## Abstract
As we increasingly rely on information systems to support a multitude of critical operations, it becomes more and more important that these systems are able to deliver Quality of Service (QoS), even in the face of intrusions. This report examines two host-based resources, a router and a web server, and presents simulated models of modifications that can be made to these resources to make them QoS-capable. Two different QoS models are investigated for the router. The first model implements a router with a feedback control loop that monitors the instantaneous QoS guarantee and adjusts the router's admission control of new requests accordingly. The second router model, called Adjusted Weighted Shortest Processing Time, queues data packets according to a weight which is dependent on their initial priority weight and the amount of time they have awaited service. For the web server, six queuing disciplines are simulated and analyzed for their efficiency in delivering QoS. These disciplines are compared on the basis of selected QoS measurements, including lateness, drop rate, time-in-system and throughput. We find that there is not necessarily one best queuing rule to follow; the appropriate selection depends on the needs of that web server.
Abstract

As we increasingly rely on information systems to support a multitude of critical operations, it becomes more and more important that these systems are able to deliver quality of service, even in the face of intrusions. One common class of cyber-attacks is the flooding of the system’s resources with requests for service. Thus, a reliable information system must be able to adeptly handle a large number of requests efficiently so that legitimate users may still use the system even as illegitimate users are attempting to flood the system.

This report examines two host-based resources and presents simulated models of modifications that can be made to these resources to make them capable of handling a number of requests. The two resources examined are a router and a web server.

There are two different quality of service models presented for the router. The first model implements a router with a feedback control loop that monitors the instantaneous quality of service guarantee and adjusts the router’s admission control of new requests accordingly. This model is compared to the basic router model that represents the typical configuration currently in use. The resulting comparison indicates that the feedback control loop is an improvement on the existing basic router. It decreases the time-in-system for data packets, and reduces packet loss, but does not fully utilize its bandwidth as well as a basic router with over-characterization.

The second router model suggests a new approach of queuing new requests for service. This approach is called Adjusted Weighted Shortest Processing Time and queues data packets according to a weight, which is dependent on their initial priority weight and the amount of time they have awaited service. The new approach is compared to two other queuing disciplines – Weighted Shortest Processing Time and First-Come First-Serve. We present data that indicate that the Adjusted Weighted Shortest Processing Time discipline improves the high time-in-system variance that exists in the Weighted Shortest Processing Time discipline, but it does not fairly allocate resources to both high and low priority data packets.

For the web server, six queuing disciplines are simulated and analyzed for their efficiency in delivering quality of service. These disciplines are Best Effort, Differentiated Services, Apparent Tardiness Cost, Earliest Due Date, Weighted Shortest Processing Time, and Weighted Only. These disciplines are compared on the basis of selected quality of service measurements, including lateness, drop rate, time-in-system, and throughput. We find that there is not necessarily one best queuing rule to follow; the appropriate discipline selection depends on the needs of that web server.

Introduction

Over the last decade, there has been an explosion in the usage of the Internet and other information systems for personal and official purposes. As we increasingly rely on information systems to support critical operations in defense, banking, telecommunication, transportation, electric power and many other systems, intrusions into these systems have become a significant threat to our society with potentially severe consequences [1-2]. Therefore, it becomes increasingly important that these systems are designed with a level of intrusion tolerance that enable them to continue functioning correctly and providing services in a timely manner even in the face of intrusions, that is, to maintain the quality of service (QoS) regardless of what intrusions occur.

Currently, information systems are designed using the “best-effort” model, in which their resources are available to use regardless of their state. This model leaves the system vulnerable to a depletion of its resources if it is sent a large number of service requests from malicious users, which will effectively deny the availability of resources to legitimate users. For example, massive amounts of data packets can be directed to a web server at a site, thereby making the web server unavailable to take legitimate service requests. Especially for mission-critical purposes, information systems must adopt a robust design to resist such malicious exploits and to provide quality of service (QoS) guarantees even in the face of intrusions.

The project described herein is the first part of a research project that will establish the QoS-centric model of stateful resource management for building intrusion-tolerant information systems. Unlike most existing efforts, which focus mostly on QoS of network resources, such as ATM networks and multimedia communication over communication channels, this project is focused on the QoS of host-based resources. Since host-based resources are involved in all applications, their QoS management is critical to the effectiveness of intrusion-tolerant information systems. The goal of this project is to develop a control-theoretic approach to intrusion tolerance from a QoS-centric resource management perspective in order to enable an information system to continue its correct functioning and maintain QoS in the face of intrusions.
The research described within fulfills the requirements of the first phase of this project. In this phase, we focused on two host-based resources – a router and a web server – which we then analyzed and used to establish and demonstrate the feasibility of the QoS and control-theoretic techniques. For each of these resources, we determined and analyzed the characteristics of processes requesting services from the resource, and defined the QoS metrics of the output performance of processes accordingly. We then selected reliable control trigger techniques to monitor and detect changes in these metrics and tested their performance in detecting intrusions. The next step was to develop probes and tests that reveal the state of the resources when significant changes in the QoS metrics of processes are detected, and test their performance in diagnosing the impact of intrusions on the state of the resources. We used these results to develop control mechanisms for the resources and then tested their performance in configuring resources and scheduling processes to maintain QoS even under the impact of intrusions. Finally, we implemented a prototype of the control loop integrating the reliable control trigger techniques and the robust control mechanisms, and tested the integration prototype for its overall performance of intrusion tolerance.

For the router, two control mechanisms were developed and analyzed. The first mechanism is one that utilizes a feedback control loop that is capable of monitoring the instantaneous QoS guarantee and adapting the admission control to reflect the router’s resource availability. This model is described in detail in Chapter 1. The second mechanism for the router is the modification of its service discipline. This new service discipline queues packets according to their weight, adjusting a packet’s weight based on the amount of time it has been waiting in the queue. In the event of congestion, lower priority packets are simply dropped. This mechanism is described in more detail in Chapter 2.

For the web server, we analyzed its performance under different queuing rules in an attempt to find the rule that would maximize the QoS of the server. Six queuing rules were analyzed, including the “best-effort” model currently employed to compare QoS of the new models to the existing one. The details of these rules and the results of these tests are described in Chapter 3.
Chapter 1: Router Quality of Service Model with Feedback Control

1-1 Router with Feedback Control Loop

One definition of QoS provided by Geoff Huston is “the ability to differentiate between traffic or service types so that the network can treat one or more classes of traffic differently than other types” [2]. According to this definition, QoS roots in the ability to provide differentiated services with regards to different service requirements.

Currently, a typical router operates using one of two QoS architectures – either Integrated Service (InteServ) or DiffServ. The difference between these two models is that InteServ delivers QoS on a per-flow basis, while DiffServ delivers QoS on a per-aggregate basis. In this context, flow is defined as “a distinguishable stream of related datagrams that results from a single user activity and requires the same QoS” [3], and aggregate is a superset of flow. An end-to-end bandwidth reservation is required to guarantee the bandwidth to individual flow.

The InteServ model is made up of predictive service, best effort service and link-sharing service. A reference framework is proposed for its implementation, under which are packet scheduling, packet classification, admission control, and path reservation. The per-flow based service differentiation provides a fine granularity to isolate flows from each other, and thus, achieve firm end-to-end service guarantees. However, flow-based technology is vulnerable to the scalability problem, especially in backbone networks, where there are millions of flows and the management overhead is extremely high.

Differentiated Service (DiffServ) [4], which provides its QoS guarantee on a per-aggregate basis, divides the network into domains. At the edge of the domain, traffic is classified into aggregates, policed and marked in accordance to given administrative policies. The core routers sitting inside the domain provide per-hop behavior (PHB) corresponding to the traffic aggregate. Compared to InteServ, DiffServ needs no end-to-end path reservation, pushing the complexity to the network edge. The coarser granularity
scales down the number of entities in the router, but it results in a weaker service guarantee compared to that of the per-flow based approach.

Due to the variable nature of network traffic, the characterization of performance requirements for traffic presents a significant challenge to providing QoS guarantees. Jim Kurose [5] writes about four classes of approach to providing a QoS guarantee. Some approaches – such as tightly controlled approaches – prevent a change in the traffic characterization. Others – such as approximate approaches, bounding approaches, and observation-based approaches – tolerate the change by taking into consideration the change in the peak rate. Tightly controlled approaches condition the traffic with a non-work conserving queuing discipline. To maintain consistent traffic characterization, the tightly controlled approaches may purposely block the arriving session while allowing the output link to be idle, causing potential low utilization of the output link. The other approaches all require some sort of traffic characterization, but their characterizations are approximate based on estimation or prediction. This inevitably leads to inaccuracies in the traffic characterization, which in turn leads to inappropriate deliveries of QoS. In both these approaches and tightly controlled approaches, there is always the possibility that the actual incoming traffic either overuses or underutilizes allocated resource. Overuse may result in delay increase and packet loss, which downgrades the QoS guarantee. Under-use results in the waste of service capacity. This suggests that a new approach is needed.

