14. ABSTRACT (Maximum 200 Words)

Stark differences in the actions of linoleic acid (LAA), an omega-6 fatty acid, and eicosapentaenoic acid (EPA), an omega-3 fatty acid, on breast cancer tumors have been described. We propose that transactivation of peroxisome proliferators-activated receptor gamma (PPARγ) mediates the physiological effects of different dietary fatty acids on breast cancer. PPARγ plays a role in the development and progression of breast cancer tumors. We have demonstrated that individual ligands of PPARγ can selectively activate PPARγ in three different ways. Selective activation of PPARγ by a single ligand occurs between tissue types and between individual breast cancer cell lines. Also, unique ligands selectively activate PPARγ within a single cell type. We propose that fatty acids will elicit their effects on breast cancer cells in a similar manner. The objectives of forthcoming studies will be to assess the necessity of transactivation of PPARγ by LAA and EPA in mediating the effects of fatty acids on breast cancer cells and to determine what effect this selective activation has on gene transcription. We hypothesize that LAA and EPA can selectively regulate gene expression profiles that favor either cellular differentiation or proliferation and that these effects are dependent on transactivation of PPARγ.

Introduction

Breast cancer remains one of the leading forms of cancer in American women. One in every eight women in the United States will be diagnosed with breast cancer, a 5-fold higher rate than that observed in women living in Japan and China. Studies examining women that emigrate from Asian countries to the United States have found similar breast cancer risk as American women within 40 years suggesting that genetics alone can not account for differences in breast cancer incidence between these populations (1). A number of environmental aspects are being explored to elucidate factors that might influence breast cancer risk. Though controversial, it has been estimated that diet influences the development of up to 50% of all breast cancer cases in American women (2). A growing body of literature indicates that the type of dietary fat consumed (diets high in omega-3 fatty acids versus diets high in omega-6 fatty acids) influences breast cancer (3, 4) suggesting that consumption of specific fatty acids may impact breast cancer differently. Animal studies, have also provided convincing evidence of a correlation between types of fats ingested and mammary tumor development and growth (5-8). The focus of this proposal is to define the molecular link between specific fatty acids and the progression of breast cancer. We are exploring the possibility that fatty acids may elicit their effects in breast cancer cells by acting as ligands of the peroxisome proliferator-activated receptor gamma (PPARγ). Our laboratory has previously demonstrated that individual fatty acids can activate a PPAR-response element (PPRE), but whether this effect was the direct result of PPARγ activation has been left unexplored (9). Evidence suggests PPARγ is involved in the initiation (10, 11) and progression (12-14) stages of breast cancer. The objective of this proposal is to determine the mechanism of action that individual fatty acids use to either positively (increase cellular differentiation and/or decrease cellular proliferation) or negatively (increase cellular proliferation and/or tumor metastases) impact breast cancer cells. We propose that PPARγ is the molecular target responsible for the physiological effects of different dietary fatty acids on breast cancer.
The orphan nuclear receptor, PPARγ, is one of three in a family of receptors (PPAR α, β, and γ) (15-17). It is expressed in numerous cell types including adipocytes, epithelial cells of the breast, colon, and lung, and macrophages among others (18-22). Several ligands of PPARγ have been identified including 15-deoxy-Δ12,14-prostaglandin J₂ (PGJ₂), linoleic acid (LAA), lysophosphatidic acid, and the thiazolidinedione class of anti-diabetic drugs such as ciglitazone (Cig) and rosiglitazone (Ros) (9, 23-26). Transactivation of the receptor requires ligand binding, heterodimerization with retinoid X receptor alpha (RXRα), and binding of this complex to PPAR-specific response elements (PPREs) in the promoter regions of target genes (22, 27).

To begin to explore the role that individual fatty acids might play in the progression of breast cancer we wanted to first demonstrate that individual ligands of PPARγ could selectively modulate the receptor. The ability of individual ligands to selectively mediate the activity of a nuclear receptor dependent on the tissue type examined has been used to develop compounds that act as selective estrogen-receptor modulators (SERMs). Tamoxifen, which was originally described as an estrogen-receptor antagonist, has been found to act as an agonist in several different tissue types (28-30). It has been proposed that individual ligands may be able to act as selective PPARγ modulators (SPARMs) in a manner similar to the way other compounds function as SERMs (31). We previously demonstrated that individual fatty acids can selectively activate a PPRE-reporter assay in estrogen-dependent breast cancer (MCF-7) cells (9). However, left unexplored was whether individual ligands could elicit unique responses between cell lines of a single cancer type as well as across cancers of different tissue origin.

To address these fundamental questions we have conducted a series of experiments that tested the ability of individual PPARγ ligands to selectively activate PPARγ. To this end we have utilized a PPRE-reporter construct transfected into the cells prior to ligand treatment. The data from these studies has been collected, analyzed, and the resulting manuscript was recently accepted for publication in the May issue of Molecular and Cellular Endocrinology (see appendix).

In these studies, we first tested the ability of several different PPARγ ligands to activate the PPRE-reporter in either normal mammary epithelial (HMEC), estrogen-dependent breast cancer cells (T47-D and MCF-7), or estrogen-independent breast cancer cells (MDA-MB-231). Following transfection with a PPRE reporter plasmid, HMEC, T47-D, MDA-MB-231, and MCF-7 cells were treated with either vehicle control or PPARγ ligands for 18 hours. For the four cell lines, differences in ligand activity were observed. In the HMEC, Ros and PGJ₂ both significantly increased reporter activity over control (Fig. 1). Interestingly, GW, a known antagonist of PPARγ, also significantly stimulated reporter activity in HMECs. GW treatment did not change reporter activity compared to control in any of the other breast cancer cell lines. No treatments significantly increased reporter activity in the T47-D cells (Fig. 1). In MDA-MB-231 cells Ros, Cig, and PGJ₂ all significantly enhanced PPARγ activation over control, while these same three treatments also increased reporter activation in MCF-7 cells when compared to control (Fig. 2). Both Ros and PGJ₂ treatments resulted in significantly higher activity than Cig in MCF-7 cells.
After a breast tumor has formed, PPARγ transactivation appears to have multiple effects. In vitro, treatment of breast cancer cells with troglitazone results in lipid accumulation, changes in gene expression associated with cellular differentiation, reduction in growth rate and clonogenic capacity (11). Others have observed that distinct PPARγ ligands induce apoptosis (13). Conversely, a recent report by Saez et al. found that when mice expressing a constitutively active form of PPARγ in the mammary gland were crossed with mice prone to mammary gland cancer, bigenic animals develop tumors that express higher levels of markers of malignancy (32). The authors conclude that once an initiating event takes place, increased PPARγ signaling serves as a tumor promoter in the mammary gland of these experimental animals.

