In this work, we develop a framework for image segmentation which partitions an image based on the statistics of image intensity where the statistical information is represented as a mixture of probability density functions defined in a multi-dimensional image intensity space. Depending on the method to estimate the mixture density functions, three active contour models are proposed: unsupervised multi-dimensional histogram method, half-supervised multivariate Gaussian mixture density method, and supervised multivariate Gaussian mixture density method. The implementation of active contours is done using level sets. The proposed active contour models show robust segmentation capabilities on images where traditional segmentation methods show poor performance. Also, the proposed methods provide a means of autonomous pattern classification by integrating image segmentation and statistical pattern classification.
Active Contours for Multispectral Images with Non-homogeneous Sub-regions

Wesley Snyder

September 16, 2005
Abstract

Image segmentation is a fundamental task in image analysis responsible for partitioning an image into multiple sub-regions based on a desired feature. Active contours have been widely used as attractive image segmentation methods because they always produce sub-regions with continuous boundaries, while the kernel-based edge detection methods, e.g. Sobel edge detectors, often produce discontinuous boundaries. The use of level set theory has provided more flexibility and convenience in the implementation of active contours. However, traditional edge-based active contour models have been applicable to only relatively simple images whose sub-regions are uniform without internal edges.

A partial solution to the problem of internal edges is to partition an image based on the statistical information of image intensity measured within sub-regions instead of looking for edges. Although representing an image as a piecewise-constant or unimodal probability density functions produces better results than traditional edge-based methods, the performances of such methods is still poor on images with sub-regions consisting of multiple components, e.g. a military vehicle covered by a camouflage pattern. The segmentation of this kind of multispectral images is even a more difficult problem. The object of this work is to develop advanced segmentation methods which provide robust performance on the images with non-uniform sub-regions.

In this work, we propose a framework for image segmentation which partitions an image based on the statistics of image intensity where the statistical information is represented as a mixture of probability density functions defined in a multi-dimensional image intensity space. Depending on the method to estimate the mixture density functions, three active contour models are proposed: unsupervised multi-dimensional histogram method, half-supervised multivariate Gaussian mixture density method, and supervised multivariate Gaussian mixture density method. The implementation of active contours is done using level sets.

The proposed active contour models show robust segmentation capabilities on images where traditional segmentation methods show poor performance. Also, the proposed methods provide a means of autonomous pattern classification by integrating image segmentation and statistical pattern classification.

Chapter 1

Introduction

In most image analysis operations, pattern classifiers require individual objects to be separated from the image, so the description of those objects can be transformed into a suitable form for computer processing. **Image segmentation** is a fundamental task, responsible for the separating operation. The function of segmentation is to partition an image into its constituent and disjoint sub-regions\(^1\), which are uniform according to their properties, e.g. intensity, color, and texture. Segmentation algorithms are generally based on either discontinuity among sub-regions, i.e. edges, or uniformity\(^2\) within a sub-region, though there are some segmentation algorithms relying on both discontinuity and uniformity.

### 1.1 Image Segmentation and Pattern Classification

The distinction between image segmentation and pattern classification is often not clear. The function of segmentation is simply to partition an image into multiple sub-regions, while the function of pattern classification is to identify the partitioned sub-regions. Thus, segmentation and pattern classification usually function as separate and sequential processes. However, they might function as an integrated process depending on the image analysis problem and the performance of the segmentation method. In either way, segmentation critically affects the results of pattern classification, and often determines the eventual success or failure of the image analysis.

Since segmentation is an important task in image analysis, it is involved in most image analysis applications, particularly those related to pattern classification, e.g. medical imaging, remote sensing, security surveillance, military target detection. The level to which segmentation is carried depends on the problem being solved. That is, segmentation should stop when the region of interest (ROI) in the application have been isolated. Due to this property of problem dependence, autonomous segmentation is one of the most difficult tasks in image analysis. Noise and mixed pixels caused by the poor resolution of sensor images make the segmentation problem even more difficult. In this document, we propose novel segmentation methods using a variational framework, called active contours.

---

\(^1\) **Partitions**, **sub-regions**, **parts**, **sections**, **objects**, and **segments** are often interchangeably used. The term **sub-regions** will be consistently used in this document.

\(^2\) The terms **uniformity** and **homogeneity** are often interchangeably used. The term **uniformity** will be consistently used in this document.
1.2 Active Contours

Active contours are connectivity-preserving relaxation [1] methods, applicable to the image segmentation problems. Active contours have been used for image segmentation and boundary tracking since the first introduction of *snakes* by Kass et al. [2]. The basic idea is to start with initial boundary shapes represented in a form of closed curves, i.e. contours, and iteratively modify them by applying shrink/expansion operations according to the constraints of the image. Those shrink/expansion operations, called *contour evolution*, are performed by the minimization of an energy function like traditional region-based segmentation methods or by the simulation of a geometric partial differential equation (PDE) [3].

An advantage of active contours as image segmentation methods is that they partition an image into sub-regions with continuous boundaries, while the edge detectors based on threshold or local filtering, e.g. Canny [4] or Sobel operator, often result in discontinuous boundaries. The use of level set theory has provided more flexibility and convenience in the implementation of active contours. Depending on the implementation scheme, active contours can use various properties used for other segmentation methods such as edges, statistics, and texture. In this document, the proposed active contour models using the statistical information of image intensity within a sub-region.

1.3 Terminology

A *multispectral image* is defined as a function on a two-dimensional spatial domain Ω, given by

\[ I(x, y) : \Omega \rightarrow \mathbb{R}^B, \quad (1.1) \]

where the input of the function is a two-dimensional vector denoting the coordinates \((x, y)\), and the output is a vector-valued image intensity \(I \in \mathbb{R}^B\). \(B\) denotes the dimension of \(I\), and is equivalent to the number of spectral bands. Figure 1.1 shows an example of a \(B\)-band image.

In this document, we define a multispectral image as a general form of images and a scalar

![Figure 1.1: A multispectral image \(I(x, y) : \Omega \rightarrow \mathbb{R}^B\)](image)

---

---

\[4\] Four terms, *multispectral images*, *multi-channel images*, *vector-valued images* [5], and *multi-valued images* [6], are often interchangeably used. Only the term *multispectral images* will be used in this document to avoid a confusion between *vector-valued images* and *vector (format) images* [7]. Every image function introduced in this document forms a bitmap image.
image as a particular case of multispectral images when $B = 1$. The most common example of multispectral images is an RGB image, consisting of three spectral bands: red, green, and blue. Hyperspectral images, used in remote sensing, are other examples of multispectral images. A set of images, measured by physically different sensors and registered, are also examples of multispectral images. As sensor fusion approaches become more popular in industrial and medical imaging, there will be more chances to encounter multispectral images in image analysis.

In image processing, particularly medical image processing, modality refers to the type of input [8], such as the type of sensors, e.g. MRI, CT, or the bandwidth of spectrum. Thus, a multimodal image often refers to a multispectral image, where each channel is measured by different modalities. In statistical pattern classification, a statistical distribution consisting of, or representable by, multiple sub-classes\textsuperscript{4} is called multimodal distribution, while the other case is called unimodal distribution. Figure 1.2 shows examples of the two cases. The probability density function (PDF) $p(I)$, presented as the solid curve, shows a unimodal distribution, while the mixture density function $p(I) = \alpha p_1(I) + (1 - \alpha)p_2(I)$, presented as the dotted curve, shows a multimodal distribution. A multi-dimensional statistical distribution, e.g. a two-dimensional Gaussian distribution, is called a multivariate distribution instead of a multimodal distribution. Note that the terminology of modality is different in image processing and statistical pattern classification. In this document, we use the terminology used in statistical pattern classification, so unimodal or multimodal refers to the statistical property of image intensity whether composed of a single class or multiple sub-classes, and univariate or multivariate refers to the dimensionality of image intensity such as a scalar image or a multispectral image.

![Figure 1.2: An example of unimodal (solid) and multimodal (dotted) distributions](image)

\textsuperscript{4}Three terms sub-classes, components, and modes are often interchangeably used. The term sub-classes will be consistently used in this document.

1.4 Motivations

Although most image segmentation methods as well as active contours assume that each sub-region in the image has a uniform property, we often encounter images with non-uniform sub-regions. Figure 1.3 shows examples of an image with uniform and non-uniform sub-regions. The zebra shown in figure 1.3(b) consists of white and black strips, while the triangle shown in figure 1.3(a) has a uniform image intensity. The statistical distribution of image intensity...
Figure 1.3: Examples of gray images with uniform and non-uniform sub-regions: (a) a triangle with uniform intensity, (b) a zebra with white and black strips

within the triangle and zebra would be similar to the graph shown in figure 1.2. Since the statistical distribution of image intensity within the zebra has at least two modes, i.e. one for black stripes and the other for white stripes, the segmentation method should be able to recognize a mixture of sub-classes as the class representing the zebra. Otherwise, the segmentation method would produce an over-segmentation result separating the white and black stripes or an under-segmentation result not separating the white stripes and the background. For this kind of problems, we propose advanced image segmentation methods using the statistical information of image intensity, where the statistical distribution of image intensity is represented as a mixture density function.

The image segmentation problem of images with non-uniform sub-regions becomes even more difficult when the image has multiple bands. Figure 1.4 shows examples of an RGB image with uniform and non-uniform sub-regions. The toy car shown in figure 1.4(a) is painted with uniform gray color, and the background is also uniform. The toy tank shown in figure 1.4(b) is painted with multiple different colors due to the camouflage pattern. The statistical distribution of vector-valued image intensity within the toy car has a single mode, while the statistical distribution of vector-valued image intensity within the toy tank has multiple modes in a multi-
dimensional image intensity space. For this kinds of problems, we need to estimate the statistics of vector-valued image intensity as a mixture of multivariate density functions. As the estimation of a multivariate mixture density function is a tough problem and requires high computation, image segmentation using the multivariate mixture density functions is even a more difficult problem. We propose smart ways to deal with this problem.

Image segmentation has often been considered as a preprocessing of pattern classification, but they are not necessarily separate procedures in the case of statistical pattern classification and region-based segmentation. A few active contour models [9, 5, 10] have integrated those two procedures as an unsupervised segmentation, which partitions an image based on the statistics of image intensity within each subset. We propose two methods which integrate image segmentation and statistical pattern classification as a supervised segmentation, which partitions an image based on the image intensity at each pixel and the statistical information of training samples. This integration reduces the processing time and helps to build an autonomous pattern recognition system.

The proposed active contour models are aimed at providing robust segmentation results for complicated image analysis, i.e. multispectral images with non-uniform sub-regions, but they are also applicable to any image segmentation problem. Possible applications are multi-sensor radiology in medical imaging, hyperspectral image segmentation in remote sensing, and color image segmentation.
Chapter 2

Image Segmentation: background

There are two main approaches in image segmentation: edge- and region- based. Edge-based segmentation partitions an image based on discontinuities among sub-regions, while region-based segmentation does the same function based on the uniformity of a desired property within a sub-region. In this chapter, we briefly discuss existing image segmentation technologies as background.

2.1 Edge-based Segmentation

Edge-based segmentation looks for discontinuities in the intensity of an image. It is more likely edge detection or boundary detection rather than the literal meaning of image segmentation, introduced in chapter 1. An edge can be defined as the boundary between two regions with relatively distinct properties. The assumption of edge-based segmentation is that every sub-region in an image is sufficiently uniform so that the transition between two sub-regions can be determined on the basis of discontinuities alone. When this assumption is not valid, region-based segmentation, discussed in the next section, usually provides more reasonable segmentation results.

Basically, the idea underlying most edge-detection techniques is the computation of a local derivative operator. The gradient vector of an image $I(x, y)$, given by

$$\nabla I = \left[ \frac{\partial I}{\partial x}, \frac{\partial I}{\partial y} \right] : \Omega \to \mathbb{R}^2,$$  \hspace{1cm} (2.1)

is obtained by the partial derivatives $\partial I/\partial x$ and $\partial I/\partial y$ at every pixel location. The local derivative operation can be done by convolving an image with kernels shown in figure 2.1. The magnitude of the first derivative

$$|\nabla I| = \sqrt{(\partial I/\partial x)^2 + (\partial I/\partial y)^2} : \Omega \to \mathbb{R}$$  \hspace{1cm} (2.2)

Figure 2.1: Examples of gradient kernels along: (a) vertical direction, (b) horizontal direction
determines the presence of edges in an image\textsuperscript{1}.

The Laplacian of an image function $I(x, y)$ is the sum of the second-order derivatives, defined as

$$\nabla^2 I = \frac{\partial^2 I}{\partial x^2} + \frac{\partial^2 I}{\partial y^2} : \Omega \rightarrow \mathbb{R}. \quad (2.3)$$

The general use of the Laplacian is in finding the location of edges using its zero-crossings \textsuperscript{11}. A critical disadvantage of the gradient operation is that the derivative enhances noise. As a second-order derivative, the Laplacian is even more sensitive to noise. An alternative is convolving an image with the Laplacian of a Gaussian (LoG) function \textsuperscript{12}, given by

$$\text{LoG}(x, y) = -\frac{1}{\pi\sigma^4} \left[ 1 - \frac{x^2 + y^2}{2\sigma^2} \right] \exp\left(-\frac{x^2 + y^2}{2\sigma^2}\right) : \Omega \rightarrow \mathbb{R}, \quad (2.4)$$

where a two-dimensional Gaussian function with the standard deviation $\sigma$ is defined as

$$G(x, y) = \frac{1}{2\pi\sigma^2} \exp\left(-\frac{x^2 + y^2}{2\sigma^2}\right) : \Omega \rightarrow \mathbb{R}. \quad (2.5)$$

The LoG function produces smooth edges as the Gaussian filtering provides smoothing effect \textsuperscript{13}.

