Environmental Effects of Dredging
Technical Notes

The $K_{oc}$ of Nonpolar Organic Compounds in Sediment

Purpose

This technical note describes testing conducted to determine the partitioning of contaminants between sediment organic carbon and sediment interstitial water, assess the effects of sediment organic carbon upon $K_{oc}$ of selected PCBs and fluoranthene, and investigate the effect of time of contact between contaminants and sediment upon the value of $K_{oc}$.

Background

The U.S. Environmental Protection Agency is authorized to develop and implement sediment quality criteria (SQC) under section 304(a) of the Clean Water Act. SQC, when promulgated, will profoundly affect U.S. Army Corps of Engineers (USACE) dredging and disposal operations. Aquatic disposal of dredged material and selection of aquatic disposal sites will be based on SQC. Most SQC approaches currently under development involve a determination of the relationship between contaminant concentrations in sediment and biological effects on organisms exposed to the contaminated sediment. The USACE is presently investigating the link between contaminant levels in sediment and sediment geochemistry, as well as contaminant levels and effects in aquatic organisms. Knowledge of these interactions will provide the Corps with a means of evaluating the adequacy of proposed SQC approaches for estimating the potential impacts of dredged material disposal.

Introduction

Sediment organic carbon has been identified as the most important factor controlling partitioning of nonpolar organic contaminants between sediment and water (Karickhoff 1981). Studies have also shown that partitioning of nonpolar organic compounds is strongly related to the octanol-water partitioning coefficient of the compound (Karickhoff 1981). Sediment concentrations expressed on a total organic carbon (TOC) basis have been used to predict concentrations of nonpolar organic compounds in sediment pore water for use as sediment quality criteria by the U.S. Environmental Protection Agency (EPA) (Brannon and others 1990).

The EPA approach for predicting interstitial water concentrations is called the Equilibrium Partitioning (EP) approach. The EP approach allows estimation of the concentration of a contaminant in interstitial water from sediment contaminant concentrations normalized to organic carbon. The calculated interstitial water concentrations are then compared to water quality criteria. If the predicted sediment interstitial water concentration for a given contaminant exceeds its chronic water quality criterion, the sediment is categorized as contaminated (Brannon and others 1990).

Prediction of pore-water contaminant concentrations based on values of $K_{oc}$ (derived from $K_{ow}$, the octanol/water partition coefficient), total organic carbon content, and total contaminant concentration is likely to be incorrect. Measured pore-water concentrations have been shown to differ significantly from predicted values (Brannon and others 1991 and Steinberg, Pignatello, and Sawhney 1987). These differences can result from lack of equilibrium in the system or from factors related to organic matter composition (Gauthier, Seitz, and Grant 1987, Grathwohl 1990, Whitehouse 1985, and Schrap and Oppenhuizen 1989) or other sediment factors affecting sorption capacity (Mingelgrin and Gerstl 1983). The source of organic matter affects the partitioning behavior of nonpolar organic compounds and can result in large variability in measured values of $K_{oc}$. Gauthier, Seitz, and Grant (1987) reported that $K_{oc}$ can vary by a factor of 10 as a function of organic carbon aromaticity.

The laboratory experiments described in this technical note were designed to examine the relationships between sediment organic carbon and sediment interstitial water, the effects of sediment organic carbon on $K_{oc}$ of selected polychlorinated biphenyls (PCBs) and fluoranthene, and the effects of time of contact between contaminants and sediment on interstitial water partitioning.

Materials and Methods

Three sediments of varying TOC content were used in this study — Hamlet City Lake sediment (9.0 percent TOC) from Hamlet, North Carolina; U.S. Army Engineer Waterways Experiment Station (WES) reference soil (silt) (0.5 percent TOC) from Vicksburg, Mississippi; and sediment from Brown's Lake (2.8 percent TOC), a freshwater lake in Vicksburg, Mississippi. These sediments were
amended with 10 μg of either radiolabeled PCB 52 (2,2',5,5'-tetrachlorobiphenyl-UL-14C), PCB 151 (2,2',3,5,5',6-hexachlorobiphenyl-UL-13H), or fluoranthene (3-14C-fluoranthene) per g dry sediment weight using methods described previously (Brannon and others 1989). Sample bottles containing the sediments were stored upright to allow the sediments to settle and maintain a water cover. Samples were incubated for up to 180 days, with samples taken at intervals. At all sampling periods, concentrations of free and bound PCB 52, PCB 151, and fluoranthene were determined in the interstitial water using reverse phase partitioning (Landrum and others 1984).