Collectively, these data suggest that the physiological consequence of PPARγ activation is dependent on many factors including the stage of development of the specific breast cancer cell. Our demonstration that individual PPARγ ligands distinctively modulate PPRE reporter activity in breast cancer cell lines differently has implications for breast cancer treatment. Specifically, T47-D cells were fairly unresponsive to any of the three PPARγ agonists tested, whereas, Ros, Cig, and PGJ2 significantly increased reporter activity in MCF-7 and MDA-MB-231 cells. It can be concluded that individual breast cancer cell types are likely to respond to PPARγ ligands in unique physiological ways and our data suggests that, in part, variant cellular responses are the result of selective PPARγ transactivation. Furthermore, we report that GW, a known PPARγ antagonist in adipocytes (33, 34) and other cell lines, significantly increased reporter activity in HMECs. These findings are significant because they suggest that an individual compound can function as a PPARγ antagonist in one tissue and as an agonist in other tissues. It is possible that the agonist activity of GW is specific to normal epithelial cells and that changes occur during cancer cell formation that results in the loss of this responsiveness. It is also possible that the actions of GW are mammary specific. Further investigation is necessary to explore these possibilities.

Data from these experiments demonstrated that selective activation of PPARγ occurs in multiple ways. Distinct ligands selectively activate PPARγ dependent on the tissue type from which the cell line was derived (data not shown, see MCE manuscript for full description). SPARM activity was also observed between different cell lines of the same tissue origin. Specifically, normal mammary cells and breast cancer cells responded differently to individual ligands and differences were observed between unique breast cancer cell lines. Also, individual ligands selectively activated the PPRE reporter within single breast cancer cell lines.

Next we wanted to determine if mRNA levels of PPARγ and its heterodimeric partner,
RXRα, in cells were predictive of how the breast tumor cells would respond to PPARγ ligands. To do this, mRNA concentrations of PPARγ and RXRα were measured in all four cell lines (HMEC, T47-D, MDA-MB-231, and MCF-7) used previously in the transfection assays in the absence of ligand treatment. Data is presented as fold change in expression compared to the HMECs. T47-D cells had significantly lower levels of PPARγ than all of the cell lines (Fig. 3). However, these cells had the highest expression of RXRα among all cell lines. MCF-7 cells express significantly higher levels of PPARγ expression than the HMECs or T47-Ds and higher RXRα than all of the cells tested except T47-Ds. MDA-MB-231 cells had PPARγ mRNA levels similar to MCF-7 cells, but had lower RXRα expression.

We then chose two breast cancer cell lines to determine if unique patterns of expression of PPARγ and RXRα would be predictive of how the cells responded to co-treatment with Ros (a PPARγ agonist) and 9cis-retinoic acid (a RXRα agonist). MDA-MB-231 cells express higher levels of PPARγ relative to RXRα and would therefore, not be expected to have increased reporter activity with co-treatment (Ros + 9cis-retinoic acid) compared to Ros alone. Conversely, MCF-7 cells having higher expression of RXRα relative to PPARγ would demonstrate enhanced reporter activity when treated with both ligands compared to Ros alone. MCF-7 cells had enhanced activation of the PPRE reporter with co-treatment over Ros treatment alone (Fig. 4). The MCF-7 cell line supports the possibility that relative expression levels may be predictive in identifying cells that will more readily respond to co-treatment with both ligands. However, MDA-MB-231 cells did not support this hypothesis. Co-treatment with both ligands had a significantly higher effect on reporter activity when compared to single treatment with Ros even though relative PPARγ expression was higher than RXRα expression in these cells. These data suggest that while this approach may work for certain cancer cell types, receptor expression alone may not be predictive for how cells will respond to co-treatment.

Data discussed thus far has identified the possibility that unique PPARγ ligands can function as SPARMs in several ways that may have a significant impact on breast cancer development and progression. Furthermore, these data provide in principal the potential mechanism by which fatty acids may function uniquely in breast cancer cells. Beyond collecting the previously discussed data we have spent the first year of the funding schedule developing methodology to effectively deliver fatty acids into the cells. Because of the number of different outcomes that will be analyzed in this grant we wanted to develop a protocol for fatty acid delivery that would provide us a reliable methodology. In the last twelve months, we...
attempted several different delivery methods using the PPRE reporter assay as a means to measure the
efficacy of each protocol. Early on, we were unsuccessful at getting agonistic responses with several
of our fatty acid protocols. However, we have now developed a protocol that has provided us a
mechanism of fatty acid delivery that results in measurable responses in the PPRE reporter assay (Fig.
5). Furthermore, this methodology is reproducible and reliable for use in a number of different assays.
The details of the fatty acid protocol are listed in the methodology below. We anticipate that this form
of fatty acid delivery will be used throughout the remainder of the experiments funded by this grant.

Methods:

Cell Culture: HMEC, MDA-MB-231, T-47D and MCF-7 were obtained from the ATCC (Rockville,
MD) and maintained as described in the attached manuscript.