Sobel operation is performed by convolving an image with kernels shown in figure 2.2. Sobel operators have the advantage of providing both a derivative and a smoothing effect \textsuperscript{11, 14}. The smoothing effect is a particularly attractive feature of the Sobel operators compared to the gradient kernels shown in figure 2.1 because the derivative enhances noise.

Canny edge detector \textsuperscript{15, 4} is based on the extrema of the first derivative of the Gaussian operator applied to an image. The operator first smoothes the image to eliminate noise, and then finds high gradient regions. After non-maximum suppression, the edges are finally determined by two thresholds, i.e. $\tau_{\text{min}}$ and $\tau_{\text{max}}$ as shown in table 2.1. Canny edge detector is known as an optimal edge detector because it satisfies the criteria of low error rate, good localization of edge points, and a single response to a single edge pixel \textsuperscript{16}.

Edge detection by gradient operations generally work well only in the images with sharp intensity transitions and relatively low noise. Due to its sensitivity to noise, some smoothing operation is generally required as preprocessing, and the smoothing effect consequently blurs the edge information. However, the computational cost is relatively lower than other segmentation methods because the computation can be done by a local filtering operation, i.e. convolution

\textsuperscript{1} Although the literal meaning of the term \textit{gradient} is the gradient vector $\nabla I$, it often refers to the magnitude of gradient $|\nabla I|$ in many publications.
Table 2.1: Path searching in Canny edge detector

- If $|\nabla I(x, y)| > \tau_{\text{max}}$, then $I(x, y)$ is an edge pixel.
- If $\tau_{\text{min}} < |\nabla I(x, y)| < \tau_{\text{max}}$,
  - If there is a path from $(x, y)$ to neighbor $(\hat{x})$ and $|\nabla I(\hat{x})| > \tau_{\text{min}}$, then $I(x, y)$ is an edge pixel.
  - Otherwise, $I(x, y)$ is a non-edge pixel.
- If $|\nabla I(x, y)| < \tau_{\text{min}}$, then $I(x, y)$ is a non-edge pixel.

of an image with a kernel. Edge-based active contour models, discussed in section 3.3, use the magnitude of gradient $|\nabla I|$ to determine the position of edges.

2.2 Region-based Segmentation

Region-based segmentation looks for uniformity within a sub-region, based on a desired property, e.g. intensity, color, and texture. Clustering techniques encountered in pattern classification literature have similar objectives and can be applied for image segmentation [17].

Region growing [18] is a technique that merges pixels or small sub-regions into a larger sub-region. The simplest implementation of this approach is pixel aggregation [11], which starts with a set of seed points and grows regions from these seeds by appending neighboring pixels if they satisfy the given criteria. Figure 2.3 shows a simple example of pixel aggregation. Segmentation starts with two initial seeds, and then the regions grow if they satisfy a criterion such as

$$|I(x, y) - I(\text{seed})| < \tau.$$  \hspace{1cm} (2.6)

Despite the simple nature of the algorithm, there are fundamental problems in region growing: the selection of initial seeds and suitable properties to grow the regions. Selecting initial seeds can be often based on the nature of applications or images. For example, the ROI is generally brighter than the background in IR images. In this case, choosing bright pixels as initial seeds would be a proper choice.

Additional criteria that utilize properties to grow the regions lead region growing into more sophisticated methods, e.g. region competition. Region competition [19, 20] merges adjacent sub-regions under criteria involving the uniformity of regions or sharpness of boundaries. Strong
criteria tend to produce over-segmented results, while weak criteria tend to produce poor segmentation results by over-merging the sub-regions with blurry boundaries. An alternative of region growing is *split-and-merge* [21], which partitions an image initially into a set of arbitrary, disjointed sub-regions, and then merge and/or split the sub-regions in an attempt to satisfy the segmentation criteria.

Another common approach in region-based segmentation is characterizing statistical uniformity of sub-regions using parametric models, so called *statistical estimation*. With this approach, two sub-regions are considered to be uniform, and consequently merged, if they can be represented by a single instance of the model, i.e. if they have common parameter values within a threshold. In practice, the parameters of a sub-region cannot be observed directly but can only be inferred from the observed data and the knowledge of the imaging process. In statistical approaches, this inference is often made using *Bayes’s rule* [22] and the conditional PDF $p(I(x, y)|\theta_m)$, which presents the conditional probability that certain data $I(x, y)$ (or statistics derived from the data) will be observed, given that sub-region $m$ has the parameter values of $\theta_m$. In typical statistical region merging algorithms [23], stochastic estimates in the parameter space are obtained for different sub-regions, and merging decisions are based on the similarity of these parameters.

A limitation of most estimation-based segmentation methods is that they do not explicitly represent the uncertainty in the estimated parameter values and, therefore, are prone to error when parameter estimates are poor. A *Bayesian probability of homogeneity* directly exploits all of the information contained in the statistical image models, instead of estimating parameter values [24]. The probability of homogeneity is based on the ability to formulate a prior probability density on the parameter space, and measures homogeneity by taking the expectation of the data likelihood over a posterior parameter space.

Image segmentation is often approached by *edge-preserving smoothing* operations as well as the partitioning operation. Edge-preserving smoothing techniques can be classified roughly two approaches [25]: Markov random field (MRF) including energy-based methods [26, 27] and diffusion-based methods [28, 29]. Both approaches show similar restoration characteristics because the diffusion-based methods can be viewed as an energy-based method that uses only the prior energy term at a given temperature [30]. Snyder et al. [31, 32, 33] proposed an edge-preserving smoothing method for image segmentation based on the technology called *mean field annealing* (MFA) [30, 34, 35, 36, 37, 38], and the same segmentation method was extended to vector-valued images by Han et al. [25, 39]. MFA is an energy-based method for finding the minimum of complex functions which typically have many minima [40]. For the image segmentation problem, a proper energy function is defined intending to keep the edges and to smooth the rest of areas in the image. The segmentation is performed by minimizing the energy function using MFA. MFA approximates a stochastic algorithm called simulated annealing (SA) [41], which has shown to converge to the global minimum, even for non-convex problems [42]. Hiriyanannaiah et al. [43] derived MFA using the analogy to physics for the restoration of piecewise-constant images, and Bilbro et al. [42] did the same job applying the MFA to the images with varying gray values.

Region-based approaches are generally less sensitive to noise, and usually produce more reasonable segmentation results as they rely on global properties rather than local properties, but their implementation complexity and computational cost can be often quite large. Statis-
tical segmentation methods, both estimation-based and Bayesian-based, have been extended to many active contour models including the proposed models. Those active contour models based on statistical segmentation will be discussed in section 3.4.

2.3 Other Segmentation Methods

The *watershed* algorithm [46, 47] is a morphology-based segmentation method [48, 49, 50]. It is based on the assumption that any gray-tone image can be considered as a topographic surface [51]. If we flood this surface from its minima preventing the merge of the waters coming from different sources, the surface is eventually separated as two different sets: the catchment basins and the watershed lines. If we apply this transformation to the magnitude of image gradient $|\nabla I|$, the catchment basins correspond to the uniform sub-regions in the image and the watershed lines correspond to the edges. The flooding operation is simulated using morphological distance operators [52, 53, 54].

Fusions of different principles have produced good results. There have been a few approaches to integrate region- and edge-based segmentation [55, 56], and also an approach to integrate region- and morphology-based segmentation called watersnakes [57].

Texture is another feature that we can use to determine the segmentation criteria. Images can be considered as either a collection of pixels in the spatial domain or the sum of sinusoids of infinite extent in the spatial-frequency domain. Gabor observed that the spatial representation and the spatial-frequency representation are just opposite extremes of a continuum of possible joint space/spatial-frequency representations [58]. In a joint space/spatial-frequency representations for images, frequency is considered as a local phenomenon that can vary with position throughout the image. The human visual system is performing a form of local spatial-frequency analysis on the retinal image, and the analysis is done by a bank of bandpass filters [59].

The same approach can be used to partition textured images in image analysis. Perceptually significant texture differences presumably correspond to differences in the local spatial-frequency content using the space/spatial-frequency paradigm. Texture segmentation is done by two steps: decomposing an image into a joint space/spatial-frequency representation with a bank of bandpass filters and using this information to locate the regions of similar local spatial-frequency content. The response of the filter bank generates a kind of multispectral images, where each band represents the response of the textured image at a particular spatial-frequency bandwidth. The multi-channel filtering has been implemented by the convolution of the image with a stack of two-dimensional Gabor filters [60, 61, 62, 63, 64] or wavelets [65, 66].
Chapter 3

Active Contours: background

The technique of active contours has become quite popular for a variety of applications, particularly image segmentation and motion tracking, during the last decade. This methodology is based upon the utilization of deformable contours which conform to various object shapes and motions. This chapter provides a theoretical background of active contours and an overview of existing active contour methods.

There are two main approaches in active contours based on the mathematic implementation: snakes and level sets. Snakes explicitly move predefined snake points based on an energy minimization scheme, while level set approaches move contours implicitly as a particular level of a function. More details about these two approaches will be discussed respectively in section 3.1 and 3.2. As image segmentation methods, there are two kinds of active contour models according to the force evolving the contours: edge- and region-based. Edge-based active contours use an edge detector, usually based on the image gradient, to find the boundaries of sub-regions and to attract the contours to the detected boundaries. Edge-based approaches are closely related to the edge-based segmentation discussed in section 2.1. Region-based active contours use the statistical information of image intensity within each subset instead of searching geometrical boundaries. Region-based approaches are also closely related to the region-based segmentation discussed in section 2.2. More details of these two active contour models are respectively discussed in section 3.3 and section 3.4.

3.1 Snakes

The first model of active contour was proposed by Kass et al. [2] and named snakes due to the appearance of contour\footnote{Although snakes can be defined as opened curves, we are interested in only the case of closed curves, i.e. contours $C(0) = C(L)$, because our objective is image segmentation.} evolution. Let us define a contour parameterized by arc length $s$ as

$$C(s) \equiv \{(x(s), y(s)) : 0 \leq s \leq L\} : \mathbb{R} \rightarrow \Omega,$$

where $L$ denotes the length of the contour $C$, and $\Omega$ denotes the entire domain of an image $I(x, y)$. The corresponding expression in a discrete domain approximates the continuous expression as

$$C(s) \approx C(n) = \{(x(n), y(n)) : 0 \leq n \leq N, s = 0 + n\Delta s\},$$
where \( L = N \Delta s \). An energy function \( E(C) \) can be defined on the contour such as

\[
E(C) = E_{\text{int}} + E_{\text{ext}},
\]

where \( E_{\text{int}} \) and \( E_{\text{ext}} \) respectively denote the internal energy and external energy functions. The internal energy function determines the regularity, i.e. smooth shape, of the contour. A common choice for the internal energy is a quadratic functional given by

\[
E_{\text{int}} = \int_0^L \alpha |C'(s)|^2 + \beta |C''(s)|^2 ds \approx \sum_{n=0}^N (\alpha |C'(n)|^2 + \beta |C''(n)|^2) \Delta s.
\]

Here \( \alpha \) controls the tension of the contour, and \( \beta \) controls the rigidity of the contour. The external energy term determines the criteria of contour evolution depending on the image \( I(x,y) \), and can be defined as

\[
E_{\text{ext}} = \int_0^L E_{\text{img}}(C(s)) ds \approx \sum_{n=0}^N E_{\text{img}}(C(n)) \Delta s,
\]

where \( E_{\text{img}}(x,y) \) denotes a scalar function defined on the image plane, so the local minimum of \( E_{\text{img}} \) attracts the snakes to edges. A common example of the edge attraction function is a function of image gradient, given by

\[
E_{\text{img}}(x,y) = \frac{1}{\lambda |\nabla G_\sigma * I(x,y)|} : \Omega \rightarrow \mathbb{R},
\]

where \( G_\sigma \) denotes a Gaussian smoothing filter with the standard deviation \( \sigma \), and \( \lambda \) is a suitably chosen constant. Solving the problem of snakes is to find the contour \( C \) that minimizes the total energy term \( E \) with the given set of weights \( \alpha, \beta, \) and \( \lambda \). In numerical experiments, a set of snake points residing on the image plane are defined in the initial stage, and then the next position of those snake points are determined by the local minimum \( E \). The connected form of those snake points is considered as the contour.

The classic snakes provide an accurate location of the edges only if the initial contour is given sufficiently near the edges because they make use of only the local information along the contour. Estimating a proper position of initial contours without prior knowledge is a difficult problem. Also, classic snakes cannot detect more than one boundary simultaneously because the snakes maintain the same topology during the evolution stage. That is, snakes cannot split to multiple boundaries or merge from multiple initial contours. Level set theory [3] has given a solution for this problem.