1-1.1 Overview of Router Design

The router model proposed in this chapter circumvents the question of how to accurately characterize traffic by not requiring accurate traffic characterization at all. This QoS model employs a performance-centric approach for QoS guarantee while best utilizing the available resource. In this approach, the router is able to monitor the performance output of the QoS guarantee. The traffic characterization of admission control may be varied to a significant degree as long as the router is able to guarantee the QoS with the allocated resource. The admission control admits enough traffic to maximize the utilization of allocated resource while satisfying the performance requirement. To support this approach, the router needs to be aware of the instantaneous
performance of QoS guarantee, and admission control needs to dynamically vary the traffic characterization. However, the QoS model of the average router lacks the adaptability needed to implement the proposed approach. In these models, the router is unaware of the instantaneous state of both the utilization of resources and how well the guarantee is provided. Also, the admission control policy of the routers is fixed during operation until it is manually changed. Thus, to implement our performance-centric approach, we must design a feedback control loop.

The designed control loop is made up of performance monitoring, the feedback controller, and adaptive admission control. The performance of the QoS guarantee is closely monitored according to the two important performance metrics for a router: timeliness and precision [6]. In the context of a router’s QoS, the timeliness is measured by the packet delay. Knowing that the queuing delay is the only controllable delay component in the scope of this study, we take the time-in-system of the packet’s wait in the queue as the measure of timeliness. The precision of the router is measured by the packet loss rate.

The router should guarantee the timeliness and precision to all admitted packets. If the router is running out of its service capacity, the packets are denied service upon arrival to avoid deteriorating either the timeliness or packet loss of the router. Admission control is customized with the ability to dynamically characterize the incoming traffic, and traffic is admitted against this dynamic traffic profile. A feedback controller parses the performance output, calculates the adjustment to the traffic characterization, and feeds the adjustment to the admission control for actuation.

The design of the performance-centric QoS model is carried out in two steps. First, we design a basic QoS model, which is capable of basic service differentiation, resource allocation and fixed rate admission control. Then, we introduce a feedback control loop to realize the performance-centric QoS guarantee.
1-1.2 Design Specification

Before the feedback control loop can be applied to implement the performance-centric QoS guarantee approach, a QoS model capable of basic service differentiation and resource allocation is designed, as shown in Figure 1-1. The basic QoS model provides two classes of service – high priority service and low priority service. The high priority service is the traffic with timeliness and precision requirements. The low priority service accommodates applications tolerable to both delay and packet loss. Our primary interest is to guarantee the QoS to the high priority traffic. To simplify the study, we assumed that the packets of each type of service have been tagged before they arrive at the router, eliminating the needs for packet classification and marking. At each input port, the admission control characterizes and conditions the high priority traffic using the token bucket model. In the token-bucket model, allowed traffic is characterized by two parameters – token rate \( r \) and bucket depth \( p \). \( r \) dictates the long-term rate of admitted traffic, and \( p \) specifies the maximum burst size of admitted traffic. The packets beyond the allowed traffic characterization are discarded immediately upon arrival. An in-depth discussion and introduction of the token bucket model are covered in Parekh and Gallager’s work [7]. At each output port of the router, the packets are accepted into a queuing buffer and scheduled for transmission with a priority queuing discipline. The priority queue discipline enforces the bandwidth allocation between two classes of service based on priority. Two queues, a high priority queue and a low priority queue, are provided to contain the packets. The high priority queue and low priority queue are dedicated to serve exclusively the high priority traffic and the low priority traffic.

---

Figure 1-1. The basic router QoS model
respectively. A certain amount of buffer is allocated to both the high priority and low priority queue to tolerate the burst of traffic. With the priority queuing discipline, the output link always serves the packets in the high priority queue as long as it is not empty. The packets in the low priority queue obtain the service only when the high priority queue is empty. Within each queue, the packets are served in first-come-first-serve (FCFS) order. As a result of priority queuing, in this study, the high priority traffic is actually assigned the full capacity of the bandwidth.

Figure 1-2. The QoS model with feedback control.

Building on the basic QoS model, we introduce the feedback control loop, as shown in Figure 1-2, to implement the performance-centric QoS guarantee to high priority traffic. The feedback control loop is made up of two components – a performance probe and a controller. The performance probe monitors the queue length of the high priority queue at the output port. As we know from Little’s Law, the time-in-system of a packet is proportional to the queue length. By knowing that the queue length is less than the capacity of the queue by at least one maximum packet length, we can deduce that no packet loss is happening at the moment. As a result, the instant queue length of the high priority queue reflects both the timeliness and precision of the QoS guarantee of high
priority traffic. The time-in-system can be bounded and the packet loss can be prevented by bounding the queue length. An upper bound is set for the high priority queue length. The error $e$ is calculated from equation

$$e = l - S$$  \hspace{1cm} (1-1)$$

where $l$ is the actual queue length of queue at the moment and $S$ is the upper bound of the queue length. A Proportional-Integral-Differential (PID) controller [8] constantly reads the error $e$ and calculates the adjustment $\mu$ with the PID equation

$$\mu = K_pe + K_i\int e\,dt + K_d\frac{de}{dt}$$  \hspace{1cm} (1-2)$$

where $K_p$, $K_i$ and $K_d$ are proportional gain, integral gain and differential gain respectively, and are all non-negative constants.

The adjustment for the rate of admission of packets is fed to the admission control at each input port either to scale up or to scale down the admission rate of traffic. To achieve fair admission control, the admission rate adjustment is split up among input ports in proportion to the actual rate of incoming high priority traffic at each input port. The input port contributing the most to the increase of queue length receives the largest adjustment to its admission rate. For example, in case of a router with only two input port, the total adjustment is split up between two input ports using equations

$$\mu = \mu_x + \mu_y$$  \hspace{1cm} (1-3)$$

and

$$\frac{\mu_x}{\mu_y} = \frac{X^*}{Y^*}$$  \hspace{1cm} (1-4)$$

where $\mu_x$, $\mu_y$ are the adjustments allocated for the two input ports respectively, and $X^*$, $Y^*$ are the actual rate of incoming high priority traffic at the two input ports respectively. The divided adjustment is applied to bring down the token rate $r_i$ of the token bucket at the corresponding input port for $\mu_i$ units, that is

$$r_i' = r_i - \mu_i$$  \hspace{1cm} (1-5)$$

where $r_i$ and $r_i'$ stand for the token rate of input port $i$ at current moment and next moment respectively, and $i \in \{\text{all input ports}\}$. By adjusting the token rate $r_i$, admission control is able to scale up and down the amount of traffic actually admitted. When the
actual queue length exceeds the upper bound, the PID controller decreases the token rate to slow down the incoming traffic, tending to bring the actual queue length back to within upper bound.

1-2 Simulation and Experiment

To examine performance of the QoS guarantee with feedback control, the router QoS model with feedback control (“feedback” model hereafter) and the basic router QoS model without feedback control (“basic” model hereafter) are simulated and compared. The simulation and experiment are accomplished in OPNET Modeler of OPNET Technologies, Inc.

1-2.1 Simulation Models

![Figure 1-3. Simulated router with “basic” QoS model.](image)

The simulated router of the “basic” QoS model, shown in Figure 1-3, is composed of two input ports, port 0 and 1, and only one output port, with an IP forwarder module
simulating the function of forwarding the packets from input ports to output port. Each input port is associated with three traffic sources. In this study, we assume that all packets come from either one of two input ports and go to the only output port. A priority based queuing system is modeled at the output port. The queuing system is made up of a high priority queue and a low priority queue with limited capacity, and uses a priority queuing discipline. A packet sink is connected with the queuing module to collect the output packets. The token bucket of the admission control has a fixed token rate, which is unchanged during the whole simulation.

Each traffic source generates a traffic stream with a certain QoS requirement. Two types of traffic are considered in this simulation – high priority and low priority. The priority of traffic is marked in the Type-of-Service (ToS) field of the IP header of belonging packets. In this study, ToS is set to 7 to indicate high priority traffic, and 0 for low priority traffic. Since it is a general practice to assume the random arrival process as a Poisson process, we specify that the inter-arrival time of packets is exponentially distributed. Similarly, the size of packets generated by each source assumes normal distribution. The expectation of the rate (bits per second) of the incoming traffic generated by each source can be estimated by the ratio of mean packet size and mean inter-arrival time.
The simulated router that utilizes the “feedback” QoS model (Figure 1-4) is designed by adding to the “basic” router model an additional feedback control loop composed of a queue length probe, a PID controller, and admission control. Ideally, the probe should monitor the queue length continuously. Since the arrivals and departures of packets at the queue are discrete events, the queue length may undergo extreme and abrupt variation. In the simulation, to avoid the high frequency vibration of the token rate and to maintain the relative stability of the admission policy, the queue length is sampled with a 2s interval, which is selected intuitively. To better bind the queue length, the maximum value of the queue length in the interval is taken as the sample value of that interval. For each admission control, the token rate starts with an initial level $R$. The PID equation is simplified as the equation

$$
\mu = K_p e_k + K_i e_k (T_k - T_{k-1}) + K_d (e_k - 2e_{k-1} + e_{k-2})/(T_k - T_{k-1})
$$

(6)

with the integral and differential terms replaced with rectangular integration and linear approximation of differentiation respectively. In the above equation, $e_i$ stands for the
error at time $T_i$, and $T_{i-1}$ stands for the last measure moment previous to $T_i$. The adjustment splitter takes the real time statistic measure of the actual admission rate of high priority traffic from both input ports to allocate their adjustments.