Transfection Assays: Cells were transiently transfected with 5μg of PPRE reporter plasmid per 12
well plate. Cells were transfected with ESCORT transfection reagent for four hours. Cells were
subsequently treated with either 10μM Ros, 10μM Cig, 1μM PGJ2, 1μM GW, or 150μM LAA for 18
hrs. In all cases, PPARγ ligand concentrations for each compound used were those shown to be
maximally effective following dose reponse studies. Proper vehicle controls including ethanol,
DMSO, and methyl acetate were run for each treatment group. Following treatment, cells were lysed
in 50μl passive lysis buffer and treated according to manufacturer's instructions (Promega dual
luciferase assay kit). Luminometry was performed on a Berthold Lumat 9507 and data calculated as
raw Luciferase units (RLU's) divided by raw Renilla units. Mean fold induction was obtained by
dividing the RLU data from each treatment well by the mean values of the vehicle control
appropriate for each treatment. Each set of treatments were performed in replicates of 6 in 3 separate
experiments.

RT-PCR: Real-time PCR was performed on total RNA using the TaqMan One-Step RT-PCR Master
Mix Kit purchased from Applied Biosystems and used according to manufacturers instructions.
Commercial FAM labeled probe/primer pairs constructed by Applied Biosystems using the Celera
genomic database were used to asses PPARγ and RXRα mRNA levels. Quantitation of mRNA was
performed using an ABI Prism 7700 Sequence Detection System and the TaqMan methodology,
which uses the 5' nuclease activity of the Taq DNA polymerase to generate a real-time quantitative
DNA assay. Data were analyzed using a Ct cycle method. At the completion of the amplification
(40 cycles), the amount of target message in each reaction was recorded as a threshold cycle number
(Ct), which is inversely correlated to the abundance of the initial message level. Ct measures the
fractional cycle number at which the amount of amplified target reaches a fixed threshold. The
amount of target was normalized to the endogenous reference target, human GAPDH, again using a
FAM labeled Taqman probe/primer solution available from Applied Biosystems. This normalized
target Ct value was then set relative to a normalized calibrator sample (i.e. untreated normal cell
type) as given by the equation 2-ΔΔCt where ΔΔCt represents ΔCt, target sample minus ΔCt,
calibrator. Finally, this value was then used to produce a relative quantity by comparison to an
appropriate control sample.

Fatty Acid Preparation: Fatty acids were purchased in pure fatty acid form and then dissolved in
hexane to create a fatty acid stock solution. This stock solution was maintained under nitrogen gas at
all times and fresh fatty acid preparations were made before every experiment. Appropriate volumes
of the stock solution were then combined with calculated volumes of 6N NaOH to form fatty acid
salt complexes. The preparations were then dried under nitrogen gas until no fluid remained. The
fatty acid salt was then dissolved in cell culture media containing 10% fetal bovine serum (FBS). It
has been reported that the availability of free fatty acids in the body is dependent on the presence of
albumin and therefore depends on albumin concentration (35). As a result, the chosen FBS conditions were necessary to form fatty acid/albumin complexes. Once the fatty acid was completely dissolved in the media, hydrochloric acid was used to balance the pH and the media was filter sterilized through a 0.2μm syringe filter.
Key Research Accomplishments

- We have demonstrated that individual PPARγ ligands can selectively activate the receptor in cancer cell lines derived from different tissues.
- We have shown that selective modulation of PPARγ occurs between normal mammary epithelial cells as well as different breast cancer cell lines when the cells are treated with PPARγ ligands. These data suggest that breast tumors in individual patients may respond to PPARγ differently.
- We have shown that individual PPARγ ligands can selectively modulate the receptor within a single cell line.
- We have demonstrated that distinct expression patterns of RXRα and PPARγ mRNA in tumor cells may be predictive of how they will respond to PPARγ ligand treatment, but further investigation is necessary to better define this approach.
- We have now developed a methodology for delivering fatty acids into cells that is reproducible and reliable for use in all future experimentation.

Reportable Outcomes

- Initial data resulting from this funding has led to the preparation and acceptance of a peer reviewed manuscript to be published in Molecular and Cellular Endocrinology in May of 2005.
- Data supported by this grant was presented in a poster format at the Twenty Third Annual University of Kentucky Symposium in Reproductive Sciences in May of 2004.
- Collected data has led to an invited oral presentation at the Twenty Fourth Annual University of Kentucky Symposium in Reproductive Sciences in May of 2005.
- The most recent data associated with this grant will be presented at the 2005 Era of Hope meeting.
- Through studies and collaborations associated with this grant I have become active in the Reproductive Sciences Training Program at the University of Kentucky. This is a federally funded program and prior to the 2004/2005 academic year I was selected to act as seminar coordinate for this program.

Conclusions

PPARγ is highly expressed in breast cancer tumors and treatment of these cells with known PPAR agonists in vitro have been shown to suppress tumor cell growth. This has led to the possibility that PPARγ may be utilized as a therapeutic target in the treatment and prevention of breast cancer. Thus far, we have demonstrated that PPARγ ligands, have distinct activities within a cell type, between tumor cells derived from the same tissue, and across distinct tissues. These general principles are the mechanism by which we hypothesize that individual fatty acids influence breast cancer development and progression. With reliable methodology for delivering the free fatty acids to the breast cancer cell lines in place, we are poised to shed new light on the molecular pathway by which fatty acids function in these cells. The end result of these studies will be a stepping stone toward developing dietary recommendations for fatty acid consumption for patients with breast cancer as well as those at high risk of developing the disease.

Selective activation of PPARγ in breast, colon, and lung cancer cell lines

Clinton D. Allred, Michael W. Kilgore*

Department of Molecular and Biomedical Pharmacology, Markey Cancer Center, University of Kentucky College of Medicine, MS 305, Chandler Medical Center, 800 Rose St., Lexington, KY 40536, USA

Received 16 December 2004; received in revised form 16 February 2005; accepted 17 February 2005

Abstract

Peroxisome proliferator-activated receptor gamma (PPARγ) plays a critical albeit poorly defined role in the development and progression of several cancer types including those of the breast, colon, and lung. A PPAR response element (PPRE) reporter assay was utilized to evaluate the selective transactivation of PPARγ in 10 different cell lines including normal mammary epithelial, breast, lung, and colon cancer cells. Cells were treated with one of four compounds including rosiglitazone (Ros), ciglitazone (Cig), 15-deoxy-A \textsubscript{12,14}-prostaglandin J\textsubscript{2} (PGJ\textsubscript{2}), or GW 9662 (GW). We observed differences in transactivation between cell lines from different tissue origin, across cell lines from a single tissue type, and selective modulation of PPARγ within a single cell line by different ligands. Interestingly, GW, a PPARγ antagonist in adipocytes, enhanced PPRE reporter activation in normal mammary epithelial cells while it had virtually no effect in any of the cancer cell lines tested. Within each cancer type, individual cell lines were found to respond differently to distinct PPARγ ligands. For instance, Ros, Cig, and PGJ\textsubscript{2} were all potent agonist of PPARγ transactivation in lung adenocarcinoma cell lines while these same ligands had no effect in squamous cell or large cell carcinoma of the lung.