### 3.2 Level Set Methods

Level set theory, a formulation to implement active contours, was proposed by Osher and Sethian [3]. They represented a contour implicitly via a two-dimensional Lipschitz-continuous function \( \phi(x,y) : \Omega \rightarrow \mathbb{R} \) defined on the image plane. The function \( \phi(x,y) \) is called level set
function, and a particular level, usually the zero level, of $\phi(x, y)$ is defined as the contour, such as
\[ C \equiv \{(x, y) : \phi(x, y) = 0\}, \forall (x, y) \in \Omega, \tag{3.7} \]
where $\Omega$ denotes the entire image plane. Figure 3.1(a) shows the evolution of level set function $\phi(x, y)$, and figure 3.1(b) shows the propagation of the corresponding contours $C$. As the level set function $\phi(x, y)$ increases from its initial stage, the corresponding set of contours $C$, i.e. the red contour, propagates toward outside.\(^2\) With this definition, the evolution of the contour is equivalent to the evolution of the level set function, i.e. $\partial C / \partial t = \partial \phi(x, y) / \partial t$. The advantage of using the zero level is that a contour can be defined as the border between a positive area and a negative area, so the contours can be identified by just checking the sign of $\phi(x, y)$. The initial level set function $\phi_0(x, y) : \Omega \rightarrow \mathbb{R}$ may be given by the signed distance from the initial contour such as,
\[
\phi_0(x, y) = \begin{cases} 
\phi(x, y) : t = 0 & \\
\pm D((x, y), N_{x,y}(C_0)) & \forall (x, y) \in \Omega, 
\end{cases} \tag{3.8}
\]
where $\pm D(a, b)$ denotes a signed distance between $a$ and $b$, and $N_{x,y}(C_0)$ denotes the nearest neighbor pixel on initial contours $C_0 \equiv C(t = 0)$ from $(x, y)$. Figure 3.2(a) shows an example of initial contours $C_0$, and figure 3.2(b) shows the initial level set function $\phi_0(x, y)$ as the signed distance computed from the initial contour $C_0$. $\phi_0(x, y)$ increases, i.e. become brighter, as a pixel $(x, y)$ is located further inwards from the initial contours $C_0$, while $\phi_0(x, y)$ decreases, i.e. become darker, as the pixel is located further outwards from the initial contours. The initial level set function is zero at the initial contour points given by, $\phi_0(x, y) = 0$, $\forall (x, y) \in C_0$.

The deformation of the contour is generally represented in a numerical form as a PDE. A formulation of contour evolution using the magnitude of the gradient of $\phi(x, y)$ was initially proposed by Osher and Sethian [69, 70, 3], given by
\[
\frac{\partial \phi(x, y)}{\partial t} = |\nabla \phi(x, y)|(\nu + \varepsilon \kappa(\phi(x, y))) \, , \tag{3.9}
\]
\(^2\)In figure 3.1, the amount of level set evolution is set as a constant along the entire domain, $\partial \phi(x, y) / \partial t = c$, $\forall (x, y) \in \Omega$, for easy understanding. Normally, $\partial \phi(x, y) / \partial t$ is a function of spatial coordinates $(x, y)$. 

---

Figure 3.1: Level set evolution and the corresponding contour propagation: (a) topological view of level set $\phi(x, y)$ evolution, (b) the changes on the zero level set $C : \phi(x, y) = 0$
where $\nu$ denotes a constant speed term to push or pull the contour, $\kappa(\cdot) : \Omega \rightarrow \mathbb{R}$ denotes the mean curvature of the level set function $\phi(x, y)$ given by

$$
\kappa(\phi(x, y)) = \text{div} \left( \frac{\nabla \phi}{\|\nabla \phi\|} \right) = \frac{\phi_{xx} \phi_y^2 - 2 \phi_x \phi_y \phi_{xy} + \phi_{yy} \phi_x^2}{(\phi_x^2 + \phi_y^2)^{3/2}},
$$

(3.10)

where $\phi_x$ and $\phi_{xx}$ denote the first- and second-order partial derivatives of $\phi(x, y)$ respect to $x$, and $\phi_y$ and $\phi_{yy}$ denote the same respect to $y$. The role of the curvature term is to control the regularity of the contours as the internal energy term $E_{\text{int}}$ does in the classic snakes model, and $\varepsilon$ controls the balance between the regularity and robustness of the contour evolution.

Another form of contour evolution was proposed by Chan and Vese [9, 71]. The length of the contour $|C|$ can be approximated by a function of $\phi(x, y)$ [72, 73], such as

$$
|C| \approx L_\varepsilon(\phi(x, y)) = \int_{\Omega} |\nabla H_\varepsilon(\phi(x, y))| dx dy
= \int_{\Omega} \delta_\varepsilon(\phi(x, y)) |\nabla \phi(x, y)| dx dy,
$$

(3.11)

where $H_\varepsilon(\cdot)$ denotes the regularized form of the unit step function\(^3\) $H(\cdot) : \Omega \rightarrow \mathbb{R}$ given by

$$
H(x, y) = \begin{cases} 
1, & \text{if } \phi(x, y) \geq 0 \\
0, & \text{if } \phi(x, y) < 0
\end{cases}, \forall (x, y) \in \Omega,
$$

(3.12)

and $\delta_\varepsilon(\cdot)$ denotes the derivative of $H_\varepsilon(\cdot)$. Since the unit step function produces either 0 or 1 depending on the sign of the input, the derivative of the unit step function produces non-zero only where $\phi(x, y) = 0$, i.e. on the contour $C$. Consequently, the integration shown in equation 3.11 is equivalent to the length of contours on the image plane. The associated Euler-Lagrange equation [74] obtained by minimizing $L_\varepsilon(\cdot)$ with respect to $\phi$ and parameterizing the

\(^3\)This unit step function is often referred to Heaviside function.
descent directions by an artificial time $t$ is given by

$$\frac{\partial \phi(x, y)}{\partial t} = \delta_\epsilon(\phi(x, y))\kappa(\phi(x, y)).$$

(3.13)

The contour evolution motivated by the equation above can be interpreted as the motion by mean curvature minimizing the length of the contour. Therefore, equation 3.9 is considered as the motion motivated by PDE, while equation 3.13 is considered as the motion motivated by energy minimization.

An outstanding characteristic of level set methods is that contours can split or merge as the topology of the level set function changes. Therefore, level set methods can detect more than one boundary simultaneously, and multiple initial contours can be placed. Figure 3.3(a) shows an example of the topological changes on a level set function, while figure 3.3(b) shows how the initially separated contours merge as the topology of level set function varies. This flexibility and convenience provide a means for an autonomous segmentation by using a predefined set of initial contours. The computational cost of level set methods is high because the computation should be done on the same dimension as the image plane $\Omega$. Thus, the convergence speed is relatively slower than other segmentation methods, particularly local filtering based methods. The high computational cost can be compensated by using multiple initial contours. The use of multiple initial contours increases the convergence speed by cooperating with neighbor contours quickly. Level set methods with faster convergence, called fast marching methods [75], have been studied intensively for the last decade. Because of these attractive properties, we implement the proposed active contour model using the level set method.

### 3.3 Edge-based Active Contours

Edge-based active contours are closely related to the edge-based segmentation. Most edge-based active contour models consist of two parts: the regularity part, which determines the shape of contours, and the edge detection part, which attracts the contour towards the edges.
**Geometric active contour** model was proposed by Caselles et al. [79] adding an additional term, called *stopping function*, to the speed function shown in equation 3.9. It was the first level set implemented active contour model for the image segmentation problem. Malladi et al. [80, 76] proposed a similar model given by

\[
\frac{\partial \phi(x, y)}{\partial t} = g(I(x, y))(\kappa(\phi(x, y)) + \nu)|\nabla \phi(x, y)|,
\]

where \(g(\cdot) : \Omega \rightarrow \mathbb{R}\) denotes the stopping function, i.e. a positive and decreasing function of the image gradient. A simple example of the stopping function is given by

\[
g(I(x, y)) = \frac{1}{1 + |\nabla I(x, y)|^n},
\]

where \(n\) is given as 1 in [79] and 2 in [80]. Note that \(|\nabla I(x, y)|\) can be interchangeably used with \(E_{img}\) shown in equation 3.6. The contours move in the normal direction with a speed of \(g(I(x, y))(\kappa(\phi(x, y)) + \nu)\), and therefore stops on the edges, where \(g(\cdot)\) vanishes. The curvature term \(\kappa(\cdot)\) maintains the regularity of the contours, while the constant term \(\nu\) accelerates and keeps the contour evolution by minimizing the enclosed area [81].

**Geodesic active contour** model was proposed by Caselles et al. [82, 83] after the geometric active contour model. Kichenassamy et al. [84] and Yezzi et al. [85] also proposed a similar active contour model. Based on the principle of the classic dynamic systems, solving the active contour problem is equivalent to finding a path of minimal distance, called *geodesic curve* [86] given by

\[
\frac{\partial C}{\partial t} = (g(I(x, y))\kappa(\phi(x, y)) - \nabla g(I(x, y)) \cdot \nabla \phi(x, y)),
\]

where \(\mathcal{N}\) denotes the inward unit normal\(^4\) given by

\[
\mathcal{N} = -\frac{\nabla \phi}{\|\nabla \phi\|}.
\]

From the relation between a contour and a level set function and the level set formulation of the steepest descent method, solving this geodesic problem is equivalent to searching for the steady state of the level set evolution equation [82, 87] given by

\[
\frac{\partial \phi(x, y)}{\partial t} = g(I(x, y))(\kappa(\phi(x, y)) + \nu)|\nabla \phi(x, y)| + \nabla g(I(x, y)) \cdot \nabla \phi(x, y),
\]

where \(\nu\) is an additional speed term to accelerate the evolution.\(^5\) The equivalence between classic snakes and geodesic active contours has been also shown by other authors [88, 89, 90, 91] in slightly different views. We can notice that the geodesic active contour model shown in equation 3.18 is identical to the geometric active contour model shown in equation 3.14 except for the advection term \(\nabla g(I(x, y)) \cdot \nabla \phi(x, y)\). Geodesic active contours have been the most popular methods among the edge-based active contour models, and their applications have been extended to multispectral images by Sapiro.

**Color snakes** is the geodesic active contour model particularly for multispectral images proposed by Sapiro [86, 92, 93, 87]. In order to detect the edges in multispectral images, a

\(^4\)Some authors define \(\mathcal{N}\) as the outward unit normal with an opposite sign.

\(^5\)The level set function still slowly converges even without \(\nu\).
special gradient function based on Riemannian geometry, called color gradient function, is used instead of the traditional image gradient function. A simple example of the color gradient function is given by

\[ g(I(x, y)) = \frac{1}{1 + (\lambda_+ - \lambda_-)} \]  

(3.19)

where \( \lambda_+ \) and \( \lambda_- \) respectively present the maximal and the minimal rate of changes on the multispectral image \( I(x, y) \). \( \lambda_+ \) and \( \lambda_- \) are the eigenvalues of the metric tensor [94] given by

\[
\begin{bmatrix}
g_{11} & g_{12} \\
g_{21} & g_{22}
\end{bmatrix} = \sum_b \left[ \left( \frac{\partial I_b}{\partial x} \right)^2 \left( \frac{\partial I_b}{\partial y} \right)^2 \right],
\]

(3.20)

where \( I_b \) denotes the \( b \)-th band of the multispectral image \( I(x, y) \). In the case of scalar images, i.e. gray images, \( \lambda_+ = |\nabla I|^2 \) and \( \lambda_- = 0 \), so the stopping function shown in equation 3.19 become identical to equation 3.15. Sapiro also introduced color self-snakes [86, 95, 93, 87], which diffuse the image in the same way that we evolve the level set function. This is an edge-preserving smoothing method like MFA or image diffusion using active contours.

Due to the structure of the speed functions and the stopping functions in equation 3.9 and equation 3.18, edge-based active contour models have a few disadvantages compared to the region-based active contour models, discussed in the next section. Because of the constant term \( \nu \), edge-based active contour models evolve the contour towards only one direction, either inside or outside. Therefore, an initial contour should be placed completely inside or outside of ROI, and some level of a prior knowledge is still required. Also, edge-based active contours inherit some disadvantages of the edge-based segmentation methods due to the similar technique used. Since both edge-based segmentation and edge-based active contours rely on the image gradient operation, edge-based active contours may skip the blurry boundaries, and they are sensitive to local minima or noise as edge-based segmentation does. Gradient vector flow fast geodesic active contours [96, 97] proposed by Paragios replaced the edge detection (boundary attraction) term with gradient vector field [98, 99, 100, 101, 102], that refers to a spatial diffusion of the boundary information and guides the propagation to the object boundaries from both sides, to give more freedom from the restriction of initial contour position.

### 3.4 Region-based Active Contours

Most region-based active contour models consist of two parts: the regularity part, which determines the smooth shape of contours, and the energy minimization part, which searches for uniformity of a desired feature within a subset. A nice characteristic of region-based active contours is that the initial contours can be located anywhere in the image as region-based segmentation relies on the global energy minimization rather than local energy minimization. Therefore, less prior knowledge is required than edge-based active contours.