1-2.2 Experiment

The experiments for all router models are carried out under both “heavy” and “light” traffic conditions. The heavy traffic condition simulates overwhelming high priority traffic, in which the rate exceeds the capacity of output link. All six traffic sources generate packets with size normally distributed, with mean 10,000 b and variance 2,000 b. The setting of the six traffic sources and rates of generated traffic are shown in Table 1-1. Source 0, 1, 3, and 4 generate high priority traffic, and source 2 and 5 generate low priority traffic. Each input port generates high priority traffic at an average rate of 350,000 b/s and low priority traffic at 150,000 b/s. The total high priority traffic is generated at 700,000 b/s, which is above the bandwidth of the output link.

The configuration for the light traffic condition is summarized in Table 1-2. Each input port generates high priority traffic at a rate of 150,000 b/s and low priority traffic at a rate of 150,000 b/s. Total high priority traffic generated by both input ports is 350,000 b/s, which is lower than the bandwidth of the output link.

As mentioned previously, our primary concern is the timeliness and precision of the QoS guarantee to high priority traffic, and its utilization of allocated bandwidth. Thus, we collect the data concerning the time-in-system and the packet loss rate of the high priority queue. We also collect throughput, which is the output rate of traffic, to reflect the utilization of the bandwidth.

The experiment is designed to compare admission control schemas of the feedback router, the basic router with over-characterization (“basic (over)”), and the basic router with under-characterization (“basic (under)”). The configurations of the routers of each schema are shown in Table 1-3. The over-characterization admission control characterizes the traffic with a loose upper bound, allowing great variance in the rate of incoming traffic. In the basic (over) model, the token rates at both input ports are set to 450,000 b/s, allowing most of the traffic to enter the router. The under-characterization admission control characterizes the traffic with a stringent bound. The basic (under) model sets the token rates at both input ports to 250,000, which is lower than the average rate of incoming traffic, with all other settings exactly the same as basic (over) model.

To make the feedback router comparable to the basic routers, it shares the same setting as the basic models, except that it has a feedback control loop and variable token rates for both admission controls. The proportional, integral and differential gains $K_p$, $K_i$ and $K_d$ of the feedback router are selected empirically through three sets of preliminary simulation runs respectively. The criterion for selecting these parameters is the rate of convergence and level of oscillation of the token rate. A quick convergence with modest oscillation is preferable. For all of these preliminary simulation runs, the incoming traffic is set to heavy traffic conditions. The feedback router under observation sets its parameters, except for $K_p$, $K_i$ and $K_d$, to the configuration shown in Table 1-3.
A set of four simulation runs was conducted to select $K_p$, with $K_p$ set to 5, 1, 0.2 and 0.04 respectively, and $K_i$, $K_d$ both set to 0.2. By visually inspecting the token rate plot as shown in Figure 1-5, we observe that when $K_p$ is equal to 1, the traffic conditioner converges fast to a stable level with modest oscillation. We assume 1 as the value of $K_p$.
We ran another set of four simulations to determine the integral gain $K_i$. $K_i$ is set to 5, 1, 0.2, and 0.04 respectively, with $K_p$ fixed at 1 and $K_d$ set to 0.2. By inspecting the token rate plot (Figure 1-6), we observe that when $K_i$ is equal to 0.2, the token rate converges fast and exhibits modest oscillation. We take 0.2 as the value of integral gain.
Figure 1-7. Token rates with different differential gain values.

The differential gain, $K_d$, is determined in a similar way. $K_d$ is set to 5, 1, 0.2, and 0.04 respectively, with $K_p$ equal to 1 and $K_i$ equal to 0.2. By visually examining the plot of the token rate (Figure 1-7), we see that when $K_d$ is equal to 0.2, the token rate exhibits fast convergence and modest oscillation. We take 0.2 as the value of differential gain.

The upper bound of queue length is also determined through a set of preliminary simulation runs. Three runs are conducted with the upper bound set to 90,000 b, 80,000 b, and 70,000 b respectively, and the other parameters are set to follow the configuration shown in Table 1-3. The selection of the queue length upper bound is based on how it affects the packet loss and throughput of high priority traffic. The number of packet losses for an upper bound of 90,000 b, 80,000 b, and 70,000 b are 232, 107 and 43 packets respectively. The throughput is plotted in Figure 1-8, and inspection of this figure indicates that there is a trade-off between the packet loss and throughput. When the queue length upper bound approaches the queue capacity, the packet loss and throughput
increase at the same time. When the upper bound is set to 80,000 b, the packet loss and throughput are both moderate, so we take 80,000 b as the upper bound of queue length. In total, there are three simulation runs conducted with different QoS models. Each simulation run lasts for 180 seconds. Simulation results are collected and compiled.

**Figure 1-8.** Throughput of high priority traffic with different queue length upper bound.

### 1-3 Results and Discussion

We now compare the feedback router to the basic model with over-characterization and the basic model with under-characterization in turn. The comparisons are carried out in terms of three performance measures: time-in-system, packet loss and, throughput.
1-3.1 Heavy Traffic Condition

The feedback router losses total 107 packets, accounting for 1% of all admitted high priority traffic, while the basic router with over-characterization loses 1,299 packets, accounting for 10.3% of admitted high priority traffic. From these results, it is evident that the feedback router greatly improves the precision performance of the QoS guarantee. The feedback router also exhibits a shorter bounded time-in-system than that of the basic router with over-characterization admission control. In addition, the time-in-system of the feedback router is well bounded.

However, the throughput of the feedback router is slightly lower than that of the basic router with over-characterization. The latter almost fully utilizes all of its bandwidth allocation. The basic router with under-characterization condition loses no packets during the whole simulation and achieves lower time-in-system than that of feedback router. It does this, however, at the price of lower bandwidth utilization than that of feedback router. The results of timeliness and throughput for all three models are shown in Figure 1-9 and Figure 1-10 respectively.

![Figure 1-9. Time-in-system of feedback router and basic routers (heavy traffic).](image-url)
1-3.2 Light traffic condition

Figure 1-10. Throughput of feedback router and basic routers (heavy traffic)

Figure 1-11. Time-in-system of feedback router and basic routers (light traffic).
Under light traffic conditions, the three simulated routers exhibit similar behaviors. The time-in-system of the high priority traffic is low, as shown in Figure 1-11. All three routers achieve very similar throughput of high priority traffic. Finally, in all three routers, there are no packets lost.

The throughput results for the feedback router and the basic router (both with over-characterization and under-characterization) are shown in Figure 1-12.

![Figure 1-12. Throughput of feedback router and basic routers (light traffic).](image)

1-3.3 Conclusions

Under heavy traffic conditions, the feedback router is an improvement over the basic router. Compared to the rigid admission control of over-characterization, adaptive admission control with feedback control improves both the time-in-system and packet loss. Compared to rigid admission control of under-characterization, adaptive admission control with feedback control improves the utilization of the bandwidth. There is a tradeoff between the benefit of high utilization of the bandwidth and the risks of losing packets and increased time-in-system. With fixed bandwidth and buffer allocation, the higher the bandwidth utilization, the greater possibility there is of losing packets and the
longer time-in-system will be. The adaptive admission control dynamically balances the needs of high resource utilization and the goals of timeliness and precision to achieve the QoS guarantee while maximizing the use of resources.
Chapter 2: Router Service Differentiation by Adjusted Weighted Shortest Processing Time Service Discipline

2-1 A-WSPT Service Discipline

Today’s Internet employs a simple service model, named best effort, which employs a First-Come-First-Serve (FCFS) service discipline to serve the packets at Internet routers. At the output interface of router, a single queuing is maintained in the buffer and the packets are served in a first-come-first-serve fashion. The packets are dropped at the tail of the queue if the buffer is full. The network allocates its resource to its users as best as it can, making no commitment with regard to service quality, and “all packets are treated the same without any discrimination or explicit delivery guarantees.” [9] The success of the Internet is largely contributed to the simplicity of the best effort service model. It is the end users’ responsibility to maintain the state of connections. The management overhead in routers is low and cheap. The applications don’t ask for permission before beginning transmission. No admission control is needed.

Using an FCFS service discipline can, however, lead to performance problems. When congestion occurs, the queuing delay increases along with the queue length, and the packets are discarded at the tail of queue when the queuing buffer reaches its capacity. Most importantly, the resource of the router is allocated on a first-come-first-service basis, neglecting the service requirement of individual traffic entities and treating all the packets the same way.

Recent years have witnessed considerable research to extend the Internet architecture to deliver QoS to support different levels of services. The two most significant of these efforts are InteServ and DiffServ, which were briefly discussed in Chapter 1. However, both service models introduce great complexity in implementation and suggest substantial and radical changes to the existing infrastructures.

The scheduling mechanism employed in a service discipline is a key component in realizing different levels of services. Therefore, we argue that different levels of services can be provided by replacing FCFS with a different service discipline without
making major changes to internal functions of existing routers. Several service disciplines have been proposed, such as PGPS, Delay-EDD, Jitter-EDD, and WFQ. A thorough survey of the literature is available in Gevros, 2001 [9].

In this chapter, we describe a new service discipline called Adjusted Weighted Shortest Processing Time (A-WSPT), which provides services at different levels while retaining much of the simplicity of the FCFS service discipline. In A-WSPT, the traffic stream with a higher weight is treated with lower delay and less packet loss. Packets with a lower priority are discarded in the event of congestion. The only requirement of implementing this discipline is that each traffic flow must be assigned a weight to indicate its relative importance. A-WSPT builds on the ideas found in the Weighted-Shortest-Processing-Time (WSPT) rule. WSPT was designed to minimize the total completion time of a finite number of jobs that were ready at beginning time. WSPT itself is just an extension of the Shortest Processing Time (SPT) rule that associates a weight factor with each job. The priority of each job is given by the ratio of the weight factor to the processing time of the packet. The jobs are served in a decreasing order of the priority [10]. A-WSPT further extends the WSPT to a design that will work in a networking context. The weight is assigned on a per-flow basis to indicate the priority of flow. The priority of individual packets is calculated with the weight of the traffic stream.