Message levels of PPARγ and retinoid X receptor alpha (RXRα) in the individual cell lines were quantitated by real time-polymerase chain reaction (RT-PCR). The ratio of PPARγ to RXRα was predictive of how cells responded to co-treatment of Ros and 9-cis-retinoic acid, an RXRα agonist, in two out of three cell lines tested. These data indicate that PPARγ can be selectively modulated and suggests that it may be used as a therapeutic target for individual tumors.

1. Introduction

The American Cancer Society estimated that collectively cancers of the breast, colon and lung accounted for 42% of all cancer deaths in men and 50% of all cancer deaths in women in 2004. In fact, breast, lung, and colon cancer rank as the top three types of malignancies identified in women today and one out of every eight women will develop breast cancer. In men, lung cancer is the most prevalent cause of cancer related death with malignancies of the prostate and colon following as next most common. A wide variety of chemotherapeutic options are being explored to treat these diseases. Novel therapeutic targets are being developed in an effort to identify endogenous, hormonal targets to either suppress cancer cell growth or induce apoptosis. One of the emerging targets for such treatments is peroxisome proliferator-activated receptor gamma (PPARγ).

The orphan nuclear receptor, PPARγ, is one of three of a family of receptors (PPARα, β, and γ) (Dreyer et al., 1992; Issemann and Green, 1990; Kliewer et al., 1994). It is expressed in numerous cell types including adipocytes, epithelial cells of the breast, colon, and lung, and macrophages among others (Braissant et al., 1996; Kilgore et al., 1997; Lemberger et al., 1996; Nagy et al., 1998; Tontonoz et al., 1994). Several ligands of PPARγ have been identified including 15-deoxy-\textsubscript{12,14}-prostaglandin J\textsubscript{2} (PGJ\textsubscript{2}), linoleic acid, lysophosphatidic acid, and the thiazolidinedione class of anti-diabetic drugs such as ciglitazone (Cig) and rosiglitazone (Ros) (Forman et al., 1995; Kliwer et al., 1997; Larsen...
et al., 2003; McIntyre et al., 2003; Thoennes et al., 2000). Transactivation of the receptor requires ligand binding, heterodimerization with retinoid X receptor alpha (RXRα), and binding of this complex to PPAR-specific response elements (PPREs) in the promoter regions of target genes (Kliwer et al., 1992; Tontonoz et al., 1994).

Recent evidence demonstrates that PPARγ is overexpressed in many different tumor types (DuBois et al., 1998; Tontonoz et al., 1997). In the breast, adenocarcinoma cells from patients expressed higher levels of PPARγ than normal epithelial cells from the surrounding mammary gland (Elstner et al., 1998). Similarly, in the colon, expression of PPARγ protein is significantly higher in human colon cancer sections when compared with non-tumor tissue (Chen et al., 2002). PPARγ has also been identified in both adenocarcinoma and squamous cell carcinomas of the lung (Theocharis et al., 2002). Exposing cancer cells to PPARγ ligands produces physiological effects that may be exploited for treatment purposes. In culture, synthetic PPARγ ligands have been shown to inhibit growth of several tumor cell lines (Brockman et al., 1998; Elstner et al., 1998; Mueller et al., 1998). A number of studies have determined that PPARγ ligands induce cellular differentiation and/or apoptosis in breast, colon, and lung cancer cells (Chang and Szabo, 2002; Elstner et al., 1998; Mueller et al., 1998; Sarraf et al., 1998). The combination of receptor overexpression in tumors and known physiological effects of its ligands on cancer cells makes PPARγ a viable target of future chemotherapeutic agents.

The ability of individual ligands to selectively mediate the activity of a nuclear receptor dependent on the tissue type examined has been used to develop compounds that act as selective estrogen-receptor modulators (SERMs). Tamoxifen, which was originally described as an estrogen-receptor antagonist, has been found to act as an agonist in several different tissue types (Fisher et al., 1998; Jordan and Morrow, 1999; Levenson and Jordan, 1999). It has been proposed that individual ligands may be able to act as selective PPARγ modulators (SPARMs) in a manner similar to the way other compounds function as SERMs (Sporn et al., 2001). We previously demonstrated that individual fatty acids can selectively activate a PPRE-reporter assay in estrogen-dependent breast cancer (MCF-7) cells (Thoenes et al., 2000). Specifically, omega-3 fatty acids inhibited transactivation of PPARγ to levels below control while omega-6, monounsaturated and saturated fatty acids stimulated the activity of the PPRE reporter. These data demonstrated that individual compounds can selectively activate PPARγ within the context of a single breast cancer cell line. However, compounds have yet to be identified that act as PPARγ agonists in one tissue while functioning as antagonists of the receptor in other tissues.

In the studies presented here, we sought to determine if distinct ligands could selectively activate PPARγ across different cell lines of mammary, colon, and lung origin. To this end we have utilized a PPRE-reporter construct transfected into the cells prior to ligand treatment. Data from these experiments demonstrated that selective activation of PPARγ occurs in multiple ways. Distinct ligands selectively activate PPARγ dependent on the tissue type from which the cell line was derived. SPARM activity was also observed between different cell lines of the same tissue origin and individual ligands selectively activated the PPRE reporter within single cell lines. These data indicate that it may be possible to design PPARγ ligands that can be used to selectively mediate receptor activity and thus customize treatment regiments against specific cancers.