Piecewise-constant active contour\(^6\) model was proposed by Chan and Vese [9, 71] using the Mumford-Shah segmentation model [105, 106]. Piecewise-constant active contour model moves

\(^6\)Although the titles of [9, 71] are “Active Contours without Edges,” all region-based active contours introduced in this section also do not use edge information. Thus, we refer to this method as piecewise-constant active contour model through this document.
deformable contours minimizing an energy function instead of searching edges. A constant approximates the statistical information of image intensity within a subset, and a set of constants, i.e. a piecewise-constant, approximate the statistics of image intensity along the entire domain of an image. The energy function measures the difference between the piecewise-constant and the actual image intensity at every image pixel. The level set evolution equation is given by

\[
\frac{\partial \phi(x, y)}{\partial t} = \delta_t(\phi(x, y)) \left[ \nu_\kappa(\phi(x, y)) - \left\{ (I(x, y) - \mu_1(x, y))^2 - (I(x, y) - \mu_0(x, y))^2 \right\} \right],
\]

(3.21)

where \(\mu_0\) and \(\mu_1\) respectively denote the mean of the image intensity within the two subsets, i.e. the outside and inside of contours. The final partitioned image can be represented as a set of piecewise-constants, where each subset is represented as a constant. This method has shown the fastest convergence speed among region-based active contours due to the simple representation. Lee et al. [107] showed an improvement to the piecewise-constant active contour model on illuminated images by proposing an alternative energy function.

**Piecewise-smooth active contour** model, an extension of piecewise-constant model using a set of smoothed partial images, was also proposed by Chan and Vese [108, 109, 110, 111, 112]. The same segmentation principles used for piecewise-constant model partitions an image, but a smoothed partial images instead of constants represent each subset. The level set evolution equation is given by

\[
\frac{\partial \phi(x, y)}{\partial t} = \delta_t(\phi(x, y)) \left[ \nu_\kappa(\phi(x, y)) - \left\{ (I(x, y) - \mu_1(x, y))^2 - (I(x, y) - \mu_0(x, y))^2 \right\} \right] - \omega(\nabla \mu_1(x, y)^2 - |\nabla \mu_0(x, y)|^2),
\]

(3.22)

where \(\mu_0(x, y)\) and \(\mu_1(x, y)\) respectively denote the smoothed images within the outside and inside of contours. The segmentation result of piecewise-smooth active contours is similar to the segmentation by color self-snakes because of the similar approach.

Although traditional region-based active contours partition an image into multiple subregions, those multiple regions belong to only two subsets: either the inside or the outside of contours. Chan and Vese proposed **multi-phase active contour** model\(^7\) [108, 74, 113, 114, 115], which increases the number of subsets\(^8\) that active contours can find simultaneously. Multiple active contours evolve independently based on the piecewise-constant model shown in equation 3.21 or the piecewise-smooth model shown in equation 3.22, and multiple subsets are defined by a group of disjoint combination of the level set functions. For example, \(N\) level set functions define maximum \(2^N\) subsets of the entire region. An example of subsets defined by 4-phase active contours is

\[
\begin{bmatrix}
\Omega_0 \\
\Omega_1 \\
\Omega_2 \\
\Omega_3
\end{bmatrix} = \left\{ (x, y) : \begin{cases}
\phi_2(x, y) < 0, \phi_1(x, y) < 0 \\
\phi_2(x, y) < 0, \phi_1(x, y) > 0 \\
\phi_2(x, y) > 0, \phi_1(x, y) < 0 \\
\phi_2(x, y) > 0, \phi_1(x, y) > 0
\end{cases} \right\},
\]

(3.23)

\(^7\)Here, the term *multi* refers to more than two instead of more than one. Two terms *phase* and *subset* are considered identical in the image segmentation problem, and used interchangeably in this document.

\(^8\)A *sub-region* refers to a group of image pixels that have similar property and reside within the same boundaries. A *subset* refers to a group of the subregions that have similar property but does not necessarily reside within the same boundary.
where \( \{\Omega_0, \Omega_1, \Omega_2, \Omega_3\} \) denote the four subsets defined by two level set functions \( \{\phi_1, \phi_2\} \), i.e., two active contours. The level set evolution equation for this case is given by

\[
\frac{\partial \phi_1(x, y)}{\partial t} = \delta(\phi_1(x, y)) \nu \kappa \phi_1(x, y) - \left\{ \begin{array}{l} (I(x, y) - \mu_3)^2 \\ (I(x, y) - \mu_2)^2 \\ (I(x, y) - \mu_1)^2 \\ (I(x, y) - \mu_0)^2 \end{array} \right\} \begin{cases} H_2+ \\ H_1+ \\ (1-H_2) \\ (1-H_1) \end{cases},
\]

\[
\frac{\partial \phi_2(x, y)}{\partial t} = \delta(\phi_2(x, y)) \nu \kappa \phi_2(x, y) - \left\{ \begin{array}{l} (I(x, y) - \mu_3)^2 \\ (I(x, y) - \mu_2)^2 \\ (I(x, y) - \mu_1)^2 \\ (I(x, y) - \mu_0)^2 \end{array} \right\} \begin{cases} H_2+ \\ H_1+ \\ (1-H_2) \\ (1-H_1) \end{cases},
\]

where \( H_n \equiv H_n(\phi_n(x, y)) \) and \( \{\mu_0, \mu_1, \mu_2, \mu_3\} \) denote the mean of image intensity within the corresponding subsets \( \{\Omega_0, \Omega_1, \Omega_2, \Omega_3\} \). Rousson and Deriche [116, 10, 117] and Yezzi et al. [118, 119] proposed a similar multi-phase active contour model for segmentation problems, and Samson et al. [120, 121, 122] also proposed a multi-phase active contour model for pattern classification problems. Multi-phase active contours provide a means to integrate segmentation and pattern classification tasks. m-phase active contours partition the image into multiple sub-regions (≫ m), and they simultaneously identify those regions into m-subsets, i.e. classes. Depending whether training samples are provided or not, supervised or unsupervised segmentation can actually perform supervised or unsupervised pattern classification. This provides a way to the autonomous pattern classification technology reducing the number of procedures and processing time.

The same segmentation principle can be extended to multispectral images by taking the mean of energy functions measured at each band [5, 123]. The level set evolution equation of 2-phase active contour model is given by

\[
\frac{\partial \phi(x, y)}{\partial t} = \delta(\phi(x, y)) [\nu \kappa \phi(x, y)] - \sum_b \left\{ \omega_{1b}(I_b(x, y) - \mu_{1b})^2 - \omega_{0b}(I_b(x, y) - \mu_{0b})^2 \right\},
\]

where \( \mu_b = [\mu_{i_1}, \mu_{i_2}, \ldots, \mu_{i_b}, \ldots, \mu_{i_B}]^T \) denotes the mean vector of the vector valued image intensity \( I(x, y) \) within the corresponding subset \( \Omega_i \).

Rousson and Deriche proposed a variational formulation obtained from a Bayesian segmentation model [116, 10, 117]. While the piecewise-constant active contour model uses a group of constants to represent subsets, this method implicitly uses a conditional PDF of a given value \( I(x, y) \) with respect to the hypothesis, i.e. a unimodal (multivariate) Gaussian distribution, given by

\[
p(I(x, y)|\{\mu_i, \Sigma_i\}) = \frac{1}{(2\pi)^{d/2}|\Sigma_i|^{1/2}} \exp \left( -\frac{1}{2}(I(x, y) - \mu_i)^T \Sigma_i^{-1}(I(x, y) - \mu_i) \right),
\]

where \( \mu_i \) and \( \Sigma_i \) are the parameters of a (multivariate) Gaussian distribution. Taking the negative log form of the PDF as an energy function, the level set evolution equation minimizing the energy function is given by

\[
\frac{\partial \phi(x, y)}{\partial t} = \delta(\phi(x, y)) [\nu \kappa \phi(x, y)] - \{e_1(x, y) - e_0(x, y)\},
\]
where the objective functions $e_i$ are given by

\[
e_i(x, y) \equiv -\log p(I(x, y)|\mu_i, \Sigma_i) \\
\simeq \log |\Sigma_i| + (I(x, y) - \mu_i)^T \Sigma_i^{-1} (I(x, y) - \mu_i).
\]

The extension of this method for multispectral images is trivial as the energy function is based on the multivariate PDF. A unique feature of this method is that multivariate PDF consider each band of multispectral images as independent dimension of an image intensity space. Multivariate PDF does not make big improvement in this active contour model, but it does make a significant improvement in the proposed active contour models using a mixture density function. More detail of the improvement will be discussed in chapter 5.2.

Due to the global energy minimization, region-based active contours generally do not have any restriction on the placement of initial contours. That is, region-based active contour can detect interior boundaries regardless of the position of initial contours. The use of pre-defined initial contours provides a method of autonomous segmentation. Also, they are less sensitive to local minima or noise than edge-based active contours. However, due to the assumption of uniform image intensity, most methods are applicable only to images where each subset is representable by a simple expression, e.g. single Gaussian distribution or a constant. If a subset, i.e. class, consists of multiple distinctive sub-classes, e.g. the zebra shown in figure 1.3(b), these methods would produce over-segmented or under-segmented results. We propose novel region-based active contour models which produce improved results using multivariate mixture density functions.

3.5 Active Contours Integrating Edge- and Region-based Segmentation

In order to improve the segmentation performance, the integration of edge- and region-based information sources using active contours has been proposed by a few authors. Geodesic active region is a supervised active contour model, proposed by Paragios [124, 125, 126], integrating edge- and region-based segmentation module in an energy function. A statistical analysis based on the Minimum Description Length (MDL) criterion and the Maximum Likelihood (ML) principle for the observed density function, i.e. an image histogram, indicates the number of sub-regions and the statistical PDF within those sub-regions using a mixture of Gaussian elements. Regional probability is estimated from the statistical PDF based on prior knowledge, i.e. training samples. Then, the boundary information is determined by a probabilistic edge detector, estimated from the regional probabilities of neighborhood [127, 128]. For example, an image pixel is more likely an edge pixel if the neighborhood pixels, located on the opposite sides, have high regional probabilities for a different class. The level set evolution equation is given by

\[
\frac{\partial \phi(x, y)}{\partial t} = |\nabla \phi(x, y)| \left[ \alpha \sum_b \omega_b \log \left( \frac{p_1(I_b(x, y))}{p_2(I_b(x, y))} \right) + (1 - \alpha) \left\{ g(p_B(x, y)) \kappa(\phi(x, y)) + \nabla g(p_e(x, y)) \cdot \frac{\nabla \phi(x, y)}{\left| \nabla \phi(x, y) \right|} \right\} \right]
\]

where $I_b(x, y)$ denotes $b$-th band of a multispectral image $I(x, y)$, and $p_i(I_b(x, y))$ denotes the regional probability presenting a probability that a pixel $I_b(x, y)$ belongs to sub-region $i$, $p_e(x, y)$
denotes the probabilistic edge detector presenting a probability that a boundary pixel is located at \((x, y)\), and \(g(p_e)\) denotes a positive and decreasing function of the probability. The regional probability is computed from each band and accumulated. A detail to determine both probabilities, \(p_i(I_b(x, y))\) and \(p_e(x, y)\), is explained in [128]. The geodesic active region model is later applied to a medical imaging problem [129, 130] with a gradient vector flow-based boundary component. The approach was based on a coupled propagation of two active contours, and integrates visual information with anatomical constraints.

Jehan-Besson et al. also proposed an active contour model [131, 132] minimizing an energy criterion involving both region and boundary functionals. These functionals are derived through a shape derivative approach instead of classical calculus of variation. They focus on statistical property, i.e. the PDF of the color histogram of a sub-region. Active contours are propagated minimizing the distance between two histograms for matching or tracking purposes.
Chapter 4

Region-based Segmentation using Active Contours

Region-based segmentation looks for uniformity within a sub-region based on a desired feature, e.g. intensity, color, and texture. Region-based active contour models have shown attractive characteristics, such as the unrestricted position of initial contours, the automatic detection of interior boundaries, and reasonable segmentation due to global energy minimization though the segmentation results are still case dependent. Region-based active contours evolve deformable shapes based on two forces: energy minimization based on the statistical properties, which pursues the uniformity within each subset, and curvature motion motivated by level set function, which keeps the regularity of active contours. In this chapter, we propose a novel segmentation principle based on regional energy minimization using the statistics of image intensity. First, we redefine the terminology used in the image segmentation problem in section 4.1. Then, we discuss the base segmentation model, proposed by Mumford-Shah, of the proposed active contour model in section 4.2. Finally, we discuss the proposed segmentation principle and its implementation in section 4.3.

4.1 Image, Subset, and Sub-region

Let us redefine the notation of terms used in our segmentation model.1 As introduced in chapter 1, an image $I(x, y)$ is the native input data of the image analysis, given as a form of a function defined on a two-dimensional spatial domain. We define a multispectral image as a general form of images and a scalar image as a particular case of multispectral images. A multispectral image $I(x, y)$ can be defined as a set of vectors given by

$$I(x, y) \equiv [I_1(x, y), I_2(x, y), \ldots , I_b(x, y), \ldots , I_B(x, y)]^T : \Omega \rightarrow \mathbb{R}^B,$$  \hspace{1cm} (4.1)

where $I_b(x, y)$ denotes a scalar image measured at band $b$. Let the vector-valued image intensity of $I(x, y)$ be a multi-dimensional random variable $I \in \mathbb{R}^B$ where $B$ denotes the dimension of $I$ and is equivalent to the number of optical bands measured.