Another important issue addressed by the A-WSPT service discipline is the large variance in delay caused by the dynamic service order of WSPT under the condition of infinite arrivals. In WSPT, arrival packets of higher priority are inserted before those of lower priority in the service queue. This dynamic insertion may defer the service to low priority packets for an indefinite period of time. In some case, low priority packets suffer extreme long delay, or are dropped entirely. As part of A-WSPT, we introduce an exponential compensation to penalize the long delay of individual packets. The exponential compensation is based on the intuition of scaling up the priority when the delay increases.

A queuing system with the A-WSPT service discipline can be conceptualized as a dynamic priority queuing system with infinite arrivals, in which the packets arrive at the router without termination in the duration of observation. The priority of each packet is
dynamically determined, and the service order is constantly refreshed. The introduction of the A-WSPT rule is carried out in two steps.

First, the WSPT is customized to the per-flow context. A weight factor is associated with each traffic stream to claim its service priority. The individual packets inherit the weight from the associated traffic streams. The priority of each packet is determined by both the processing time of that packet and the weight of the traffic stream, as is given by equation

\[ p_i = \frac{w}{t_i}, \]

where \( p_i \) is the priority of packet \( i \), \( w \) is the weight associated with the traffic stream it belongs to, and \( t_i \) is the service time of that packet. Service time \( t_i \) is given by the equation

\[ t_i = \frac{S_i}{\Phi}, \]

where \( S_i \) denotes the size of the packet, and \( \Phi \) denotes the bandwidth of the link. Thus, the priority of the packet can be expressed as equation

\[ p_i = \frac{w \cdot \Phi}{S_i}. \]

The packet is accepted as long as there is enough space available in queuing buffer. When the remaining queuing buffer is not sufficient for the arrival packet, a preemptive packet dropper is used to drop packets. The preemptive dropper compares the priority of arrival packet with that of the packet with lowest priority. If the arrival packet has lower priority, it is dropped. Otherwise, the packet of lowest priority is dropped from the queue. The comparison is carried iteratively, until there is enough space to accommodate the arrival packet.

Packets are stored in the queue in the order of decreasing priority, so that there is always \( p_k > p_l \) as long as \( k < l \), where \( k \) and \( l \) denote the position of packets in the queue respectively. The packet of highest priority is always sent out immediately whenever the server is available. Those with lower priorities are held in the buffer until they are either transmitted or otherwise discarded. The order of packets is dynamically refreshed to reflect the arrival of packets. When an arrival packet is accepted, it is inserted into the
queue solely based on the value of its priority. The packet $i$ is inserted between adjacent packets $m$ and $n$ so that there is always $p_n < p_i < p_m$, as described in Figure 2-1.

![Figure 2-1. Service order and the insertion of the packet.](image)

Second, the packet priority is adjusted to penalize the delay. The insertion of arrival packets may cause serious delay in queue to some packets with low priority. To contain long delay caused by dynamic insertion of packets, the priority of a packet is multiplied by the exponential compensation of delay, which is given by

$$ P_i = \frac{\lambda P}{e^{\frac{\lambda P}{T_i + P}}} $$

where $T_i$ stands for the delay in queue of packet, $\lambda$ and $\gamma$ are constants scaling the exponential compensation, and $P$ is the average processing time of incoming packets. The A-WSPT priority of the packet, then, is given by

$$ p_i = \frac{w_i \Phi}{S_i} e^{-\frac{\lambda P}{T_i + P}} $$

The compensation increases to 1 when the delay increases from 0 to infinite. The longer the delay is, the greater the compensation will be. The value of exponential compensation is solely determined by the delay, given $\lambda$, $\gamma$ and $P$. The average processing time is given as a constant empirically. The exponential compensation varies between some initial level $\alpha$ and maximum 1. The initial level is the compensation value when the delay is zero, which is given by equation

$$ \alpha = e^{-\frac{\lambda P}{0 + P}} $$

with $T_i$ equal to 0.
The parameters $\lambda$ and $\gamma$ can be determined by setting the upper bound of tolerable delay in terms of $n$ times the average processing time $P$ and corresponding compensation value $\beta$. That is when $T_i$ rises from 0 to $nP$, the compensation will increase from $\alpha$ to $\beta$. By solving the equations

$$\alpha = e^{\frac{\beta P}{nP+P}}$$

and

$$\beta = e^{\frac{\lambda P}{nP+P}},$$

we have

$$\lambda = -\frac{\ln \alpha \ln \beta}{\ln \alpha - \ln \beta}n,$$

and

$$\gamma = \frac{\ln \beta}{\ln \alpha - \ln \beta}n.$$

The priority of packets in the queue is constantly refreshed to reflect the delay each packet has experienced. After each refresh, the queue is dynamically resorted to maintain a service order of decreasing priority.

Services are differentiated between traffic streams by assigning different weights. According to the definition of packet priority, the priority is in direct proportion to the weight of the associated traffic stream. Increasing the weight of a traffic stream will increase the priority of all belonging packets. Given identical probability distributions of packet size for all traffic streams, we argue that the greater weight of a traffic stream gives higher priority, in a statistical sense, to the belonging packets. As a result, the packets of a high priority traffic stream have a better chance to be located before those of a low priority stream in the queue, experiencing shorter delay, and less chance of being discarded from the tail. Moreover, the controlled variance of delay enables an upper bound to be set upon the delay.

### 2-2 Simulations and Experiment

To examine the service guarantee of the A-WSPT service discipline, three separate routers are modeled using the A-WSPT, the WSPT and the FCFS service disciplines
respectively. A comparative experiment is conducted between three router models. The simulation and experiment are accomplished with the OPNET Modeler of OPNET Technologies, Inc.

![Router model in OPNET Modeler.](image)

**Figure 2-2. Router model in OPNET Modeler.**

The router models (Figure 2-2) used in the simulation are composed of two input ports and an output port, with an IP forwarder module simulating the function of forwarding the packets from input ports to the output port. Each input port is associated with three traffic sources. In this study, we assume that all packets come from one of the two input ports and go to the only output port. A queuing system is used at the output port. The queuing system is made up of a single queue and uses the service discipline assigned to that router. A packet sink is connected with the queuing module to collect the output packets. Since the primary concern of this study is the performance of the service discipline of the queuing system, we assume that the transmission of packets between the traffic source, IP forwarder and queuing system incurs neither delay nor packet drop.

Each traffic source generates a traffic stream with a certain service requirement and a constant average bit rate. Two types of traffic are considered in this simulation – high priority and low priority. High priority traffic is assigned a larger weight. The priority of traffic is marked in the Type-of-Service (ToS) field of the IP header of
belonging packets. In this study, ToS is set to 7 to indicate high priority traffic, and 0 for low priority traffic. Since it is a general practice to assume the random arrival process as a Poisson process, we specify the inter-arrival time of packets as exponentially distributed. Similarly, the size of packets generated by each source assumes a normal distribution. The expectation of the rate (bits/second) of the incoming traffic as generated by each source can be estimated by the ratio of mean packet size and mean inter-arrival time.

2-3 Results and Discussion

The performance collected from the simulation runs are categorized along the axes of traffic setting, performance metrics and object of measures. Within each group, the performances of the three service models are compared. Then, the results are inspected and the comparison between the models is analyzed. Conclusions are drawn from the results.

2-3.1 Heavy traffic

Time-in-System

As we observe from Figure 2-3, in the case of overwhelming high priority traffic, the A-WSPT service discipline demonstrates a marked improvement over both FCFS and WSPT in the area of time-in-system performance of high priority traffic. In addition, although we note some variance in the time-in-system under the A-WSPT model, it is a great improvement over the variance demonstrated by the WSPT.
The time-in-system of the FCFS service discipline is shown in Figure 2-4. The reason that the A-WSPT and WSPT service disciplines are excluded from this figure is that there was little data to collect because in these disciplines, low priority traffic gets little chance to be served when traffic conditions are heavy. Compared to the FCFS service discipline, very few low priority packets are served by the A-WSPT router. The low priority packets that do get served experience much longer time-in-system, due to the low priority they have.

Figure 2-3. Time-in-system of high priority traffic (heavy traffic).
Packet loss

Table 2-1 summarizes the packet loss rates of high priority traffic, low priority traffic and overall traffic under heavy traffic conditions. For high priority traffic, both the A-WSPT and the WSPT service discipline greatly reduce the packet loss rate. However, because the overwhelming high priority traffic takes almost all the bandwidth, the packet loss rate of low priority traffic is extremely high. Thus, for overall traffic, all service disciplines have roughly the same packet loss rate.

**Throughput**

The throughput performance for high priority traffic and low priority traffic is shown in Figure 2-5 and Figure 2-6 respectively. The WSPT service discipline allocates full bandwidth capacity to high priority traffic, and prohibits the low priority packets from being served. The A-WSPT discipline allocates a very small portion of bandwidth to the low priority traffic. The FCFS discipline, instead of discriminating any one stream, allocates bandwidth roughly in proportion to their incoming rate.
Figure 2-5. Throughput of high priority traffic (heavy traffic).