2. Materials and methods

2.1. Reagents

All PPARγ ligands were purchased from Cayman Chemical Company (Ann Arbor, MI). Ciglitazone (Cig) and GW9662 (GW) were solubilized in ethanol purchased from Aapar Alcohol and Chemical Company (Shelbyville, KY). Rosiglitazone (Ros) was dissolved in dimethyl sulfoxide (DMSO) and PGJ2 was solubilized in methyl acetate purchased from Sigma (St. Louis, MO).

2.2. Cells and cell culture

Ten individual cell lines were used in these experiments. Four mammary cell lines including normal mammary epithelial (HMEC) and three breast cancer cell lines (MCF-7, T47-D, and MDA-MB-231). Two colon cancer cell lines (Caco-2 and HT-29) and four lung cancer (A549, H358, H520, and H1299) were utilized. HMEC were purchased from Cambrex (Rockville, MD) while the MCF-7, T47-D, MDA-MB-231, H358, H520, and H1299 cells were all purchased from American Type Culture Collection (Bethesda, MD). The HT-29 and A549 cells were generously provided by Dr. David Kaetzel (University of Kentucky, College of Medicine) and the Caco-2 cells were a gift from Dr. Charlotte Kaetzel (University of Kentucky, College of Medicine). All cells were cultured in medium previously described to provide optimal conditions for their growth. When possible multiple cell lines were maintained in the same medium to reduce error when comparing across cell types. Cells were maintained in medium containing 10% FBS. All cell types were grown in medium lacking phenol red at 37°C in a 5% CO2 atmosphere. Cells were grown in T-75 flasks before being transferred to 12-well plates in preparation for transfection.

2.3. PPRE reporter plasmid

The reporter construct, 3XPPRE-TK-pGL3, contains three copies of a PPRE sequence (AGGACAAAGGTCA) upstream of the mTK promoter between the Xhol and HindIII restriction enzyme sites of the pGL3 basic vector (Promega, Madison, WI). BamHI and BgIII were then used to release the 2.2 kb fragment containing the 3XPPRE-mTK-Luciferase. This fragment was ligated into the BamH I receptor site
of pRL-TK plasmid (Promega) completing the new reporter which contains both Luciferase and Renilla in a single expression plasmid. Renilla expression was used as a transfection efficiency control.

2.4. Transfection assays

Cells were transiently transfected with 5 μg of PPRE reporter plasmid per 12-well plate. Cells were transfected with ESCORT transfection reagent for 4 h. Cells were subsequently treated with either 10 μM Ros, 10 μM Cig, 1 μM PGJ2, or 1 μM GW for 18 h. In all cases, PPARγ ligand concentrations for each compound used were those shown to be maximally effective following dose response studies (data not shown). Proper vehicle controls including ethanol, DMSO, and methyl acetate were run for each treatment group. Following treatment, cells were lysed in 50 μl passive lysis buffer and treated according to manufacturer’s instructions (Promega dual luciferase assay kit). Luminometry was performed on a Berthold Lumat 9507 and data calculated as raw Luciferase Units (RLUs) divided by raw Renilla units. Mean fold induction was obtained by dividing the RLU data from each treatment well by the mean values of the vehicle control appropriate for each treatment. Each set of treatments were performed in replicates of six in three separate experiments.

2.5. RNA preparation

Total RNA was isolated from cultured cells utilizing an RNeasy® Mini Kit (Qiagen, Valencia, CA) according to manufacturer’s instructions. Untreated cells from each cell line were used for RNA isolation. All cell lines were maintained in optimal growth conditions prior to RNA collection. RNA was stored at −80°C and concentration was measured at by spectrophotometry.

2.6. Real-time quantitative reverse transcriptase-polymerase chain reaction (RT-PCR)

Real-time PCR was performed on total RNA using the TaqMan One-Step RT-PCR Master Mix Kit purchased from Applied Biosystems (Foster City, CA) and used according to manufacturers instructions. Commercial FAM labeled probe/primer pairs constructed by Applied Biosystems using the Celera genomic database were used to asses PPARγ (cat#: Hs00234592_ml) and RXRα (cat#: Hs00172565_ml) mRNA levels. Quantitation of mRNA was performed using an ABI Prism 7700 Sequence Detection System and the TaqMan methodology, which uses the 5'-nuclease activity of the Taq DNA polymerase to generate a real-time quantitative DNA assay. Data were analyzed using a Cq cycle method.

At the completion of the amplification (40 cycles), the amount of target message in each reaction was recorded as a threshold cycle number (Cq), which is inversely correlated to the abundance of the initial message level. Cq measures the fractional cycle number at which the amount of amplified target reaches a fixed threshold. The amount of target was normalized to the endogenous reference target, human GAPDH (cat#: Hs99999905.m1), again using a FAM labeled Taqman probe/primer solution available from Applied Biosystems. This normalized target Cq value was then set relative to a normalized calibrator sample (i.e. untreated normal cell type) as given by the equation 2\(^{-\Delta\Delta Cq}\), where \(\Delta\Delta Cq\) represents \(\Delta Cq\), target sample minus \(\Delta Cq\), calibrator. Finally, this value was then used to produce a relative quantity by comparison to an appropriate control sample.

2.7. Statistical analysis

As previously described (Thoennes et al., 2000), fold changes in luciferase to renilla ratios were subject to a two-factor analysis of variance (ANOVA) hypothesis testing (α = 0.05) based on the two nominal variables of treatment and experimental date using a custom designed program running on the StatServer 6.1 (Insightful, Seattle, WA) server housed in the University of Kentucky’s Department of Statistics. In every case, the post-hoc test, Tukey’s pair-wise comparison, was performed to identify significant differences between the various treatments within a cell line. Briefly, the Tukey methodology simultaneously determined the presence of significant differences between individual treatment mean estimations across the entire balanced set of pairwise comparisons using the studentized range distribution, q. Mean fold changes in luciferase/renilla ratios of treatments compared to vehicle controls were displayed by column graph with one-half of the critical value for comparison from the Tukey’s comparison as an estimation of error. Significant differences within those comparisons for a single cell line are designated by an alpha-numeric system.

