Figure 6 shows that the values of yawing moment are the same for ring-off and ring-on conditions up to an angle of attack
of 15°. Above this point, the yawing-moment coefficients for the plain fuselage become more positive with angle of attack, whereas the yawing-moment coefficients for the model with the ring on the nose show an opposite tendency and become negative as the angle of attack is increased. However, the absolute values of yawing moment are smaller for the ring-on condition. A study of the lateral-force coefficients presented in figure 6 indicates that the decrease in yawing-moment coefficients is caused by a reduction of lateral load and by a shift in the center of pressure of the lateral load.

A cursory tuft-probe examination at 35° angle of attack and very low speed showed that the vortex disposition along the plain fuselage was asymmetrical, even for positions very near the apex. The asymmetrical disposition of the vortices was responsible for the large values of yawing moment obtained with the plain fuselage at angles of attack above 15°. This initial asymmetrical disposition of the vortices was considerably altered and appeared reversed when the ring was placed on the fuselage nose. This altered disposition of the vortices accounts for the difference in the variations of the lateral-load and yawing-moment coefficients with angle of attack obtained for the plain model and those obtained for the model with ring on the nose. The ring decreased the absolute values of yawing moment, and a study of the lateral-force coefficients, presented in figure 6, indicates that this effect is due to a reduction of lateral load and, also, to a shift in center of pressure of the lateral load. The reversal in direction of the load at one section of the fuselage, caused by the ring, can readily be seen in figure 7, which presents a comparison of the pressure distributions for the ringed and the plain fuselage obtained around the periphery about 17\(\frac{1}{2}\) inches from the nose at a dynamic pressure of 64.3 pounds per square foot. The pressure distributions shown in the figure appear equal and opposite; this result indicates equal and opposite local lateral loads. The pressure differences measured by the two yaw orifices, which should give a good indication of the magnitude of the lateral load at the yaw-orifice location, indicates the reversal in direction of load caused by the ring; however, the pressure difference is not of equal magnitude for both conditions. (See fig. 8.) The ring, therefore, must affect the pressures at different lengthwise stations to different extents; such action, of course, would not only change the resultant loading but would also cause a shift in the center of pressure. The mechanism behind the change in initial vortex disposition, and hence in the load, brought about by the ring is not apparent; nevertheless, even when the model is at -6° sideslip angle, which gives the model a larger initial positive yawing moment, the ring is capable of causing a reversal in direction of the load at some angles of attack. (See fig. 9.) Results (not presented) of tests with the ring skewed about different radial axes in the plane of the ring did not have any apparent effect on the action of the ring in reversing the direction of load.
From the foregoing discussion, it appears that the effects of the ring not only can overshadow the model characteristics that initially caused the yawing moment to increase positively with angle of attack but also can overcome initial tendencies which are caused by an angle of sideslip of at least 6°, the largest sideslip angle tested.

Records of the instantaneous yawing moment and yaw-orifice pressure difference are presented in figure 10 for the plain fuselage and the fuselage with ring 1 inch from the nose. This figure shows that the moments and pressures were very unsteady at high angles of attack. However, since the natural frequency of the model and strain gage, determined experimentally to be 45 to 50 cycles per second, is the predominant frequency of the yawing moments recorded, it is unlikely that the records of the yawing moments obtained give a reliable indication of either the frequency or the amplitude of the forcing function. Although the natural frequency of the pressure pickup system was not determined, it appears to be very high, and any changes in pressure difference recorded (other than the high-frequency "hash" seen on most of the records) are believed to be more representative of the forcing impulses than the yawing-moment records. In figure 10(b), a square-wave variation can be seen in the record of pressure difference for the model with ring on at 36° angle of attack. In the present tests, this was the only instance in which this type of variation was obtained; however, although the magnitude of the pressure difference varied considerably, the sign did not change as it did in earlier tests of a plain conical-nosed pitot tube. This variation indicates a periodic shifting but not a complete reversal of the original vortex disposition. The differences in shape of the fuselage and the pitot tube rearward of the conical nose section (pitot tube had a straight, cylindrical portion of constant diameter) probably caused the results for the fuselage to be somewhat different from those expected on the basis of the tests of the conical-nosed pitot tube.

A comparison of the yawing moments obtained from balance readings with those obtained from strain-gage records (such as fig. 10) is shown in figure 11. (The values of yawing moment were obtained from the records used in the comparison by taking half the amplitude defined by two horizontal lines which bounded a majority of the wave traces of instantaneous yawing moment.) The variation of yawing moment with angle of attack is seen to be similar in each case. The differences in values determined by the two methods can probably be attributed mainly to differences in strut-tare values, which were not determined for either case.

The effects on the yawing moment of varying the location of the ring from \( \frac{1}{4} \) inch to 8 inches from the nose of the model can be seen in figure 12. As the distance of the ring from the nose increases, the
effectiveness of the ring in reducing the yawing moment appears to
decrease, and the first 3 inches of the nose apparently is the most
critical region so far as altering the load on the fuselage is concerned.
Tests of a fuselage having a short elliptical nose showed that the ring
had only a small effect on the yawing moment of the fuselage.

The effects of cutting 1 and 3 inches off the nose of the fuselage,
to form a blunt nose, can be seen in figure 13. The yawing moments were
of opposite sign to those obtained with the plain fuselage at angles of
attack above 25° and were small throughout the angle-of-attack range,
in contrast to those obtained with the plain fuselage.

In the course of the present investigation it was found that the
loading on the fuselage could also be reversed by increasing the rough-
ness of the nose with carborundum grains. Figure 14 shows that the
effect of the carborundum grains on the yawing-moment coefficient is
very similar to that of the ring.

In figure 15 is shown a comparison of the yawing moments of the
plain fuselage and of the fuselage with a rectangular tail of aspect
ratio 2. The general variation of yawing moment is the same for both
cases but, in the angle-of-attack range between 20° and 30°, the tail-
on configuration has a smaller yawing moment than the plain fuselage,
possibly because of the effects of the asymmetrical vortex distribution
on the tail. At higher angles of attack, the tail is probably at least
partly outside the region of influence of the vortices. The effects of
the ring on the tail-on configuration (fig. 16) are similar to those
obtained when the ring is used with the plain fuselage; however, the
ring is not quite as effective in reversing the moments as it was with
the plain fuselage.

CONCLUDING REMARKS

An investigation was made in the Langley stability tunnel to deter-
mine the directional characteristics of a sharp-nosed fuselage model
through a large angle-of-attack range at zero angle of sideslip. The
results showed that the fuselage experienced a large increase in yawing
moment as the angle of attack increased, owing to asymmetrical dispo-
sition of the pair of trailing vortices emanating from the nose.

A ring or other roughness used on the nose caused (mainly by
altering the vortex disposition) a large decrease in the yawing moment
obtained at high angles of attack; in fact, for some angles of attack
the yawing moment was of a sense opposite to that obtained with a plain
fuselage. Although the reason that the ring altered the vortex dispo-
sition has not been established, the use of a ring may be convenient.
for studying the reversal of vortex disposition, and hence of load, which has been found to be self-induced and to occur aperiodically for some fuselages in other investigations.