Let $\Psi$ represent the entire region of an image $I(x, y)$. Image segmentation is a task to partition the entire region $\Psi$ into $n$ sub-regions, $\{\Psi_1, \Psi_2, \ldots , \Psi_i, \ldots , \Psi_n\}$, with the criteria shown in table 4.1. $C_i$ denotes the boundary wrapping sub-region $\Psi_i$. The first and second condi-

Table 4.1 lists the criteria of general image segmentation, and we here introduce slightly different criteria for region-based segmentation. Let a set \( \Omega \), instead of a region \( \Psi \), represent the entire domain of an image \( \mathbf{I}(x, y) \). The region-based image segmentation is a task to partition the entire set \( \Omega \) of an image into \( m \) subsets, \( \{\Omega_1, \Omega_2, \ldots, \Omega_i, \ldots, \Omega_m\} \), with the criteria shown in table 4.2. The only difference between a subset \( \Omega_i \) and a sub-region \( \Psi_j \) is that a subset \( \Omega_i \) does not necessarily form a spatial unit. That is, \( \Omega_i \) may contain multiple sub-regions \( \Psi_j \) residing in different spatial locations on the entire set \( \Omega \) of an image. Following expression shows the relation between \( n \) subsets and \( m \) sub-regions:

\[
(\Omega = \Psi) \supseteq \Omega_i \supseteq \Psi_j \supseteq (x, y),
\]

2The width of a boundary is often considered as infinitely small in continuous expression.
where \( i = 1, 2, \ldots, m \) and \( j = 1, 2, \ldots, n \). \((\Omega = \Psi)\) denotes the entire set of an image as the largest possible spatial unit, while \((x, y)\) denotes an image pixel as the smallest possible spatial unit. Figure 4.1 shows an example that sub-regions and subsets are not identical. The entire set of the image \((\Omega = \Psi)\) consists of two subsets \(\{\Omega_0, \Omega_1\}\) and three sub-regions \(\{\Psi_0, \Psi_1, \Psi_2\}\). A subset \(\Omega_1\) exists at two different spatial locations, where each of them is independently marked as \(\Psi_1\) and \(\Psi_2\). Therefore, two main approaches of segmentation, i.e. edge- and region-based, can be reintroduced such that edge-based segmentation partitions an image \(I(x, y)\) into multiple sub-regions \(\Psi_j\) searching for discontinuities among sub-regions, while region-based segmentation partitions an image \(I(x, y)\) into multiple subsets \(\Omega_i\) searching for uniformity within a subset \(\Omega_i\).

### 4.2 The Base Segmentation Model

Mumford and Shah [105, 106] posed the image segmentation problem as a variational problem to find an optimal piecewise-smooth approximation \(f(x, y)\) of the given scalar image \(I(x, y)\) and a set of boundaries \(C\), such that the approximation \(f(x, y)\) varies smoothly within the connected components of the subsets excluding the boundaries, i.e. \(\Omega \setminus C\). They proposed to solve the variational segmentation problem by minimizing the following global energy function [74]

\[
E^{MS}(f, C) = \int_\Omega |I(x, y) - f(x, y)|^2 dx dy + \mu \int_{\Omega \setminus C} |\nabla f(x, y)|^2 dx dy + \nu |C|,
\]

with respect to two terms, the approximation \(f\) of the given image and the variational boundaries \(C\). The global energy function \(E^{MS}\) consists of three parts. The minimization of the first part approximates the image \(I(x, y)\) with an alternative expression \(f(x, y)\) by minimizing the squared difference between the two expressions \(|I(x, y) - f(x, y)|^2\). The second part piecewisely smooths \(f(x, y)\) by minimizing \(|\nabla f(x, y)|^2\) on \(\Omega \setminus C\). \(C\) has the role of approximating the edges of \(I(x, y)\). The third part smoothes \(C\) by minimizing the length \(|C|\). The existence and regularity of the solution of the problem above is proven in [136, 105].

---

3According to the definition, \(m \leq n\) in general, but it can be \(m \ll n\) depending on the image.

4In the original publication [108, 105, 106], the integration respect to one-dimensional Hausdorff measure was used instead of \(|C|\). The equivalence between two expressions \(|C| = \int_C d\mathcal{H}^1\) is shown in [74].
The global piecewise approximation \( f(x, y) \) can be represented as a sum of sub-approximations given by

\[
    f(x, y) \equiv \sum_{i} f_{i}(x, y), \quad \forall (x, y) \in \Omega,
\]

(4.4)

where \( f_{i} \) approximates the given multispectral image \( I(x, y) \) within \( \Omega_{i} \), and \( \chi_{i}(x, y) : \Omega \rightarrow \{0, 1\} \)

is determined by the spatial domain of \( \Omega_{i} \) such as

\[
    \chi_{i}(x, y) = \begin{cases} 
        1, & \forall (x, y) \in \Omega_{i} \\
        0, & \forall (x, y) \notin \Omega_{i} 
    \end{cases}, \quad \forall i.
\]

(4.5)

Note that \( f_{i} \) is not necessarily an image function but any expression that represents the feature, used as the region-based segmentation criteria, of the image within \( \Omega_{i} \).

The global energy function \( E^{MS}(f, C) \) given in equation 4.3 can be simplified and generalized by ignoring the smoothing term and defining independent objective functions for each subset, such that

\[
    E(\{f_{i}\}, C) \equiv \sum_{i} \int_{\Omega_{i}} e(x, y|f_{i})dxdy + \nu|C|,
\]

(4.6)

where the variational contour \( C \) determines the domain of variational subsets \( \Omega_{i} \). The objective function \( e(x, y|f_{i}) : \Omega \rightarrow \mathbb{R} \) determines the condition of region-based segmentation within each \( \Omega_{i} \), e.g. the uniformity of image intensity \( I \), and how well the approximation \( f_{i} \) represents the given image. Better \( f_{i} \) results in lower \( e \) for each \( \Omega_{i} \), consequently lower \( E \). The minimum of \( E \) is achieved by two sequential minimization procedures. First, the minimization of \( E \) with respect to each of \( f_{i} \), while \( C \) is fixed, finds the best representations of each \( \Omega_{i} \) of the given image \( I(x, y) \) minimizing the objective function \( e(x, y|f_{i}) \). Then, the minimization of \( E \) with respect to \( C \), while \( \{f_{i}\} \) are fixed, smooths the variational boundaries \( C \) minimizing \( |C| \). Combination of these two minimizations leads to the region-based active contour evolution, which moves a set of contours \( C \) satisfying the segmentation constraints on the given image.

Depending on the objective function \( e(x, y|f_{i}) \) and representation \( f_{i} \), various active contour models can be achieved from the global energy function shown in equation 4.6. The energy function of piecewise-constant active contour model [5] can be transformed to equation 4.6 with an objective function

\[
    e(x, y|f_{i} \equiv \mu_{i}) = \frac{1}{B} \sum_{b=1}^{B} (I_{b}(x, y) - \mu_{i,b})^{2}, \quad \forall (x, y) \in \Omega_{i}, \forall i,
\]

(4.7)

where \( f_{i} \) is given as a vector \( \mu_{i} \equiv [\mu_{1}, \ldots, \mu_{b}, \ldots, \mu_{B}]^{T} \in \mathbb{R}^{B} \). The optimal \( f_{i} \) minimizing \( E \) is the mean vector of \( I(x, y) \) within \( \Omega_{i} \). The energy function of [10] also can be transformed to the same form with an objective function

\[
    e(x, y|f_{i} \equiv \{\mu_{i}, \Sigma_{i}\}) = \log |\Sigma_{i}| + (I(x, y) - \mu_{i})^{T}\Sigma_{i}^{-1}(I(x, y) - \mu_{i}), \quad \forall (x, y) \in \Omega_{i}, \forall i,
\]

(4.8)

where \( f_{i} \) is given as a set of parameters, i.e. the mean vector \( \mu_{i} \) and covariance matrix \( \Sigma_{i} \) of a multivariate Gaussian PDF. The optimal \( f_{i} \) minimizing \( E \) is the mean vector \( \mu \) and covariance matrix \( \Sigma \) of \( I(x, y) \) within \( \Omega_{i} \).
4.3 Proposed Region-based Segmentation Model

The objective function of a piecewise-constant active contour model shown in equation 4.7 measures the average Euclidean distance between the vector-valued image intensity \( I(x, y) \) and the mean vector \( \mu_i \) of \( I(x, y) \) within a subset \( \Omega_i \). The objective function shown in equation 4.8 measures the Mahalanobis distance \([22]\) between \( I(x, y) \) and \( \mu_i \) weighted by the covariance \( \Sigma_i \). Thus, both objective functions produce the minimum if \( I(x, y) = \mu_i \), and produce larger values as \( I(x, y) \) and \( \mu_i \) are located further from each other in the image intensity space. The assumption of these approaches is that there is a constant value, i.e. \( f_i = \mu_i \) or \( f_i = \{\mu_i, \Sigma_i\} \), which best represents \( \Omega_i \), and consequently the entire image is representable as a piecewise-constant expression \( f \). However, many images we encounter in image segmentation problems, particularly the images with non-uniform subsets such as the zebra in figure 1.3(b), are too complicated to be represented as a piecewise-constant expression. Therefore, we propose an objective function, which uses a conditional PDF of \( I(x, y) \) instead of a distance between \( I(x, y) \) and \( \{f_i\} \). With the proposed objective function, there is no certain best representation \( f_i \) but a PDF representation \( p_i \) for each \( \Omega_i \). Depending on the method to estimate the PDF, there are two approaches, unsupervised and supervised. Unsupervised method partitions images looking for uniform statistics of image intensity within a subset, while supervised method does the same job looking for similarity between the statistics of image intensity and the corresponding training samples for a subset.

If an image pixel is likely to be an element of a subset, the objective function should produce a lower value under the assumption of \( I(x, y) \in \Omega_i \). If an image pixel is unlikely to be an element of the subset, the objective function should produce higher value under the same assumption. The objective function

\[
e(x, y|p_i) = -\log p_i, \quad \forall (x, y) \in \Omega, \quad \forall i, \tag{4.9}
\]

provides the desired feature where \( p_i \) denotes an unsupervised multivariate conditional PDF of vector-valued image intensity \( I \) on the condition that \( I(x, y) \) is an element of \( \Omega_i \), given by

\[
p_i \equiv p(I(x, y)|(x, y) \in \Omega_i), \quad \forall i. \tag{4.10}
\]

If \( p_i \) is fixed as a Gaussian distribution, equation 4.9 is equivalent to equation 4.8. Note that the proposed objective function may have multiple local maxima, while the objective functions in equation 4.7 and 4.8 have only a global minimum. The corresponding global energy function is given by

\[
E\{p_i\}, C \equiv \sum_i \int_{\Omega_i} e(x, y|p_i) dxdy + \nu|C|. \tag{4.11}
\]

The minimum of \( E \) is achieved by a similar way to minimize equation 4.6. First, instead of minimizing \( E \) with respect to each \( f_i \), we estimate the conditional probability \( p_i \) from the given image, which is equivalent to finding the best fitting \( f_i \). The estimated \( p_i \) provides a force moving the active contour \( C \) to the proper position where \( C \) divides the entire domain \( \Omega \) of the image \( I(x, y) \) into multiple subsets \( \{\Omega_i\} \), i.e. satisfying the segmentation constraints. Then, the minimization of \( E \) with respect to \( C \), while \( \{p_i\} \) are fixed, smoothes the variational boundaries \( C \) minimizing \( |C| \).

If some level of prior knowledge, i.e. training samples, of an object is available, we can estimate the conditional PDF \( p(I|\Omega_i) \) directly from the training samples, such that

\[
p(I|\Omega_i) \approx \tilde{p}(I|\Omega_i) = p(I|\Omega_i), \tag{4.12}
\]
where $\mathcal{I}_i = \{\mathbf{I}_1, \ldots, \mathbf{I}_n, \ldots, \mathbf{I}_N\}$ denotes the ideally sampled training data or a statistical template of the object, which is supposed to be isolated as a subset $\Omega_i$ in the result of the segmentation. $p(\mathbf{I}|\mathcal{I}_i) : \mathbb{R}^B \to \mathbb{R}$ denotes a multivariate conditional PDF of a vector-valued image intensity $\mathbf{I}$ on the condition that the multispectral image pixel is an element of training samples $\mathcal{I}_i$. An objective function similar to equation 4.9 can be used with a supervised conditional PDF given by

$$e_i(x, y) = -\log p(\mathbf{I}(x, y)|\mathbf{I}(x, y) \in \mathcal{I}_i), \quad \forall (x, y) \in \Omega, \quad \forall i,$$

(4.13)

where $e_i(x, y)$ measures the similarity between the statistics of $\mathbf{I}$ and $\mathcal{I}_i$. Since the best fitting PDF is given from training samples instead of the given image, the minimization of $E$ with respect to $p_i$ is not necessary in supervised methods, and the global energy function shown in equation 4.11 can be simplified as a function of $C$ only, such as

$$E(C) \equiv \sum_i \int_{\Omega_i} e_i(x, y)dx dy + \nu|C|.$$

(4.14)

This will simplify the segmentation procedure, consequently reducing the convergence time of active contours. Since the best fitting $p(\mathbf{I}|\Omega_i)$ is given, the segmentation result will be also more robust than the result of unsupervised methods.