Results and Discussion

Interstitial Water

Concentrations of free contaminants in interstitial water generally decreased or remained constant over time (Figure 1), even though the fraction of bound contaminant (contaminant complexed with dissolved organic carbon and microparticulates) remained essentially constant. For this reason, average values rather than time-dependent values of the bound contaminant fraction are given (Table 1). Decreases in concentrations of free contaminant are consistent with movement of nonpolar organic contaminants into interparticle organic matter pores over time (Brusseau and Rao 1989), resulting in decreased interstitial water concentrations.

Contaminant Koc Values

The ability of EP to predict interstitial water PCB 52, PCB 151, and fluoranthene concentrations in sediment was tested by comparing estimated Koc with measured Koc values. Koc is the partition coefficient for sediment organic carbon and is one of the key components used in EP for predicting interstitial water concentrations. Estimated Koc values were computed by substituting values of log Kow (octanol/water partition coefficient) for fluoranthene (5.5) (Tetra Tech 1985), PCB 52 (5.84), and PCB 151 (6.64) (Hawker and Connell 1988) in Equation 16 from Karickhoff (1981) that relates Kow to Koc. These calculations resulted in estimated Koc values of 5.09, 5.43, and 6.22 for fluoranthene, PCB 52, and PCB 151, respectively. Measured values of Koc were determined by dividing the TOC normalized sediment concentration of PCB
Figure 1. Concentrations of free PCB 151, PCB 52, and fluoranthene in interstitial water
52, PCB 151, or fluoranthene by the free interstitial water concentration of the respective compounds.

Measured log $K_{oc}$ values for PCB 151 ranged from approximately 4.2 to 4.9 and did not vary greatly between sediments (Figure 2). Furthermore, log $K_{oc}$ values for PCB 151 generally increased as exposure time in the sediment increased. Measured values of log $K_{oc}$ for PCB 151 were considerably lower than the estimated value.

Measured values of log $K_{oc}$ for PCB 52 and fluoranthene were in relatively close agreement for silt and Brown's Lake sediment, but were considerably higher (0.5-0.9 log units) in Hamlet Lake sediment (Figure 2). Measured values of log $K_{oc}$ for PCB 52 generally increased over time, similar to the results for PCB 151. Measured values of log $K_{oc}$ for PCB 52 were generally lower than the estimated value of log $K_{oc}$ except for Hamlet Lake sediment, which was slightly higher. Measured values of fluoranthene log $K_{oc}$ generally increased over time and were lower than the estimated value, at times by as much as a full log unit.

Measured log $K_{oc}$ decreased as sediment TOC content decreased for PCB 52 (Figure 3). Fluoranthene log $K_{oc}$ varied in the same manner as did PCB 52 until TOC reached 2.8 percent, when no further change was noted. PCB 151 varied only slightly with sediment TOC. Ideally, measured values of log $K_{oc}$ should remain constant as TOC changes if EP reliably predicts free interstitial water concentrations of nonpolar organic contaminants. This situation was observed only for PCB 151. The deviation of measured $K_{oc}$ values from estimated values and the dependence of measured PCB 52 and fluoranthene $K_{oc}$ values on sediment TOC concentrations indicate that predictions of free interstitial water contaminant concentrations from EP are not reliable for all compounds. This may result from factors such as clay content and clay species increasing the sorption capacity of the sediment over that of the organic matter, resulting in a decrease in measured $K_{oc}$.

Summary of Findings

Changes in $K_{oc}$ over time and among sediments depended upon the compound tested. Values of $K_{oc}$ measured using free interstitial water concentrations did not agree with estimated $K_{oc}$ for all compounds and in all sediments. Estimated values of $K_{oc}$ were generally substantially higher than measured values of $K_{oc}$. This was especially true of PCB 151 and fluoranthene in all sediments tested. For PCB 52, PCB 151, and fluoranthene, $K_{oc}$ also generally increased as incubation time increased, indicating that sorption processes that reduced the free concentration of these compounds in the interstitial water were continuing. PCB 52 and fluoranthene $K_{oc}$ also showed a marked dependence on sediment TOC concentration, generally decreasing as sediment TOC decreased.
Figure 2. Measured log $K_{oc}$ for PCB 151, PCB 52, and fluoranthene
The data indicated that a high degree of uncertainty exists for $K_{oc}$ values among sediments and compounds. This can result in either overestimation or underestimation of free interstitial water contaminant concentrations when using equilibrium partitioning, estimated $K_{oc}$ values, and TOC. Predictive methods with a high degree of uncertainty are not good regulatory tools. The factors affecting $K_{oc}$ must be better understood before rigid regulatory criteria are promulgated.