Figure 2-6. Throughput of low priority traffic (heavy traffic).
Under overwhelming traffic condition, all three disciplines make use of full bandwidth capacity, as shown in Figure 2-7.

2-3.2 Light traffic

Time-in-system

The time-in-system of high priority traffic for the A-WSPT, WSPT and FCFS disciplines is shown in Figure 2-8. A-WSPT and WSPT have a similar time-in-system performance for premium service traffic under light traffic conditions. Both treat high priority packets with the shortest delay.

Figure 2-9 shows the time-in-system for lower priority traffic under light traffic conditions. A-WSPT has a comparable, though slightly higher, time-in-system to the FCFS service discipline. In this case, compared to WSPT, A-WSPT has a large variance of time-in-system.
Figure 2-8. Time-in-system of high priority traffic (light traffic).

Figure 2-9. Time-in-system of low priority traffic (light traffic).
Packet loss

Since the rate of total incoming traffic, including both high priority traffic and low priority service traffic, is smaller than the bandwidth of the output port, packet loss does not occur in any of the routers.

Throughput

The three service disciplines exhibit similar throughput performance for high priority (Figure 2-10), low priority (Figure 2-11) and all traffic (Figure 2-12), because, under light traffic conditions, both high priority and low priority get the share of bandwidth they need, whatever the service discipline used.

![Figure 2-10. Throughput of high priority traffic (light traffic).](image-url)
Figure 2-11. Throughput of low priority traffic (light traffic).

Figure 2-12. Throughput of all traffic (light traffic).
2-3.3 Conclusions

We summarize the results as follows. First, the A-WSPT service discipline, just like WSPT, does differentiate the services between high priority traffic and low priority traffic by assigning a larger weight to high priority traffic. Under both heavy traffic and light traffic conditions, A-WSPT achieves better time-in-system performance for high priority traffic. Second, compared to the WSPT service discipline, A-WSPT substantially prevents the time-in-system from increasing to extremely high by compensating the time-in-system. Especially under heavy traffic conditions, A-WSPT effectively contains the variance of time-in-system of high priority traffic. Finally, however, A-WSPT is not effective in fair resource allocation between the two traffic streams. High priority traffic is preemptive, and can deplete the resource exclusively as long as it needs additional bandwidth.
Chapter 3: Providing Quality of Service for a Web Server
Using Queuing Disciplines

3-1 QoS Delivery for a Web Server

Providing guarantees on the quality of service is cited as one of the key factors contributing to the success of an application and a “must” for the next-generation Internet [11]. While “quality” could mean a number of things for different types of Internet services (e.g., error-free, reliable data transmission, resolution of images, foolproof security, etc.), we will focus on QoS as it relates to the timeliness or responsiveness of the web server in satisfying the clients’ requests during an online session. In particular, we are interested in evaluating different control policies for the scheduling or sequencing of jobs in a web server queue based on the expected value of cycle time of a request; that is, the time between the submission of the request by the client and the completion of the request. Since the average cycle time metric only reflects one side of performance, we will also be looking at other performance metrics that measure responsiveness and efficiency of the web server: tardiness, lateness, average number of jobs dropped or rejected (for policies that implement admission control), and average throughput.

3-1.1 Previous Approaches

Several mechanisms have been proposed to address and provide QoS measures for a web server. Cherkasova et al. [12] developed a session-based admission control (SBAC) policy to prevent a web server from becoming overloaded, where a session is defined as a sequence of a client’s individual requests. While their mechanism provides no differentiation between sessions, the SBAC policy provides a fair guarantee of completion for any accepted sessions, independent of a session length. However, for e-commerce sites, longer sessions are generally associated with actual purchases. Statistical analysis of completed sessions reveals that the overloaded web server discriminates against longer sessions. Almeida et al. [13] studied the policy of assigning
different priorities to the requests according to the requested web content and evaluated the lateness in handling HTTP requests to the web pages. The strategies that the authors used are static and limited to affect the scheduling indirectly through the use of process priority and process blocking.

Li et al. [14] developed a measurement-based admission controlled web server, which is able to allocate a configurable percentage of the bandwidth to different client requests. When the server is fully utilized or a particular request has used more than the allocated bandwidth, the request is discarded. This implies that the admission control mechanism may drop any session in progress if the session exceeds the allocated bandwidth. While this policy would benefit several performance measures such as cycle time, such a strategy may clearly result in unsatisfactory user experience at these sites. Lu et al. [15] proposed an adaptive architecture based on a feedback control loop to provide relative delay guarantees for different service classes on a web server under HTTP 1.1 protocol.

Load balancing is also a popular approach to providing availability by balancing the service accesses among replicated web servers. Some strategies use the Domain Name System (DNS) server to govern the resources in a cluster of replicated web servers. Conti et al. [16] studied the strategy of evenly distributing the processing load among replicated web servers to provide high levels of QoS. The authors allowed the servers to be geographically distributed across the Internet. The DNS-based approach is simple, but has some drawbacks. First, since the DNS service is designed to support data that changes only infrequently, the approach is not well equipped to propagate changes in a timely fashion. Secondly, if one of the replicated web servers crashes, the caching of DNS data makes the services unavailable to all visitors. A solution to this problem is a “reverse proxy”, which is an HTTP proxy server that operates in the opposite direction of the commonly known one [17].

While the number of studies addressing the issue of providing QoS for web servers has recently increased, there is as yet, no simple or comprehensive approach to designing strategies with a QoS focus, due to the complexities associated with web server operations. In addition to the academic research on the subject, some organizations have also tried to address the QoS issue. One of these organizations is the Internet
Engineering Task Force (IETF), which implemented and tested a number of protocols or schemes for this purpose. The Integrated Services (InteServ) initiative was initiated primarily by the desire to help the Internet support real-time multicast applications. The InteServ architecture asserts that the underlying Internet architecture can support multicast backbone (MBONE) type of applications without modification. It proposes that an extension to the current architecture can be devised to provide capability beyond the traditional Best-Effort service, in which the client requests are handled on a first-come-first-served basis, without idling.

QoS in the InteServ model is concerned primarily with the timely delivery of packets. The InteServ model defines two classes of applications by distinguishing the application’s dependence on timely delivery of packets [18]. One is called elastic applications that have no strict requirements for timely delivery of packets. The other class of applications, which require timely service, is referred to as inelastic or real-time. The InteServ architecture uses Resource Reservation Setup Protocol (RSVP) [RFC2205] as its network control protocol to support QoS and traffic control requirements of application flows by setting up necessary host and router states. RSVP requires signaling to be deployed end to end in order to provide the requested type of service. However, this also leads to a scalability problem, which results from the requirement for a signaling mechanism to establish per-flow traffic states in each router that the path traverses and prevents deployment of RSVP on the Internet.

The Differentiated Services (DiffServ) architecture simplifies the forwarding path by moving the complexity of classifying traffic to the edges of the network. DiffServ supports multiple service levels based on packet marking and per-class management of routers in the network. DiffServ takes advantage of prioritizing the traffic through various queue management and scheduling mechanisms.

Compared to InteServ, DiffServ has no explicit signaling protocol that establishes session paths and maintains state tables with the routers. Packets carry the state information in the IP headers. Each router handles the packets based on the information in its differentiated services codepoint (DSCP). This is referred to as per hop behavior (PHB). Within a DiffServ network, packet scheduling, buffer management, and packet discard are required to provide differentiated service. Clearly, scheduling schemes that
are more sophisticated than the simple FIFO service protocol hold potential to improve efficiency of a packet-based network.

Several scheduling schemes have been proposed for this purpose. Priority Queuing (PQ) scheme places packets into the buffer space according to priority, and processes high-priority packets ahead of the lower priority packets. One problem with this scheme, however, is that some low priority packets may be discarded or delayed for a long time.

An enhancement to PQ is Class Based Queuing (CBQ), which permits the users to assign a particular amount of buffer space to particular traffic classes. This buffer allocation is static, which is a limitation of the CBQ scheme.

Even the best packet-scheduling algorithm, however, cannot ensure that the buffer space is fairly allocated among the waiting packets. An ideal buffer management scheme should make buffer space available to all traffic and at the same time make sure that high priority traffic will not be deprived of buffer space by lower priority packets. Hence, an intelligent packet drop scheme is needed. Weighted Fair Queuing (WFQ) with Random Early Discard (RED) is a scheme that tries to manage the buffer space intelligently by dropping the packets when there is congestion in the system.

Optimal or effective scheduling of machines and resources in production systems is a topic that has attracted a lot of attention. For this chapter, we borrow results from the scheduling literature and research their potential to improve performance of web servers. We will be studying various scheduling, or more accurately, sequencing rules that have been shown to yield optimal or effective schedules under certain conditions in production systems. In particular, we will be implementing and testing the Weighted Shortest Processing Time first (WSPT), Apparent Tardiness Cost (ATC), and Earliest Due Date (EDD) scheduling rules to a web server using simulation and observe the performance improvements these rules may bring.