Various expressions can be used for $p(\mathbf{I}|\Omega_i)$ as long as they satisfy the unit volume condition:

$$\int_\mathbf{I} p(\mathbf{I}|\Omega_i) = 1, \quad \text{or} \quad \sum_\mathbf{I} p(\mathbf{I}|\Omega_i) = 1, \quad \forall i.$$

(4.15)

For example, either a parametric continuous PDF, e.g. a Gaussian density function $p(\mathbf{I}|\mu_i, \Sigma_i)$, or a non-parametric discrete PDF can be used as long as they are integrated as one. The details of proposed model for $p(\mathbf{I}|\Omega_i)$ will be discussed in chapter 5, and the estimation methods will be discussed in chapter 6.
Chapter 5  
Probability Density Model

The objective of region-based segmentation is to partition the entire set $\Omega$ of an image into multiple disjoint subsets $\{\Omega_i\}$ based on the uniformity of a desired feature within each $\Omega_i$. Unfortunately, image intensity within a subset $\Omega_i$ is not always uniform in practical applications. Subsets often form a mixture of multiple sub-classes, e.g. the zebra shown in figure 1.3(b) or the camouflage pattern on the toy tank shown in figure 1.4(b). In this chapter, we propose a multivariate mixture density function as the statistical model of vector-valued image intensity used for image segmentation. Section 5.1 discusses the need and use of a mixture density function as the statistical model of scalar image intensity. Section 5.2 extends the use of mixture density function to the case of multispectral images comparing the multivariate mixture density function and the product of marginal density functions which has been commonly used in other segmentation methods.

5.1 Mixture Density Function

The assumption of segmentation models introduced in section 4.2 is that the statistical information of image intensity within each subset is representable by a simple expression $f_i$, such as a vector-valued constant $\mu_i$ as shown in equation 4.7 or a small number of parameters $\{\mu_i, \Sigma_i\}$ as shown in equation 4.8. However, the statistical distribution of image intensity of a subset is often unrepresentable in a simple form. Figure 5.1 shows an example of an image with non-uniform subsets and its hand-segmented result. Figure 5.1(a) shows a result of diffusion applied on figure 1.3(b). The background is quite uniform, and the statistical distribution (histogram) of image intensity within the background forms a unimodal density function as shown in figure 5.2(b). The actual histogram of the background presented as the solid line can be reasonably represented with a Gaussian density function presented as the dotted line. However, the zebra consists of black and white stripes, and the statistical distribution of image intensity within the zebra is not unimodal as shown in figure 5.2(a). The higher peaks located about $I \approx 30$ and $I \approx 50$ in figure 5.2(a) present the black stripes of zebra, and the relatively lower peaks located about $I \approx 100$ and $I \approx 150$ present the white stripes of zebra. Thus, a Gaussian density function cannot simply represent the actual statistical distribution (histogram) of image intensity within the zebra though it can represent the background.

We propose to use a mixture of probability density functions as the feature representing the statistical property of image intensity $I$ within a subset $\Omega_i$, such that the conditional
PDF of $I$ on the condition $I(x, y) \in \Omega_i$ is given by

$$p(I | \Omega_i) \equiv p_i(I) = \sum_{k=1}^{K} \alpha_k p_i(I | k), \quad \forall i,$$

(5.1)

where $K$ denotes the number of sub-classes of the mixture, and $p_i(I | k) : \mathbb{R} \rightarrow \mathbb{R}$ denotes the conditional PDF of $I$ on the condition that $I(x, y)$ is an element of $\Omega_i$ and $I(x, y)$ is generated by the sub-class $k$. The weights $\{\alpha_k\}$ of each sub-class, often called mixing probabilities, satisfy

$$\sum_{k=1}^{K} \alpha_k = 1.$$

(5.2)

Using a mixture density function, the histogram shown in figure 5.2(a) can be represented as a mixture of at least two simple parametric density functions.

5.2 Multivariate Mixture Density Function

We proposed to use a mixture density function for scalar images in section 5.1. How about multispectral images? The mixture density function of scalar image intensity $I$ shown in equa-
tion 5.1 is a complicated statistical model, and a mixture density function of vector-valued image intensity \( \mathbf{I} \) is an even more complicated statistical model. For example, the histogram of 24bit RGB image intensity requires \( 2^{24} = 16777216 \) histogram bins, while the histogram of 8bit gray image requires 256 histogram bins. Because of the complexity and the high computational cost, the active contour models employing mixture density functions [137, 124, 138, 139] as well as traditional region-based active contour models [140, 5] have used alternative expressions rather than dealing with multi-dimensional image intensity space. Based on the assumption that each band is independent, a common alternative expression of \( p(\mathbf{I}) \) is the product of marginal density functions measured at each dimension, i.e. spectral bands, such as

\[
g(\mathbf{I}) \equiv \prod_{b=1}^{B} p(I_b). \tag{5.3}
\]

If \( p(\mathbf{I}) \) is a mixture density function, the equivalent expression can be expressed as

\[
g(\mathbf{I}) \equiv \prod_{b=1}^{B} \sum_{k=1}^{K} \alpha_k p(I_b|k). \tag{5.4}
\]

Using this expression, the proposed objective functions shown in equation 4.9 or 4.13 are given by

\[
e_i(x, y) \equiv -\log \prod_{b=1}^{B} \sum_{k=1}^{K} \alpha_k p_i(I_b(x, y)|k), \quad \forall (x, y) \in \Omega, \forall i,
\]

\[
e_i(x, y) = -\sum_{b=1}^{B} \log \sum_{k=1}^{K} \alpha_k p_i(I_b(x, y)|k). \tag{5.5}
\]

The computation of \( g(\mathbf{I}) \) is relatively easier than \( p(\mathbf{I}) \) because the dimensionality of \( p(I_b) \) is as low as \( \mathbb{R} \rightarrow \mathbb{R} \) even though \( g(\mathbf{I}) \) and \( p(\mathbf{I}) \) have the same dimensionality as \( \mathbb{R}^B \rightarrow \mathbb{R} \). The expressions similar to \( g(\mathbf{I}) \) and log \( g(\mathbf{I}) \) have been used in a few other active contour models designed for multispectral images [5, 140], and we had previously proposed a similar expression [139] using the product of normalized histograms measured at each band. This is not a bad idea because the statistical meaning of \( p(\mathbf{I}) \) and \( g(\mathbf{I}) \) are equivalent as long as \( p(\mathbf{I}) \) is a unimodal distribution as shown in figure 5.3. Figure 5.3(a) presents a PDF of a two-dimensional random variable \( \mathbf{I} \in \mathbb{R}^2 \), which is distributed by a two-dimensional Gaussian density function \( p(\mathbf{I}|\mu, \Sigma) \). In figure 5.3(b), the shades on the walls present the marginal density functions of \( \mathbf{I} \), respectively given by \( p(I_1) \) and \( p(I_2) \). The three-dimensional curve presents the product of \( p(I_b) \) given by \( g(\mathbf{I}) = p(I_1)p(I_2) \). As the two expressions \( p(\mathbf{I}) \) and \( g(\mathbf{I}) \) are equivalent, we can alternatively use \( g(\mathbf{I}) \) for \( p(\mathbf{I}) \) in this case.

Unfortunately, \( g(\mathbf{I}) \) for \( p(\mathbf{I}) \) are not equivalent any more if \( p(\mathbf{I}) \) is a mixture density function as shown in figure 5.4. Figure 5.4(a) presents a PDF of \( \mathbf{I} \in \mathbb{R}^2 \), distributed by a mixture of two different two-dimensional Gaussian functions \( p(\mathbf{I}) = \alpha p(\mathbf{I}|\mu_1, \Sigma_1) + (1-\alpha)p(\mathbf{I}|\mu_2, \Sigma_2) \). The shades on the walls present \( p(I_1) = \alpha p_1(I_1) + (1-\alpha)p_2(I_1) \) and \( p(I_2) = \alpha p_1(I_2) + (1-\alpha)p_2(I_2) \), and the three-dimensional curve presents \( g(\mathbf{I}) = p(I_1)p(I_2) = \{\alpha p_1(I_1) + (1-\alpha)p_2(I_1)\}\{\alpha p_1(I_2) + (1-\alpha)p_2(I_2)\} \). As we can see in figure 5.4(a) and 5.4(b), the product of marginal density functions measured at each dimension, i.e. \( g(\mathbf{I}) \), is not equivalent to the true PDF \( p(\mathbf{I}) \) any more. Although there are only two modes in the true PDF \( p(\mathbf{I}) \), there are four modes in \( g(\mathbf{I}) \).
Figure 5.3: A unimodal distribution in a two-dimensional image intensity space and its reconstruction: (a) $p(I)$, (b) $g(I) = p(I_1)p(I_2)$

Figure 5.4: A multimodal distribution in a two-dimensional image intensity space and its reconstruction: (a) $p(I) = \alpha p_1(I) + (1-\alpha)p_2(I)$, (b) $g(I) = \{\alpha p_1(I_1) + (1-\alpha)p_2(I_1)\}\{\alpha p_1(I_2) + (1-\alpha)p_2(I_2)\}$

The two excessive modes likely result in classifying the out-class image pixels as the given class, equivalent to the false alarm [141] in pattern classification. Since $\int g(I)$ is fixed as 1, the two excessive modes result in reducing the power of the two correct modes in $g(I)$. This incident likely results in excluding the in-class image pixels from the given class, equivalent to the misclassification [141] in pattern classification. Therefore, $g(I)$, i.e. the alternative expression of $p(I)$, is not a proper choice for the multispectral images with non-uniform subsets though it is a reasonable choice for the multispectral images with uniform subsets. Therefore, we propose to use a mixture of multivariate probability density functions as the statistical information of vector-valued image intensity within a subset, such that

$$p_i(I) \equiv p(I|\Omega_i) = \sum_{k=1}^{K} \alpha_k p_i(I|k), \quad \forall i,$$  \hspace{1cm} (5.6)$$

where $p_i(I|k)$ denotes the conditional PDF of $I$ on the condition that $I(x,y) \in \Omega_i$ and $I$ is generated by a sub-class $k$. The corresponding objective function equivalent to equation 4.9
using the proposed density model is given by

\[
e(x, y|p_i) = -\log \sum_{k=1}^{K} \alpha_k p(I(x, y)|(x, y) \in \Omega_i, k), \quad \forall (x, y) \in \Omega, \quad \forall i,
\]  

(5.7)

and the corresponding objective function equivalent to equation 4.13 using the proposed density model is given by

\[
e_i(x, y) = -\log \sum_{k=1}^{K} \alpha_k p(I(x, y)|I(x, y) \in I_i, k), \quad \forall (x, y) \in \Omega, \quad \forall i.
\]  

(5.8)
Chapter 6

Density Estimation Methods

We have proposed to use a multivariate mixture density function as the conditional PDF of vector-valued image intensity $p_i(I)$. In this chapter, we discuss the estimation methods of multivariate mixture density functions as a topic of statistical pattern recognition. Estimating a mixture density function, often called mixture fitting, has been one of the most difficult tasks in statistical pattern recognition. A multi-dimensional feature space makes the estimation problem even more difficult.

Let $N$ data samples $I$ be given as $I \equiv \{I(1), I(2), \ldots, I(n), \ldots, I(N)\}$, where $I \in \mathbb{R}^B$ denotes a multi-dimensional random variable. The PDF of a random variable can be estimated from the data samples $I$ if the statistical distribution of the data samples approximates the true PDF $p(I)$, such as

$$p(I) \approx p(I). \quad (6.1)$$

The base assumption of this approximation is that each data sample $I(n)$ is generated independently and ideally from the true PDF $p(I)$.

There are two approaches to estimate $p(I)$ based on the ways to represent a mixture density function: parametric and non-parametric. Parametric approaches consider $p(I)$ as a mixture of multiple continuous parametric density functions, while non-parametric approaches consider $p(I)$ as a discrete function. Section 6.1 discusses parametric density estimation methods, and section 6.2 discusses non-parametric density estimation.

6.1 Parametric Density Estimation Methods

In the parametric approaches, a collection of parameters

$$\Theta = \left[ \begin{array}{c} \{\alpha_1, \ldots, \alpha_k, \ldots, \alpha_K\}, \\ \{\theta_1, \ldots, \theta_k, \ldots, \theta_K\} \end{array} \right] \quad (6.2)$$

represent a mixture density function $p(I)$, where each parameter set $\theta_k$ specifies the conditional PDF of a vector-valued image intensity $I$ on the condition that $I$ is generated by sub-class $k$, and $\alpha_k$ specifies the relative weight of the corresponding sub-class. The mixture density function
\( p(I) \) can be approximated by estimating a parameter set \( \Theta \) from data samples \( I \), such that

\[
p(I) \equiv p(I|\Theta) \approx p(I|\hat{\Theta}) = \sum_{k=1}^{K} \hat{\alpha}_k p(I|\hat{\theta}_k), \tag{6.3}
\]

where each \( \theta_k \) is estimated based on a particular stochastic model such as a Gaussian distribution \( p(I|\mu, \Sigma) \). As a parametric density function, we propose to use a mixture of multivariate Gaussian distributions for \( p(I|\Theta) \), such that the estimated PDF of a sub-class is given by

\[
p(I|\hat{\theta}_k) \equiv p(I|\hat{\mu}_k, \hat{\Sigma}_k). \tag{6.4}
\]

The stochastic model above is an arbitrary random distribution whose only prior knowledge is that the statistics of each sub-class \( k \) is representable as a weighted multivariate Gaussian distribution \( \alpha_k p(I|\mu_k, \Sigma_k) \). There are four sets of parameters to be estimated: the number of sub-classes \( K \), the weight of each sub-class \( \{\alpha_k\} \), the mean vector of each sub-class \( \{\mu_k\} \), and the covariance matrix of each sub-class \( \{\Sigma_k\} \).