For RT-PCR analysis, cycle threshold measurements, Cq, for the mRNA targets of both PPARγ and RXRα were repeated in triplicate within each cell line. The average Cq value for both PPARγ and RXRα in all 10 cell lines were subjected to analysis of variance hypothesis testing (ANOVA) using Microsoft Excel v10.0 at α = 0.05 significance threshold. Following ANOVA, Fisher's least significant difference, LSD, pair-wise comparison was implemented post-hoc. Briefly, the LSD test determines a single critical value based on the mean squared error within groups and a critical value (α = 0.05) found in the t distribution. If the average absolute difference between any two groups was greater than the LSD critical value, then the pair-wise comparison for those two groups were found to be significantly different at (p < 0.05).

3. Results

3.1. Effect of PPARγ ligands on reporter activation in breast cancer cells

Following transfection with a PPRE reporter plasmid, HMEC, T47-D, MDA-MB-231, and MCF-7 cells were
treated with either vehicle control or PPARγ ligands for 18 h. For the four cell lines, differences in ligand activity were observed. In the HMEC, Ros and PGJ2 both significantly increased reporter activity over control (Fig. 1A). Interestingly, GW, a known antagonist of PPARγ, also significantly stimulated reporter activity. GW treatment did not change reporter activity compared to control in any of the other breast cancer cell lines. No treatments significantly increased reporter activity in the T47-D cells (Fig. 1A). In MDA-MB-231 cells Ros, Cig, and PGJ2 all significantly enhanced PPARγ activation over control, while these same three treatments also increased reporter activation in MCF-7 cells when compared to control (Fig. 1B). Both Ros and PGJ2 treatments resulted in significantly higher activity than Cig in MCF-7 cells.

3.2. Effect of PPARγ ligands on reporter activation in colon cancer cells

Two colon cancer cell lines (HT-29 and Caco-2) were also tested in the same manner described for the mammary cells (Fig. 2). In general, HT-29 cells were more responsive to the PPARγ agonist than the Caco-2 cells. In the Caco-2 cells, only the Ros treatment caused significant increases in PPRE reporter activity when compared to control. Alternatively, in HT-29 cells Ros, Cig, and PGJ2 treatments all resulted in significantly higher reporter activation when compared to vehicle control whereas, GW treatment was not significantly different from control in either colon cell line.

3.3. Effect of PPARγ ligands on reporter activation in lung cancer cells

To examine PPARγ activation in lung cancer cells, four cell lines were chosen. A549 and H358 cells were derived from adenocarcinoma lung tumors while H520 and H1299 cell lines are non-adenocarcinoma derived cell lines. H520 cells are lung squamous carcinoma cells and H1299 cells

![Figure 1](image1.png)

Fig. 1. (A and B) Effect of PPARγ ligands on reporter activation in breast cancer cells. Cells were transiently transfected with a 3XPPRE-TK-pGL3 reporter vector. The cells were then treated with one of four PPARγ ligands for 18 h. Luciferase activity was normalized to renilla. Data is expressed as mean fold changes in luciferase to renilla ratios compared to vehicle control for each treatment group. These data are representative of three separate experiments. Error bars represent the critical value for comparison. Statistical comparisons were only made within cell lines and not between. Alphabetical letters are used to signify groups that are statistically different. Error bars that do not share a letter designation were determined to be significantly different. Letter designations between cell lines do not represent statistical differences.

Fig. 2. Effect of PPARγ ligands on reporter activation in colon cancer cells. Cells were transiently transfected with a 3XPPRE-TK-pGL3 reporter vector. The cells were then treated with one of four PPARγ ligands for 18 h. Luciferase activity was normalized to renilla. Data is expressed as mean fold changes in luciferase to renilla ratios compared to vehicle control for each treatment group. These data are representative of three separate experiments. Error bars represent the critical value for comparison. Statistical comparisons were only made within cell lines and not between. Alphabetical letters are used to signify groups that are statistically different. Error bars that do not share a letter designation were determined to be significantly different. Letter designations between cell lines do not represent statistical differences.
were derived from a metastatic site of a patient with large cell carcinoma of the lung. Cells were transfected and treated in the same manner as the other cancer cell lines. Similar to the breast and colon differences in reporter activity were observed for individual cell lines. In general, non-adenocarcinoma (H520 and H1299) cells did not respond to PPARγ ligands as well as the adenocarcinoma (H358 and A549) cell lines (Fig. 3A and B). Also, as observed in various other cancer cell lines, significant differences between the relative activation of the reporter were seen with individual ligands within single cell lines. In H1299 cells, treatment with Cig, PGJ2, or GW resulted in significantly higher activation of the PPRE reporter when compared to vehicle control while Ros and Cig treatment caused significant increases in activity in H520 cells (Fig. 3A). In H358 cells, Ros, Cig, and PGJ2 all resulted in increased activation when compared to control (Fig. 3B). However, Ros treatment resulted in significantly greater reporter activity when compared to both Cig and PGJ2 as well. Exposure of A549 cells to Ros, Cig, or PGJ2 also caused a significant increase in activation of the PPRE reporter when compared to control (Fig. 3B). However, in these cells reporter activation was greatest in Cig treated cells and the fold change for this treatment was significantly greater than that in PGJ2 treated cells. GW9662 treatment was not significantly different from control in H520, H358, or A549 cells.