3-1.2 Web Server Operation

Before presenting our model, an explanation of how web servers operate is useful. There are three basic elements that make web service possible: Uniform Resource Locators (URL) for identifying the resources, HyperText Transfer Protocol (HTTP) for
transferring the information, and the client-server based architecture. HTTP is stateless, *i.e.*, each request is processed by the web server independently from previous or subsequent requests. The client sends a URL request to the web server that provides the resource. The web server then provides the requested services and returns the results back to the client. The current version of HTTP, *i.e.*, HTTP 1.1 uses a mechanism called persistent connection, which allows multiple requests to reuse the session. The request is stored in the listen queue of the server’s well-known port, *e.g.*, 80, when the web server receives the HTTP 1.1 client’s request. When the incoming requests arrive faster than the rate at which they are removed from the queue, congestion happens.

Figure 3-1 presents our model for a “QoS web server”. Clients with different priorities or job types access the web server, consisting of a single unit. The “single machine” assumption will be relaxed later to allow for multiple requests being processed simultaneously (*i.e.*, parallel machine case). Once in the queue, each job awaits service by the server. Upon completion of service, requests exit the system, which defines the end of the ‘cycle time’. Below, we detail each component defined in our model.

![Figure 3-1. Web server QoS model.](image)

**Requests Classifier**

The requests classifier groups the requests so that certain ones are prioritized in processing. Differentiated service policies aim to provide the highest quality of service to
the most important customers. For example, it is common to prioritize the service request of the clients who pay for the service over the nonpaying clients. Some sites prioritize requests based on the clients’ access history, IP address, and current status (e.g., a customer with a full shopping cart or with a purchasing history attains a higher weight than a customer without a purchasing history or a full cart). Web QoS, developed by Bhatti and Friedrich [19], allows the incoming requests to be categorized as high, medium, or low priority based on IP address, requested URL, and so on.

Admission Control Scheme

Deferring an incoming request at the very beginning of the transaction, rather than in the middle is a desirable scheme for an overloaded web server. First, it avoids further frustration by a client by refusing to accept the requests for which it cannot satisfy the QoS requirements (e.g., limits on cycle time, lateness and tardiness, etc.). Secondly, it keeps the queue levels at relatively stable levels, resulting in a less variable output.

We define the QoS factor of an incoming request as

\[ Q_j = D_j - T_j - W_j - P_j \]  \hspace{1cm} (3-1)

where \( D_j \) is the due date of request \( j \), \( T_j \) is the arrival time of request \( j \), \( W_j \) is the predicted waiting time (i.e., sum of the processing times of the requests ahead of request \( j \)), and \( P_j \) is the expected processing time of request \( j \). According to our assumed admission control scheme, if \( Q_j \) is less than zero request \( j \) is rejected.

3-1.3 QoS Measures

Timeliness, precision, and accuracy are the attributes of QoS that people generally use to measure the performance of web servers. We define four QoS measures in this paper: number of dropped jobs per unit time (i.e., drop rate), average time in system (i.e., cycle time), average lateness and throughput. While we consider throughput as one of the performance metrics, we focus our attention to time in system, drop rate and lateness, since they represent the QoS characteristics we are most interested in.

Under the best effort and basic DiffServ policies, request drops occur only when the queue is full. Under the WSTP, ATC, and EDD policies, request drops may happen at admission control as well as when the queue is full, while requests are waiting in the
queue. Time-in-system is used to measure the responsiveness of the web server. Lateness represents the gap between the completion time and due date, and can be negative or positive. A negative lateness indicates a request completed before its due date, and a positive lateness indicates that the request was tardy. Lateness depicts how well the requirement of the due date of the request is met.

3-2 Discussion of Different Queuing Disciplines

Best Effort Policy

The Internet and most corporate intranets are built with IP protocol, which is a connectionless protocol that provides no guarantees on service time or relative order of the packets. For web servers, the incoming requests are placed into a queue and processed in a First-In-First-Out (FIFO) fashion. In the Best Effort model, there is no admission control scheme. Hence, if client requests are placed into the queue faster than they are moved from the queue to be processed, congestion occurs; requests are delayed, and finally, the requests maybe be discarded. Because of this inherent behavior, the Internet can only provide a single level of service, that of ‘Best Effort’.

Basic DiffServ Policy

Under the DiffServ policy, requests are categorized into priority classes. The server always processes the higher priority queue before serving any of the lower priority queues. DiffServ architectures generally define two kinds of classification: (1) the behavior aggregate classifier, which selects packets according to the DSCP value on ingress, and (2) the multifield classifier, which uses a more general set of classification conditions like IP header field values and source address.

To implement a DiffServ model, we classify the incoming requests into two categories: high priority and low priority, based on their assigned weights. Figure 3-2 shows two queues: one for high priority requests, another for best effort requests. Both are serviced in a FIFO manner, but the best-effort queue will only be serviced when there are no requests waiting in the high priority queue. Again, as in the Best Effort model, there is no admission control in the basic DiffServ model.
Weighted Shortest Processing Time Policy

For a single station, the Shortest Processing Time (SPT) policy, which sequences a set of existing jobs in increasing order of processing times, \( p_j \), minimizes the sum of the completion times (i.e., cycle times, assuming that all jobs are available at time zero). This classic result can easily be extended to the case in which jobs have different weights. In that case, sequencing the jobs in decreasing order of \( w_j/p_j \) minimizes the total weighted completion times, where \( w_j \) denotes the weight of job \( j \). The policy is referred to as the Weighted Shortest Processing Time (WSPT) policy (see Pinedo’s proof [10] based on an interchange argument).

We adopt the WSPT rule to accommodate dynamic arrivals of requests and argue that it can enable web servers to differentiate among requests based on the weights while also considering the expected processing time of the requests. A policy that is purely based on prioritizing the jobs based on their given weights provides a high level of service to the requests with a high weight, however, jobs with lower weights could end up with very long waiting times. Especially when a job may have a low weight but a short expected processing time, processing it ahead of a higher priority job might make sense.

Under the WSPT rule, upon each arrival, we sort the jobs in the queue in decreasing order of the priority index, which is equal to \( w_j/p_j \) for each job \( j \) in the queue.
Weight Only Policy

As a contrast of the WSPT model, we design a Weight Only (WO) model that uses only ‘weight’ to define the priority of the request to see the influences upon the model brought by processing time. In this model, the requests that belong to the same class follow the FIFO queuing discipline to be placed into the queue.

Apparent Tardiness Cost Policy

The Apparent Tardiness Cost (ATC) rule is a composite dispatching rule that combines the WSPT rule and the Minimum Slack first (MS) rule [10]. The MS policy is a dynamic dispatching rule that orders jobs in increasing order of slack, where slack of job \( j \) at time \( t \) is defined as \( \max \{d_j - p_j - t, 0\} \). \( d_j \) denotes the due date of job \( j \) and \( p_j \) denotes the expected processing time of job \( j \), as before.

Under the ATC rule, jobs are scheduled one at a time; that is, every time the machine becomes free, a ranking index is computed for each remaining job. The job with the highest-ranking index is the selected to be processed next. The index is defined as

\[
I_j(t) = \frac{w_j}{p_j} \exp \left( -\frac{\max \{d_j - p_j - t, 0\}}{k\bar{p}} \right),
\]

where \( k \) is a scaling parameter that can be determined empirically, and \( \bar{p} \) represents the average of the expected processing times of the remaining jobs in the queue at time \( t \). We can see that if \( k \) is big enough, the ATC rule will reduce to WSPT policy since the ATC index \( I_j(t) \to w_j/p_j \) as \( k \to \infty \).

Earliest Due Date First Policy

Sequencing a number of jobs in increasing order of their due date, referred to as the Earliest Due Date first (EDD) policy, minimizes the maximum lateness of a set of jobs with given due dates and processing times [10]. While we know that EDD is optimal for the case in which all jobs to be scheduled are available at time zero, it is harder to find an optimal policy for the case in which jobs are released in different points
in time, which reflects our case. The reason is that when preemption of jobs is not allowed, the optimal schedule is not necessarily a non-idling schedule.

Having noted this point, we adopt the static EDD rule in our web server model by placing the incoming requests into the queue according to their due date. The requests with an earlier due date are placed into the front of the queue and processed before the requests with a later due date.

### 3-3 Simulation of Different Queuing Rules

We simulate a web server under the policies discussed in section 3-2 using the OPNET Modeler 8.1.A simulation environment. The simulation experiments were conducted on a Micron PC with a single Pentium4 1.9GHz CPU and 512MB of RAM running on Windows 2000 operating system. Figure 3-3 depicts the simulation model based on the web server system presented in Figure 3-1. Generator 1, generator 2, and generator 3 modules generate the requests with different weights (i.e., priorities). The forwarder module forwards the requests to the queue, where the request dropper scheme is implemented. The requests are then placed into the queue based on different rules. The sink module destroys the requests after the web server processes them.

![Figure 3-3. The topology of the QoS web server simulation.](image)

We define four fields in the data packet format: processing time (denoted as proc_time), weight, due date and time in system (denoted as TIS). The processing time
(i.e., proc_time field in the packet format) represents the time to parse a request and is assumed to be a function of the packet size, which follows the normal distribution. We assume that the mean and the standard deviation of packet size are 6000 bytes and 1000 bytes, respectively. Because we focus on the connection and listening queue scheduling problem of a web server, the processing time is not the time the server spends fetching a file or executing a CGI program. We calculate the processing time by dividing the request size by a constant, deterministic service rate. For instance, if the request size is 6000 bytes and the service rate of the server is 240,000 bytes per second, the processing time for this request is assumed to be 0.025 second.