Based on the assumption that each data sample \( I(n) \) is generated independently, the likelihood measured from the data samples \( I \) is given by

\[
p(I|\Theta) = \prod_{n=1}^{N} p(I(n)|\Theta), \tag{6.5}
\]

and the log-likelihood of a K-component mixture model is given from equation 6.3 and 6.5 as

\[
\log p(I|\Theta) = \log \prod_{n=1}^{N} p(I(n)|\Theta) = \sum_{n=1}^{N} \sum_{k=1}^{K} \alpha_k p(I(n)|\theta_k). \tag{6.6}
\]

It is well known that the maximum likelihood (ML) estimate \([141, 143]\)

\[
\hat{\Theta}_{ML} = \arg \max_{\Theta} \{ \log p(I|\Theta) \} \tag{6.7}
\]

or the Bayesian maximum a posteriori (MAP)

\[
\hat{\Theta}_{MAP} = \arg \max_{\Theta} \{ \log p(I|\Theta) + \log p(\Theta) \} \tag{6.8}
\]

cannot be found analytically for this mixture density estimation problem \([144, 145]\). Therefore, an iterative learning algorithm, e.g. the EM algorithm, has been recommended \([141]\) as an attractive solution.

### 6.1.1 EM Algorithm

The *expectation-maximization* (EM) methods \([146, 147, 141, 148, 149]\) have been popularly used to obtain the ML or MAP estimates of the mixture parameters. The EM algorithm is an iterative procedure which finds local maxima of \( \log p(I|\Theta) \) or \( \log p(I|\Theta) + \log p(\Theta) \) interpreting the observed samples \( I \) as *incomplete data*. For the mixture density model, the missing part is given as a set of labels

\[
Z = \{ z(1), z(2), \ldots, z(n), \ldots, z(N) \}, \tag{6.9}
\]
where each label is a multi-dimensional binary vector

\[ \mathbf{z}(n) = [z_1(n), z_2(n), \ldots, z_k(n), \ldots, z_K(n)]^T \in \{0, 1\}^K \]  

indicating which sub-class produced the observed sample \( \mathbf{I}(n) \). That is, \( z_k(n) = 1 \) if and only if \( \mathbf{I}(n) \) is generated by the sub-class \( k \). Otherwise, \( z_k(n) = 0 \). The complete log-likelihood, i.e. the one from which we could estimate \( \Theta \) if the complete data \( \mathcal{X} = \{\mathcal{I}, \mathcal{Z}\} \) was observed [149], is given by

\[
\log p(\mathcal{I}, \mathcal{Z}|\Theta) = \sum_{n=1}^{N} \sum_{k=1}^{K} z_k(n) \log [\alpha_k p(\mathbf{I}(n)|\theta_k)] .
\]  

(6.11)

A time-varied estimate \( \hat{\Theta}(t) \) is produced by iteratively applying two sequential steps, i.e. expectation and maximization, until the given convergence criterion is met.

In the expectation stage, often called E-step, the conditional expectation of the complete log-likelihood is computed given \( \mathcal{I} \) and the current estimate \( \hat{\Theta}(t) \). Since the elements of \( \mathcal{Z} \) are binary, their conditional expectation is given by

\[
W \equiv \mathbb{E}[\mathcal{Z}|\mathcal{I}, \hat{\Theta}(t)] \in \mathbb{R}^K ,
\]  

(6.12)

where each element is given by

\[
w_k(n) \equiv \mathbb{E}[z_k(n)|\mathcal{I}, \hat{\Theta}(t)] = Pr[z_k(n) = 1|\mathbf{I}(n), \hat{\Theta}(t)] = \frac{\hat{\alpha}_k(t)p(\mathbf{I}(n)|\hat{\theta}_k(t))}{\sum_{j=1}^{K} \hat{\alpha}_j(t)p(\mathbf{I}(n)|\hat{\theta}_j(t))} ,
\]  

(6.13)

with the unit volume condition

\[
\sum_{k=1}^{K} w_k(n) = 1 .
\]  

(6.14)

Equation 6.13 may be interpreted as an instance of Bayes law, i.e. \( \hat{\alpha}_k(t) \) and \( w_k(n) \) are respectively equivalent to the a priori probability and the a posteriori probability of \( z_k(n) = 1 \) after observing \( \mathbf{I}(n) \). Since \( \log p(\mathcal{I}, \mathcal{Z}|\Theta) \) is linear with respect to the missing \( \mathcal{Z} \), the conditional expectation of the complete log-likelihood is given by substituting \( W \equiv \mathbb{E}[\mathcal{Z}|\mathcal{I}, \hat{\Theta}(t)] \) into \( \log p(\mathcal{I}, \mathcal{Z}|\Theta) \), such as

\[
Q(\Theta, \hat{\Theta}(t)) \equiv \mathbb{E}\left[ \log p(\mathcal{I}, \mathcal{Z}|\Theta)|\mathcal{I}, \hat{\Theta}(t) \right] = \log p(\mathcal{I}, W|\Theta)
\]

\[
= \sum_{n=1}^{N} \sum_{k=1}^{K} w_k(n) \log [\alpha_k p(\mathbf{I}(n)|\theta_k)] .
\]  

(6.15)

The estimated parameter set \( \hat{\Theta} \) is the one maximizing the likelihood function above.

In the maximization stage, often called M-step, the estimated parameters are updated according to

\[
\hat{\Theta}(t + 1) = \arg \max_{\Theta} \{Q(\Theta, \hat{\Theta}(t)) + \log p(\Theta)\} ,
\]  

(6.16)
in the case of MAP estimation, or
\[ \hat{\Theta}(t + 1) = \arg \max_{\Theta} \{ Q(\Theta, \hat{\Theta}(t)) \} , \] (6.17)

for the ML criterion.

Despite its popular use, the EM algorithm for mixture density estimation has several drawbacks: First, the number of sub-classes \( K \) should be provided as a prior knowledge. This requirement limits the use of EM algorithm for unsupervised learning. Second, \( K \) is fixed during the estimation process, so the EM algorithm may converge to the boundary of the parameter space. For example, the weight \( \alpha_k \) may become zero and consequently the corresponding parameters specifying the sub-class \( k \) become singular if \( K \) is significantly higher than the unknown true number of sub-classes. Third, it is a local (greedy) method, thus sensitive to initial values of parameters \( \hat{\theta}_k(t = 0) \). If \( \theta_k(t = 0) \) is too far way from the true parameter \( \theta_k \), the EM algorithm may not converge to the true or optimal parameters because the EM algorithm cannot move sub-classes across low likelihood regions\(^1\) [144, 150]. Common solutions for these problems are: using multiple random starts and choosing the final estimates with the highest likelihood [151, 148, 149, 152] or initialization by clustering [151, 148, 149]. Figure 6.1 shows the results of the standard EM algorithm using different \( K \). 1000 random samples \( I \) were generated from a mixture of 4 Gaussian density functions. The (black) solid curves present the true PDF \( p(I) \) which generated the observed data samples. The (red) solid curves present the estimated density function \( p(I|\hat{\Theta}) \), and the (red) dotted curves present the weighted density functions of sub-classes, given by \( \hat{\alpha}_k p(I|\hat{\theta}_k) \). A successful estimation is determined by how close the \( p(I|\hat{\Theta}) \) is estimated to the \( p(I) \). In figure 6.1(a), the EM algorithm cannot find any of the true sub-classes with \( K = 4 \) because the initializations of the parameters \( \{ \theta_k(t = 0) \} \) are too far away from the true position and too close from the neighbor sub-classes, while it finds all four true sub-classes with \( K = 10 \) as shown in figure 6.1(b).

---

\(^1\)Note the term region, used here, exists in a parameter space. The region, used in segmentation, exists on a spatial domain.
6.1.2 EM Algorithm with MML

The estimation of the number of sub-classes $K$ has been an important issue in mixture density estimation. If $K$ is too high, the density estimation may fail to converge to the true density due to singular parameters, while the estimated density function cannot approximate the true underlying mixture density function if $K$ is too low. Figueiredo and Jain proposed an advanced EM method based on the minimum encoding length criteria, which automatically selects the number of sub-classes $K$ by annihilating the weak candidates of sub-classes.

The minimum encoding length criteria are popular concepts in the encoding and error checking problem in the communication engineering area, and they are also widely applied in pattern classification area. According to the minimum encoding length criteria, e.g. Minimum Message Length (MML) and Minimum Description Length (MDL), a good data generation model, i.e. a parameter set $\Theta$, is a representation which minimizes the length of code required to describe the data samples $I$. Let the data samples $I$, known to have been generated according to $p(I|\Theta)$, be encoded and transmitted. If $p(I|\Theta)$ is fully known to both the transmitter and the receiver, they can both build the same code, and communication can proceed. However, if the parametric model $\Theta$ is unknown, the transmitter has to start by estimating and transmitting $\Theta$. This leads to a two-part message, whose total length is given by

$$L(\Theta, I) = L(\Theta) + L(I|\Theta), \quad (6.18)$$

The estimated parameter set $\hat{\Theta}$ is the one minimizing this length function.

According to the standard two-part code formulation of MDL and MML, the expected number of data samples generated by sub-class $k$ is $N\alpha_k$, where $N$ denotes the number of data samples. Thus, the optimal, in the MDL sense, code length of each $\theta_k$ is $(M/2)\log(N\alpha_k)$, where $M$ denotes the number of parameters specifying $\theta_k$. As the zero-weighted sub-class is considered to be removed, we need to code only non-zero weighted $\alpha_k \neq 0$ sub-classes. The optimal parameter set $\Theta$ is estimated by minimizing the cost function

$$L(\Theta, I) = \frac{M}{2} \sum_{k: \alpha_k > 0} \log \left( \frac{N\alpha_k}{12} \right) + \frac{K_{nz}}{2} \log N + \frac{K_{nz}(M + 1)}{2} - \log p(I|\Theta), \quad (6.19)$$

with respect to $\Theta$ given by

$$\hat{\Theta} = \arg \min_{\Theta} L(\Theta, I), \quad (6.20)$$

where $K_{nz}$ denotes the number of sub-classes with non-zero weight $\alpha_k \neq 0$. From the Bayesian point of view, the cost function shown above is equivalent, for fixed $K_{nz}$, to an a posteriori density resulting from the adoption of Dirichlet-type prior for the weights $\{\alpha_k\}$, given by [144]

$$p(\alpha_1, \ldots, \alpha_K) \propto \exp \left\{ -\frac{M}{2} \sum_{k=1}^{K} \log \alpha_k \right\}, \quad (6.21)$$

and a flat prior leading to ML estimates for the parameters $\{\theta_k\}$ specifying each sub-class $k$. The EM algorithm to minimize the cost function in equation 6.19, with fixed $K_{nz}$, has the following M-step:

$$\hat{\alpha}_k(t + 1) = \frac{\max \left\{ 0, \left( \sum_{n=1}^{N} w_k(n) - \frac{M}{2} \right) \right\}}{\sum_{j=1}^{K} \max \left\{ 0, \left( \sum_{n=1}^{N} w_j(n) - \frac{M}{2} \right) \right\}}, \quad \forall k, \quad (6.22)$$
\[ \hat{\theta}_k(t+1) = \arg \max_{\theta_k} Q(\Theta, \hat{\Theta}(t)) \text{, } \{ k : \hat{\alpha}_k(t+1) > 0 \} \text{,} \] (6.23)

where the conditional expectation \( w_k(n) \) are given by the E-step in equation 6.13. The M-step defined by equation 6.22 and equation 6.23 do the actual component annihilation by setting the weight \( \alpha_k \) as zero.

The parameter set \( \theta_k \) specifying the sub-classes for which \( \hat{\alpha}_k(t+1) = 0 \) become irrelevant because any sub-class for which \( \alpha_k = 0 \) does not contribute to the log-likelihood in equation 6.6, thus the algorithm explicitly removes the weakest sub-class, decreasing \( K_{nz} \). This prevents the estimation algorithm from approaching the boundary of the parameter space, one of the drawbacks of the standard EM algorithm for mixture density model. This algorithm also solves the initialization problem by starting with very high number of initial sub-classes \( K_{init} \) and removing weak sub-classes step by step. The initial parameters \( \{ \theta_k(t = 0) \} \) can be located anywhere along the whole parameter space. Although this algorithm still does not guarantee the global convergence, it does provide a flexible way to deal with.