3.4. Expression of PPARγ and RXRα mRNA

mRNA levels of PPARγ and RXRα were measured in all cell lines (Fig. 4). Total RNA was isolated from untreated cells. H1299 had the lowest expression of both PPARγ and RXRα when compared to all other cells. H520 cells had the second lowest levels of PPARγ and RXRα, while HMEC and A549 cells were next highest. H358 cells had similar expression of PPARγ as HMEC and A549 cells, but had significantly more RXRα expression when compared to the same cell lines. T47-D cells had significantly lower levels of PPARγ than all of the cell lines except the H520 and H1299 cells. However, these cells had the highest expression of RXRα among all cell lines. Caco-2 cells expressed the second largest amount of PPARγ mRNA and had high RXRα levels with only MCF-7 and T47-D cells expressing more. HT-29 cells had higher mRNA levels of PPARγ when compared to all other cell lines and RXRα expression similar to Caco-2 and H358 cells. MCF-7 cells express significantly higher levels of PPARγ expression than all but four cell lines and higher RXRα than all of the cells tested except T47-Ds. MDA-MB-231 cells had PPARγ mRNA levels similar to MCF-7 cells, but had lower RXRα expression with only two cell lines having significantly lower levels.

3.5. Effect of Ros and 9-cis-retinoic acid co-treatment on reporter activation in selected cell lines

Three cell lines were selected to determine if the relative expression of PPARγ and RXRα are predictive of the effect that co-treatment with a PPARγ agonist (Ros) and RXRα (9-cis-retinoic acid) agonist have on the PPRE reporter assay. HT-29, MCF-7, and MDA-MB-231 cells were selected to test this principal because Ros was shown to activate the reporter and the cell lines expressed varying levels of PPARγ to RXRα. MCF-7 cells were found to express more RXRα than PPARγ. Conversely, MDA-MB-231 and HT-29 cells expressed more PPARγ than RXRα. These three cell lines were transfected with the PPRE reporter construct and treated with
either vehicle, Ros alone, or co-treated with Ros and 9-cis-
retinoic acid. Ros alone and the co-treatment resulted in sig-
ificantly higher activation of the reporter in all three cell
lines when compared to vehicle controls (Fig. 5). In HT-29
cells, activation of the reporter was higher in the cells treated
with Ros alone compared to those receiving the co-treatment.
Conversely, co-treatment resulted in significantly greater re-
porter activity in the MCF-7 and MDA-MB-231 cells when
compared to Ros treatment alone.

4. Discussion

Data from the present study demonstrate that individual
PPARγ ligands have the ability to selectively activate a PPRE
reporter in cancers of the breast, colon, and lung. Differences
in PPRE reporter activation were observed between cells de-
lected from different tissue types as well as between cell lines
of the same cancer type. Also, within a single cell line, in-
dividual ligands selectively induced PPRE reporter activity.
Expression of PPARγ and RXRa mRNA were measured in
all cell lines in the absence of treatment, but expression was
not predictive of how individual cell lines responded to lig-
and treatment. Finally, differences in how individual cell lines
responded to co-treatment with PPARγ and RXRa agonists
were observed.

A growing body of evidence indicates PPARγ is in-
volved in both breast cancer development and progression.
PPARγ(+/−) mice had almost three-fold increased incidence
of mammary adenocarcinomas and decreased survival rate
when compared to PPARγ(+/+) littermates (Nicol et al.,
2004). Several reports have demonstrated that treating an-
imals with PPARγ ligands prior to chemical induction of
mammary tumors is protective against tumor development
(Mehta et al., 2000; Suh et al., 1999). It appears that expres-
sion and transactivation of PPARγ is protective against breast
tumor formation particularly when activated by PPARγ lig-
ands. Our data demonstrate that some ligands are more effec-
tive than others in transactivating PPARγ in normal mammary
epithelia.

Once a breast tumor has formed, PPARγ appears to have
multiple effects. In vitro, treatment of breast cancer cells
with troglitazone results in lipid accumulation, changes in
gene expression associated with cellular differentiation, re-
duction in growth rate and clonogenic capacity (Mueller et
al., 1998). Others have observed that distinct PPARγ ligands
induce apoptosis (Elstner et al., 1998). Conversely, a recent
report by Saez et al. (2004) found that when mice expressing a constitutively active form of PPARγ in the mammary gland were crossed with mice prone to mammary gland cancer, bigenic animals develop tumors that express higher levels of markers of malignancy. The authors conclude that once an initiating event takes place, increased PPARγ signaling serves as a tumor promoter in the mammary gland of these experimental animals. Collectively, these data suggest that the physiological consequence of PPARγ activation is dependent on many factors including the stage of development of the specific breast cancer cell. Our demonstration that individual PPARγ ligands distinctively modulate PPRE reporter activity in breast cancer cell lines differently has implications for breast cancer treatment. Specifically, T47-D cells were fairly unresponsive to any of the three PPARγ agonists tested, whereas, Ros, Cig, and PGJ2 significantly increased reporter activity in MCF-7 and MDA-MB-231 cells. It can be concluded that individual breast cancer cell types are likely to respond to PPARγ ligands in unique physiological ways and our data suggests that, in part, variant cellular responses are the result of selective PPARγ transactivation.

PPARγ also influences colon tumor development and growth. In mice predisposed to the development of intestinal polyps caused by a mutation in the adenomatous polyposis coli (APC) gene, treatment with troglitazone or Ros increases both the number and size of intestinal polyps (Lefebvre et al., 1998; Saez et al., 1998). These data are partially explained by studies demonstrating that PPARγ looses its ability to influence colon tumorigenesis in mice with a mutated APC gene, where as in wild-type APC mice, PPARγ functions as a tumor suppressor (Girnin et al., 2002). Conversely, PPARγ ligands reduce aberrant crypt foci (ACF) formation in mice following tumor induction by azoxymethane (Osawa et al., 2003). Differences in the effects of PPARγ ligands in these two models demonstrates that like mammary cells, colon cancer cells respond to a single PPARγ ligand differently dependent on the cell characteristics. When we examined the ability of PPARγ ligands to activate the PPRE reporter construct in two colon cancer cell lines, differences in cellular responsiveness was revealed. Ros significantly increased reporter activity in both Caco-2 and HT-29 cells though the level of responsiveness was much greater in the HT-29 cells. Furthermore, Cig and PGJ2 did not significantly enhance reporter signal in Caco-2 cells, but were strong agonists in the HT-29 cells. Selective modulation of PPARγ transactivation can explain the variant physiological responses observed in different colon cancer animal models. Differences in ligand activity could have significant impact on colon cancer treatment strategy as a number of studies have shown that PPARγ ligands affect colon tumor cell progression. Treatment of colon cancer cells with PPARγ agonists inhibits their growth in vivo (Brockman et al., 1998; Kitamura et al., 1999; Sarraf et al., 1998; Shimada et al., 2002) and in vitro (Sarraf et al., 1998). Inhibition of growth is often attributed to PPAR induced apoptosis and DNA fragmentation (Chen et al., 2002; Shimada et al., 2002; Yang and Frucht, 2001).