The weight field is a 4-byte integer that contains the weight information of a request. The weight value is recorded in the weight field of a request packet when the request is generated. There are some choices in selecting the proper weight value [19]. For simplicity, we only define three priority classes. In Figure 3-3, generator 1, 2, and 3 generate request arrivals with weights 1, 2 and 4, corresponding to low, medium, high priority requests.

We expect that under policies that differentiate requests based on priority, the high priority requests can be processed even when the web server is heavily overloaded and the medium requests can partly get the service while the low priority requests may not get the service at all due to request drops. Under the best effort policy, however, all requests are treated equally. Under the DiffServ policy, requests are classified into low and high categories; a request with a weight bigger than three is treated as a high priority request while the remaining requests are categorized and treated as low priority. The due date field in the packets shows the due date of a request. The due date of a request is generally a function of the time-criticality of the operation. Some time-critical applications require the web servers to respond within a specific period. If the application can’t receive the response as required, the QoS requirements can’t be met. Of course, whether the application can get the response on time or not depends not only on how fast the web server processes the request but also on the delay during transmission on the Internet. How to guarantee a lower bound of delay between routers is out of the scope of this research. Hence, we focus on the due date that the web server is required to process a request by and assume that the client will receive the processed request once
the web server sends it out. The due date indicates the amount of time for which a request can be in the system without violating the QoS requirements. We use the same distribution to model the randomness of the due dates for all classes of requests because we assume that they require the same URLs. We assume that the due dates are normally distributed with a mean of 2 seconds and a standard deviation of 0.2 seconds.

The TIS field is used to record the time interval between the time the request enters the listening queue and the time the request gets parsed and exits. We use this field to observe the effectiveness of different scheduling schemes.

Table 3-1 shows the parameters we use for the high-traffic simulation experiments. We use an exponential distribution to model the randomness in the arrival of requests to the web server. Generator 1 and generator 2 modules generate requests at a rate of 25 requests per second, while the generator 3 module generates requests at a rate of 5 requests per second. Hence, the total traffic generated is equal to \((25 + 25 + 5) \times 6000\) bytes per a second. We set the queue service rate 240,000 bits per second. The server utilization is above 100%, and we expect that on average 15 requests will be dropped per second. The capacity of the queue is assumed to be 512,000 bits.

</tbody>
</table>

We also create a set of light traffic scenarios to test the effectiveness of different policies. The arrival rate for weight 1 and weight 2 requests are reduced to 12.5 requests per second, while the arrival rate for the weight 4 requests remain at a rate of 5 per second. Hence, the total traffic generated reduces to only 75% of the traffic the web server can handle.

The forwarder module in Figure 3-3 forwards the incoming requests to the queue. OPNET uses the Finite State Machine (FSM) to implement the behavior and logic of a
process model. We use a FSM to simulate the processing in the queue. There are 5 states in the FSM: ‘init’, ‘arrival’, ‘svc_start’, ‘svc_compl’, and ‘idle’.

‘init’ State
The process enters ‘init’ state only once where we initiate the simulation variables and register the probing statistics. When the simulation begins, the first request will arrive at the ‘init’ state and then goes to ‘arrival’ state.

‘arrival’ State
When a new request enters into the system and the FSM is in ‘idle’ state, the state will also transform to ‘arrival’ state.

- Best Effort Model. When a request comes, it enters the ‘arrival’ state. If the queue is already full, the request will be dropped; if not, it will be placed into the queue by the FIFO rule. This is the way most of the current web servers deal with the incoming client requests.

- Basic DiffServ Model. After a request enters the ‘arrival’ state, we get the ‘weight’ value from the packet. If the weight is bigger than 3 and the high priority queue is not overflowed, the request will be put into the end of high priority queue. If the high priority queue is overflowed, the request will be dropped. If the weight is less than or equal to 3 and the low priority queue is not full, it will be placed into the end of the low priority queue. If the low priority queue is full, the request will be discarded.

- WSPT Model. First we execute the admission control algorithm: we traverse the queue to calculate the QoS factor in equation (3-1) for each request in the queue. If the QoS factor of a request is above 0, it will stay in the queue and wait for being scheduled to process. If the QoS factor is less than 0, it will be dropped. After implementation of the Admission Control Scheme, we will get the ‘weight’ value and packet size from a new request that goes into the ‘arrival’ state. We get the expected processing time of this request by its packet size divided by the service rate of the queue. Then we get the priority of the incoming request according to the equation \( \frac{w_j}{p_j} \). Now we will try to insert the request into the queue based on its priority. The requests with bigger priority will be placed ahead of the requests with less priority. If it is inserted successfully, we will mark
‘insert_ok’ as 1. If unsuccessfully, which means that the queue is full, we will compare the new incoming request’s priority with the priority of the request at the end of the queue. If the new request’s priority is bigger, we will drop the request at the end of the queue and insert it according to its priority, and mark ‘insert_ok’ as 1. If the new incoming request has a lower priority, we just discard it.

- **WO Model.** The process is the same as in WSPT model except that we use only ‘weight’ to decide the priority of a request.

- **ATC Model.** As an extension of WSPT, we also implement the Admission Control Scheme at the very beginning of the ‘arrival’ state. For a new incoming request, we calculate its index based on equation (3-2) as its priority. We attempt to insert a request according to its priority into the listening queue and deal with the insertion action as what WSPT does. We also assign different values to the \( k \), the scaling parameter, in equation (3-2) to investigate the impacts.

- **EDD Model.** We perform the Admission Control Scheme when the process enters the ‘arrival’ state. We extract the due date information of a new request from the packet’s ‘duedate’ field. We use its reciprocal as the priority and try to insert the request into the queue based on its priority and handle the insertion action as what WSTP does.

### ‘svc_start’ State

When the server is not busy and ‘insert_ok’ is marked as 1, the process enters the ‘svc_start’ state from the ‘arrival’ state. Another transformation to the ‘svc_start’ state happens from the ‘svc_compl’ state when the queue is not empty. In this state, we will remove a request from the head of the queue and schedule its processing based on its processing time. When the request is processed, an interrupt occurs and the state is transformed to ‘svc_compl’. If there are no jobs waiting for processing, then the FSM transforms to the ‘idle’ state.

A request goes into the sink component in Figure 3-3 after it is dequeued and processed where the requests are simply destroyed.

We set the simulation duration (*i.e.*, run length) as 4,000 seconds. To capture the QoS metrics defined above, we use the ‘Bucket’ mode, which is one of the statistics collection options in OPNet. The Bucket mode collects all of the points over the time...
interval and calculates the average of all the values collected for that bucket period, to calculate average performance metrics such as the average TIS and lateness. We use ‘sum/time’, the sum of all the values of points within a particular bucket, divided by the time duration of the bucket, to capture the drop rate and throughput metrics.

3-4 Experimental Results

In the sections above we introduced our web server QoS models design, implementation and simulation configuration. In this section, we provide detailed results on our simulation experiments for the heavy traffic and light traffic cases and provide intuition on our results for each of the QoS performance measures.

3-4.1 Heavy-traffic Case

We first present the results of the overwhelming traffic scenario.

**Time-in-System**

![Figure 3-4. Overall time-in-system in the heavy-traffic scenario.](image)

Figure 3-4 shows the TIS performance under the WSPT, ATC, EDD, Best Effort, WO and Basic DiffServ policies. We take all the requests that get processed into account and calculate the TIS over time after the 120th second when the system reaches steady state. We make the following observations:
• The overall performance is dramatically enhanced under ATC, EDD, and WSPT policies. The mean TIS under the Best Effort policy is 2.116 seconds while it is 0.179 seconds under the WSPT policy.

• The Basic DiffServ performs slightly better than Best Effort.

• ATC, EDD, and WSPT, the policies with an admission control scheme, have similar performance. The admission control scheme discards the requests whose QoS requirements can’t be met before they are even placed in the queue, which results in smaller average queue sizes (see Figure 3-5 and Table 3-6) and consequently shorter TIS. The average queue size of ATC is about 169,802 bytes while under the Best Effort policy the average queue size is about 499,602 bytes. The processing time also contributes to the smaller overall TIS of WSPT compared with that under the WO policy. The overall TIS of WO is about 0.539 seconds.

![Figure 3-5. Queue size in the heavy-traffic scenario.](image)

Table 3-2 shows the mean and standard deviation of TIS for all the three classes of requests. The TIS of class 1, 2, and 4 under the Best Effort Model is all about 2.11 seconds because there is no differentiation mechanism.

Table 3-2. Time-in-system in heavy-traffic scenario: mean and deviation values.

Figure 3-6 shows the TIS of class 4. The high priority class (with weight 4) has very small TIS under the Basic DiffServ model.

![TIS of Class 4](image)

**Figure 3-6. Time-in-system of Class 4 in the heavy-traffic scenario.**

However, the TIS of low priority and medium priority classes under the Basic DiffServ policy are even longer than that under the Best Effort policy, as shown in Figures 3-7 and 3-8. For the ATC and WSPT models, the TIS of class 4 is quite small,
0.039 second, which reveals that the high priority requests are processed with the highest priorities. The TIS of class 2 in ATC and WSPT is 0.081 second. The TIS of class 1 are shown in Figure 3-8. The TIS of class 1 is 0.499 second in WSPT and 0.052 second in ATC. We can see that requests with higher priority have smaller TIS in ATC and WSPT. As to the EDD model, class 1, 2, and 4 have similar TIS because they have the same due date which decides the priority. All requests in EDD have the same priority and thus there is no differentiation. The TIS is still much smaller for EDD than in Best Effort thanks to the request dropper.