In the lung, epithelial cells possess 15-lipoxygenases which produce a variety of metabolic products including 15(S)-hydroxyeicosatetraenoic acid (15(S)-HETE) (Profita et al., 2000). In A549 cells, 15(S)-HETE has been demonstrated to induce apoptosis by binding to PPARγ (Shankaranarayanan and Nigam, 2003). Similarly, treatment of adenocarcinoma (A549) cells with Cig resulted in growth inhibition (Chang and Szabo, 2002); however, this inhibition was not observed in either squamous cell carcinoma (H520) or large cell carcinoma (H1299) cell types (Chang and Szabo, 2002). In the present study, two adenocarcinoma (A549 and H358) and two nonadenocarcinoma (H520 and H1299) cell lines were selected for evaluation. The nonadenocarcinoma cell lines were highly unresponsive to the PPARγ ligands when compared to the adenocarcinoma cells. Ros and Cig significantly increased reporter activity in H1299 and H520 cells, but fold change compared to control was relatively small in these cells. Conversely, A549 and H358 cells were highly responsive to the PPARγ agonists. These data suggest that the varying effects of Cig on adenocarcinoma versus nonadenocarcinoma cells observed in Chang et al., 2002 are likely the down stream result of selective PPRE transactivation.

One focus of these studies was to determine whether individual ligands of PPARγ could act as SPARMs. We present evidence indicating that within each tissue type, individual ligands are capable of selectively activating the PPRE reporter construct dependent on the individual cell line tested. However, individual ligands had unique effects across tissue types as well. For instance, we report that GW, a known PPARγ agonist in adipocytes (Leesnitzer et al., 2003), significantly increased reporter activity in HMECs. This effect was observed in no other cell line except H1299 cells and in those cells the magnitude of change was very small leaving in question its biological significance. These findings are significant because they suggest that an individual compound can function as a PPARγ agonist in one tissue and as an agonist in other tissues. It is possible that the agonist activity of GW is specific to normal epithelial cells and that changes occur during cancer cell formation that results in the loss of this responsiveness. It is also possible that the actions of GW are mammary specific. Further, investigation is necessary to explore these possibilities.

Another objective of these studies was to determine if PPARγ mRNA expression is predictive of a cell line's responsiveness to PPARγ ligands with regards to PPRE activation. For three of the cell lines (MCF-7, MDA-MB-231, and HT-29) increased relative expression of PPARγ over HMECs correlated with enhanced reporter activity when exposed to the PPARγ agonists. However, A549 and H358 had higher reporter activity in response to the individual PPARγ agonist compared to Caco-2 cells despite the fact that A549 and H358 cells express much lower levels of PPARγ than the Caco-2s. Therefore, PPARγ mRNA levels alone are not predictive of PPARγ mediated PPRE activation. These data led us to ex-
explore the possibility that variances of expression of RXRα, the heterodimeric partner of PPARγ, and its relation to the levels of PPARγ in different cell lines may play a critical role in PPARγ’s ability to activate the PPRE reporter construct. Here we demonstrate that the cell lines differed in their relative expression of PPARγ to RXRα; however, there was no unifying pattern of receptor expression that was predictive of ligand activity in the reporter assay.

Unique expression patterns of PPARγ relative to RXRα in certain cell lines led us to hypothesize that the relative expression of these receptors may be used to identify cell lines in which co-treatment with an RXRα agonist (9-cis-retinoic acid) would enhance PPRE reporter activation. Three cell lines were chosen to test this hypothesis. HT-29 and MDA-MB-231 cells express higher levels of PPARγ relative to RXRα and would therefore, not be expected to have increased reporter activity with co-treatment (Ros + 9-cis-retinoic acid) compared to Ros alone. Conversely, MCF-7 cells having higher expression of RXRα relative to PPARγ would presumably demonstrate enhanced reporter activity when treated with both ligands compared to Ros alone. HT-29 cells showed no additional reporter activity in cells co-treated with Ros and 9-cis-retinoic acid over those treated with Ros alone. MCF-7 cells had enhanced activation of the PPRE reporter with co-treatment over Ros treatment alone. These two cell lines support the possibility that relative expression levels may be predictive in identifying cells that will more readily respond to co-treatment with both ligands. However, MDA-MB-231 cells did not support this hypothesis. Co-treatment with both ligands had a significantly higher effect on reporter activity when compared to single treatment with Ros even though relative PPARγ expression was higher than RXRα expression in these cells. These data suggest that while this approach may work for certain cancer cell types, receptor expression alone may not be predictive for how cells will respond to co-treatment. A better understanding of how PPARγ and RXRα function in each of the cell lines will be necessary before the predictive value of receptor expression can be realized.

In conclusion, PPARγ ligands, have distinct activities within a cell type, between tumor cells derived from the same tissue, and across distinct tissues. Although we used only one type of PPRE reporter construct in these experiments, the selective modulation of PPARγ within individual cells is likely to be a gene/promoter specific event. Nonetheless, utilizing this reporter of PPAR transactivation, differences were observed in all three cancer types (breast, colon, and lung) where a single ligand enhanced reporter activation in certain cell types, but had minimal to no effect in other cell lines of the same malignancy type. Finally, our data demonstrates that individual PPARγ ligands can selectively activate reporter activity within a single cancer cell type. These data suggest that the effectiveness of PPARγ as a target for chemotherapeutic treatment will greatly depend on the cell that is treated which opens the possibility of utilizing PPARγ for targeted gene therapy.