![TIS of Class 2](image_url)

Figure 3-7. Time-in-system of Class 2 in the heavy traffic scenario.

![TIS of Class 1](image_url)

Figure 3-8. Time-in-system of Class 1 in the heavy traffic scenario.
Figure 3-9. Overall drop in the heavy traffic scenario.

Figure 3-10. Drop of Class 4 in overwhelming scenario.

Figure 3-9 shows the overall drop rate. Figure 3-10 depicts the drop of the high priority requests. The average drop rate for high priority requests under the Best Effort policy is about 1.4 packets per second and 1.38 packets per second under EDD (see Table 3-3). EDD provides only a slight improvement in drop rate because the request with the earliest due date is given priority in processing under EDD. In this simulation, we set the
same due date for all three classes of requests which leads to no differentiation between the three classes.

Almost no high priority requests are dropped under the Basic DiffServ policy. However, more requests in low and medium priority classes are dropped even compared to Best Effort. This reveals that Basic DiffServ discriminates the Best Effort requests to give premium requests better performance. This verifies the design that only when there is no high priority request waiting for processing can a low priority request get the chance to be processed.

ATC and WSPT offer good granularity and differentiation. There is also almost no high priority requests dropped under the ATC and WSPT policies (0.005 packets/second in WSPT, and 0.007 packets/second in ATC). The low priority requests, however, have a drop rate of about 15 packets per second under the WSPT and ATC policies, as shown in Figure 3-12. So, the requests with higher priority are processed at the expense of low priority requests.

![Figure 3-11. Drop of Class 2 in overwhelming scenario.](image)
Figure 3-12. Drop of Class 1 in overwhelming scenario.

In Table 3-3, we note that the overall drop rate is at the same level for all the models. This is because the service rate of the queue is fixed at 240,000 bits per second and the simulation setting is identical for all the models.

Table 3-3. Drop in heavy-traffic scenario.

Lateness

Table 3-4 shows the results of Lateness. As we define Lateness as TIS deducted by the due date, we find that ATC, EDD, and WSPT models have negative Lateness, which means they meet the lateness QoS requirement. In DiffServ only requests of class 4 can get the service before the due date. The Best Effort Model can’t meet the lateness requirements at all.

Table 3-4. Lateness in heavy-traffic scenario.
Throughput

Table 3-5 contains the results on average throughput. The results are consistent with those contained in Table 3-3. As can be expected, higher drop rate results in smaller throughput. We find that with the same overall throughput, ATC and WSPT successfully differentiate the throughput among the three classes of requests. The Basic DiffServ policy yields a higher throughput of high priority requests compared to that under the Best Effort policy, which provides no differentiation between the requests.

Average Queue Size

The average queue size under each of the policies is shown in Table 3-6. The average queue size under ATC and WSPT are only about one third of that under the Best Effort and DiffServ policies. The smaller queue size contributes to the smaller average TIS under these two policies. We also find that the average queue size of the Basic
DiffServ is about 31,669 bytes smaller than that of the Best Effort because of its priority queuing policy.

Table 3-7 shows the parameters we use for the light traffic case. Figure 3-13 shows the overall TIS of the ATC, Best Effort, Basic DiffServ, EDD, WSPT and WO policies. The performances are quite similar, at about 0.062 second. This is because the incoming traffic is 75% of the service rate of the web server and there is almost no congestion in the queue as shown in Figure 3-14. The queue size of these models is in the same level. For example, WSPT has an average queue size of about 6,764.449711 bytes as shown in Figure 3-14 and Table 3-12.

</tr>
</tbody>
</table>

We also note that TIS of the high priority requests under the ATC, WSPT, Basic DiffServ, and WO policies is smaller than that under the Best Effort and EDD policies (see Figure 3-15 and Table 3-8). TIS of the medium priority requests under the ATC, WSPT and WO policies is smaller than that under the Best Effort and EDD policies (see Figure 3-16). Hence, requests with higher priorities have precedence over requests with lower priorities. However, TIS of the low priority requests under the ATC, WSPT, and WO policies are longer than that under the Best Effort and EDD policies (see Figure 3-17).

![TIS of Class 4](image)

Figure 3-16. Time-in-system of Class 2 in light-traffic scenario.

Figure 3-17. Time-in-system of Class 1 in light-traffic scenario.

Drop Rate

Figure 3-18 includes the overall drop rate information. There is no drop at all under the Best Effort and Basic DiffServ policies (see Table 3-9). There are very small amounts of requests dropped in ATC, WSPT, EDD and WO due to the admission control
scheme. As we can see, the average drop rate in the WSPT model is about 0.003865979 requests per second. We also find that all the drops occur only in the class of low priority requests (see Figure 3-19 and Table 3-9).

Lateness

Table 3-10 shows the results of Lateness. We find that there is no violation of due date requirements in the light traffic scenario even under the Best Effort policy.
Throughput

Table 3-11 contains the results on the throughput metric. Since the incoming traffic and service rates are the same under all of the policies, they produce almost the same level of throughput in the light traffic scenario, since the system is stable and able to handle the incoming traffic. The throughput of the Best Effort and Basic DiffServ policies are a little higher than that under the other policies since no requests are dropped, resulting in a higher arrival (and hence, throughput) rate.

Queue size

Tables 3-12 show the average queue size under each one of the policies. Since there is almost no congestion in the system under this light traffic, the average queue length under the different policies is quite similar at around 6,000 bits. The smaller queue size contributes to the smaller overall TIS compared to those observed in the heavy traffic case.

3-5 Conclusions

In this chapter, we demonstrated how to model a web server as a single machine and applied the WSPT, ATC, and EDD queuing disciplines to differentiate the services and thus to provide QoS to nowadays Best Effort web servers.

We proposed that most current web servers could be modeled via the Best Effort Model. From the simulation results we verified that the Best Effort Model couldn’t provide differentiated service at all.

In the Basic DiffServ Model, incoming requests are classified to two levels: low priority and high priority. High priority requests always have precedence over low priority requests. Low priority requests are processed only when there are no requests in the high priority queue. From the simulation results we find that the performance of high priority requests is guaranteed: no drop and low TIS. Basic DiffServ is easy to understand and implement. However, as we can see from the results, Basic DiffServ must be used with care. A large volume of high priority requests will easily starve the best effort requests; the best effort requests will never be processed if high priority requests are always in the high priority queue. In our simulation, the ratio of best effort requests and high priority requests is 10:1. Therefore, the Basic DiffServ Model should only be used for mission-critical traffic to ensure the amount of the high priority requests is limited to a small portion of the overall traffic.

We introduced a Request Drop Scheme, which contributes to the tremendous improvement in the TIS. Thanks to the Admission Control Scheme, the overall TIS of the WSPT, ATC, and EDD Models is less than 10% of the overall TIS of the Best Effort and
Basic DiffServ Models. This reveals that the Admission Control Scheme is effective to maintain timeliness for an overwhelmed web server.

We have shown that the WSPT and ATC dispatching rules can be used to provide differentiated services. Instead of simply using the weight, WSPT combines it with processing time to determine the priority of a request. Unlike Basic DiffServ, in which the high priority requests always have precedence over the Best Effort requests, a request with low weight but short processing time in WSPT and ATC still has the chance to be processed before a request with high weight and longer processing time. ATC is a composite of WSPT and MS. We perceived that in our case the main factor in ATC is WSPT, not MS. From the simulation results, the performance of ATC is quite similar to WSPT when the scaling parameter $k$ is set to 100. We also create a scenario of ATC with different scaling parameters of 1, 50, 100, 1000 and 10000. Figure 3-20 shows that when $k$ is as small as 1 the overall TIS is longer than $k$ equals 50. The TIS is quite similar when $k$ is equal to or bigger than 50. We also note that there is no differentiation between requests when $k$ is 1 and that ATC is converging to WSPT when $k$ is 10,000 as expected.

![Figure 3-20. Overall time-in-system of ATC with different scaling parameters.](image)

We can also safely conclude that our QoS models not only provide good performance when the server is overloaded but also work well under the light traffic condition. In the light-traffic scenario, the QoS models provide better TIS for high
priority requests at the cost of a very small amount of drop of lower priority requests and slightly longer TIS for lower priority requests, and thus, the cost/benefits get balanced.

However, as Pinedo stated [10], real-world scheduling problems are different from the mathematical models in academia. For example, WSPT is a static rule, which is not time dependent. It assumes that there are \( n \) jobs to be scheduled and the problem is done after the \( n \) jobs are scheduled. For a web server, the requests are submitted by clients continuously. WSPT may not be the optimal scheduling rule to gain the minimum total weighted completion time. Another important aspect of the differences is that the stochastic models usually use special distributions which may not represent the behaviors of the real system closely. Here we use request size divided by service rate to decide the processing time of a request. Request size follows the normal distribution. For a web server, the processing time of a request may be influenced by the load and configuration of the web server.

In spite of so many differences, the scheduling rules in manufacturing provide valuable insights into the scheduling problems in information infrastructures. From the results of our research, some manufacturing scheduling rules may be used to develop the framework for QoS enabled web servers.