The direct use of the standard EM algorithm with M-step in equation 6.22 and 6.23 has a failure mode, i.e. if the number of initial sub-classes \( K_{init} \) is too large, no sub-class has enough initial support \( \sum_{n=1}^{N} w_k(n) > M/2 \) , \( \forall k \) and consequently \( \{ \hat{\alpha}_k \} \) will be undetermined. Component-wise EM (CEM) algorithm [160] avoids this problem by updating each element of parameter set \( \Theta = \{ \{ \alpha_k \}, \{ \theta_k \} \} \) sequentially instead of simultaneously. That is, update \( \alpha_1 \), \( \theta_1 \), recompute \( W \), and update \( \alpha_2 \) and \( \theta_2 \), recompute \( W \) again, and so on. If one sub-class is annihilated \( \hat{\alpha}_k(t + 1) = 0 \), its probability mass is immediately redistributed to the other sub-classes with non-zero weight \( \hat{\alpha}_k(t + 1) \neq 0 \). This consequently increases their chance of survival, and allows initialization with an arbitrarily large \( K_{init} \).

Figure 6.2 shows the performance of this method applied to the same data samples used for the standard EM method in figure 6.1. 1000 random samples were generated by a mixture density function \( p(I) \), presented as the (black) solid curves. Randomly chosen 32 sub-classes are initialized \( K_{init} = 32 \), and then the weakest sub-class is removed if a criterion is satisfied. After the iterative EM processing, it eventually converges to the four sub-classes \( K = 4 \), presented as the (red) dotted curves. The estimated mixture density function \( p(I|\hat{\Theta}) \), presented as the (red) solid curves, successfully estimates the true mixture density function \( p(I) \).

![Figure 6.2: The advanced EM method proposed by Figueiredo and Jain applied to the same data used in figure 6.1. The estimation starts with \( K_{init} = 32 \) and converges to \( K = 4 \).](image)
6.2 Non-parametric Density Estimation

In non-parametric approaches, a discrete function instead of a mixture of parametric density functions approximates the true PDF of data samples. Given independently and ideally generated data samples \( \mathcal{I} \), the assumption of non-parametric approach is that we can approximate the statistical distribution of a random variable \( \mathbf{I} \) directly from the statistics of \( \mathcal{I} \) without any particular stochastic model, such that

\[
p(\mathbf{I}) \approx \hat{p}(\mathbf{I}) = h(\mathcal{I}), \tag{6.24}
\]

where \( h(\cdot) \) denotes a non-parametric density function.

If \( N \) observed data samples \( \mathcal{I} = \{\mathbf{I}(1), \mathbf{I}(2), \ldots, \mathbf{I}(N)\} \) are generated from the true PDF \( p(\mathbf{I}) \), parametric learning algorithms estimate the stochastic model of random variable \( \mathbf{I} \) based on two assumptions: the statistics of \( \mathcal{I} \) follow a particular stochastic model, e.g. a Gaussian distribution \( p(\mathbf{I}|\mu, \Sigma) \); and the stochastic model can represent \( p(\mathcal{I}) \). If the data samples \( \mathcal{I} \) do not satisfy these assumptions, the estimated parametric expressions \( p(\mathbf{I}|\hat{\mu}, \hat{\Sigma}) \) cannot approximate \( p(\mathbf{I}) \). Since non-parametric approaches do not rely on any particular stochastic model, they can estimate the true underlying PDF of data samples unless the data samples \( \mathcal{I} \) were observed in a biased manner. This is an attractive feature for a mixture density estimation because the true \( p(\mathbf{I}) \) is often difficult to express with a particular stochastic model.

6.2.1 Histogram

There are many non-parametric density estimation methods, e.g. Parzen windows, \( k \)-nearest neighbor, and histogram. **Histogram**, often called *frequency histogram*, is the most elemental method among them. Given \( N \) observed data samples \( \mathcal{I} \), the histogram divides the dynamic range of image intensity \( \mathbf{I} \) into a given number of bins, and counts the number of data samples corresponding to each bin \([161]\). Because of this simple procedure, we use a **multi-dimensional histogram density function**\(^2\) to estimate the discrete non-parametric PDF of image intensity, such that

\[
h(\mathcal{I}) = \left\{ \frac{1}{N} \frac{\text{hist}[\mathcal{I}]}{\Delta \mathbf{I}} \right\} : \mathbb{R}^B \rightarrow \mathbb{R}, \tag{6.25}
\]

where \( \text{hist}[\mathcal{I}] \) denotes a multi-dimensional histogram of \( \mathcal{I} \), \( \Delta \mathbf{I} \) denotes the volume of a histogram bin, and \( N \) denotes the number of data samples \( \mathcal{I} \). \( h(\mathcal{I}) \) should satisfy the unit volume condition given by

\[
\sum_{\mathcal{I}} h(\mathcal{I}) = 1. \tag{6.26}
\]

In the case of scalar images, \( \Delta \mathbf{I} \) is equivalent to the width of a histogram bin, and the range of each \( \Delta \mathbf{I} \) do not overlap, which is different from other non-parametric methods. The histogram density function \( h(\mathcal{I}) \) approximates \( p(\mathbf{I}) \) in a discrete manner. Figure 6.3 shows an example of the histogram density function \( h(\mathcal{I}) \) of the same data samples used in the previous graphs. The width of each bin \( \Delta \mathbf{I} \) is set to 1 in figure 6.3(a), and set to 3 in figure 6.3(b). With the same number of data samples, \( h(\mathcal{I}) \) tends to be smoother losing its precision as \( \Delta \mathbf{I} \) increases, while

\(^2\)Although \( h(\mathcal{I}) \) shown in equation 6.25 is occasionally referred to *histogram* or *frequency histogram* in other publications \([161]\), it is defined as *histogram density function* in this document. Histogram and frequency histogram are referred to the frequency number for each bin, i.e. the histogram in common sense.
Figure 6.3: An example of the histogram density function $h(I)$: (a) $\Delta I = 1$, (b) $\Delta I = 3$

$h(I)$ tends to be more sparky as $\Delta I$ decreases. If $\Delta I$ is infinitely narrow and $N$ is infinitely high at the same time, the discrete $h(I)$ can ideally approximate the true PDF $p(I)$, such that

$$p(I) \approx \lim_{\Delta I \to 0} \lim_{N \to \infty} h(I).$$

The process of computing a histogram density function $h(I)$ is simple and easy to implement. Also, $h(I)$ does not require any iterative learning process, and consequently requires shorter computation time. Since active contours have an iterative process demanding long computation time, $h(I)$ is a quite attractive density estimation method for active contours. However, the accumulation procedure requires a huge amount of memory depending on the dimensionality of $I$. For example, a histogram of a 24bit RGB image intensity consists of $2^{24} = 16777216$ bins, 128Mbytes if 8bytes/bin.

The frequency of each bin of a histogram is independent ignoring the neighborhood in the image intensity space. That is, the frequency of the bin $a$ is independent from the frequency of the bin $a + 1$. This localized frequency is a good feature for mixture density model because weak sub-classes can survive without being dominated by a strong neighbor sub-class as shown in figure 6.1(a). However, it also overfits the distribution of the histogram density function $h(I)$ to the data samples $I$, and reduces the flexibility of the estimated PDF $p(I)$. That is, the $p(I)$ from a set of data samples $I_1$ may be different from the $p(I)$ from the other set of data samples $I_2$ even if both $I_1$ and $I_2$ are generated from a statistical model. A partial solution of this problem is to provide a large data set. This problem becomes even more serious particularly if the dimensionality of $I$ is high. Thus, a histogram density function needs extremely higher number of data samples as the dimension of data grows, which is called the curse of dimensionality [162]. The high sensitivity to noise is another problem caused by the localized bins. Kernel density estimation methods, e.g. Parzen window [141], provide more flexible and smooth distribution than $h(I)$ at the expense of computation time.
Chapter 7

Active Contour Implementation
using Level Set

The proposed segmentation methods are implemented in a form of active contours. We propose to use the region-based active contour model using level set theory. The level set implementation of the proposed active contour model is based on the multi-phase active contour model proposed by Chan and Vese [108, 74, 113]. In this chapter, we discuss the level set implementation of the proposed active contour models.

7.1 The Base Active Contour Model

Multi-phase active contours can partition an image into more than two subsets simultaneously. Let us redefine the entire domain $\Omega$ of an image $I(x,y)$ as a disjoint set of subsets, such that

$$
\Omega \equiv \bigcup_i \Omega_i, \quad (7.1)
$$

where the interior regions include the contour pixels $C \subset \Omega_m$. Then, each subset can be identified by a set of binary identity functions

$$
\chi_i(x,y) \equiv \left\{ \begin{array}{ll}
1, & \text{if } (x,y) \in \Omega_i \\
0, & \text{otherwise}
\end{array} \right., \quad \forall (x,y) \in \Omega, \quad \forall i \quad (7.2)
$$

composed of a group of regularized unit step functions $H_j : \Omega \to \{0,1\}$ given by

$$
H_j \equiv H_\epsilon(\phi_j(x,y)) \approx \left\{ \begin{array}{ll}
1, & \text{if } \phi_j(x,y) \geq 0 \\
0, & \text{if } \phi_j(x,y) < 0
\end{array} \right., \quad \forall (x,y) \in \Omega, \quad \forall j. \quad (7.3)
$$

The identity functions $\{\chi_i(x,y) : \Omega \to \{0,1\}\}$ for the case of 2 subsets and 4 subsets are respectively defined as [74]

$$
\begin{bmatrix}
\chi_0(x,y) \\
\chi_1(x,y)
\end{bmatrix} = \left\{ (x,y) : \left[ \begin{array}{c}
(1-H_1) \\
H_1
\end{array} \right] \right\}, \quad \forall (x,y) \in \Omega, \quad (7.4)
$$

and

$$
\begin{bmatrix}
\chi_0(x,y) \\
\chi_1(x,y) \\
\chi_2(x,y) \\
\chi_3(x,y)
\end{bmatrix} = \left\{ (x,y) : \left[ \begin{array}{c}
(1-H_2)(1-H_1) \\
(1-H_2)H_1 \\
H_2(1-H_1) \\
H_2H_1
\end{array} \right] \right\}, \quad \forall (x,y) \in \Omega. \quad (7.5)
$$
$J$ level set functions $\{\phi_1, \ldots, \phi_j, \ldots, \phi_J\}$ can compose up to $2^J$ subsets $\{\Omega_1, \ldots, \Omega_i, \ldots, \Omega_2^J\}$ in this way. An example of subsets, defined by multi-phase level set functions, is shown in figure 7.1 where $\{\Omega_0, \Omega_1, \Omega_2, \Omega_3\}$ denote the four subsets defined by two level set functions $\{\phi_1, \phi_2\}$.

![Figure 7.1: Subsets and contours defined by two level set functions, $\{\phi_1, \phi_2\}$](image)

Using the identity functions $\{\chi_i(x, y)\}$, the integration over each subset $\Omega_i$ in the global energy function $E$ shown in equation 4.11 and 4.14 can be transformed to the integration over the entire image plane $\Omega$, such as

$$
\int e_i(x, y)dx\,dy = \int_{\Omega} e_i(x, y)\chi_i(x, y)dx\,dy, \quad \forall i,
$$

which makes the computation much easier. Also, the length of contours $|C_j|$ is equivalent to the integration of $|\nabla H_j|$ over $\Omega$, such that

$$
|C_j| = \int_{\Omega} |\nabla H_e(\phi_j(x, y))|dx\,dy, \quad \forall j,
$$

where $C_j$ denotes a set of active contours formed by the corresponding level set function $\phi_j(x, y)$ as $C_j \equiv \{(x, y) : \phi_j(x, y) = 0\}$.

The global energy function of the multi-phase active contour model and the associated Euler-Lagrange equation obtained by minimizing the energy function $E$ with respect to $\Phi = \{\phi_1, \ldots, \phi_j, \ldots, \phi_J\}$, which are introduced in [74, 113], can be generalized with an arbitrary form of objective functions $e_i(x, y)$, such as

$$
E \equiv \sum_{i=1}^{2^J} \int_{\Omega_i} e_i(x, y)dx\,dy + \nu \sum_{j=1}^{J} |C_j|
$$

$$
= \sum_{i=1}^{2^J} \int_{\Omega} e_i(x, y)\chi_i(x, y)dx\,dy + \nu \sum_{j=1}^{J} \int_{\Omega} |\nabla H_j|dx\,dy,
$$

and

$$
\frac{\partial \phi_j(x, y)}{\partial t} = \delta_j \left[ \nu \kappa_j - \sum_{i=1}^{2^J} e_i(x, y) \frac{\partial \chi_i}{\partial H_j} \right], \quad \forall j,
$$

where $\delta_j \equiv \delta_i(\phi_j(x, y))$ denotes the first derivatives of $H_j$ with respect to $\phi_j$, and $\kappa_j \equiv \kappa(\phi_j(x, y))$ denotes the mean curvature of $\phi_j(x, y)$. 

44
7.2 Proposed Active Contour Model

The proposed active contour model is obtained by substituting the two proposed objective functions \( e(x, y|p_i) \) in equation 4.9 and \( e_i(x, y) \) in equation 4.13 into the generalized multi-phase active contour model shown in equation 7.9, such that

\[
\frac{\partial \phi_j(x, y)}{\partial t} = \delta_j \left[ \nu \kappa_j + \sum_{i=1}^{2^j} \log p_i(I(x, y)) \frac{\partial \chi_i}{\partial H_j} \right], \quad \forall j,
\]

where \( p_i(I(x, y)) \equiv p(I(x, y)|(x, y) \in \Omega_i) \) for unsupervised segmentation model, and \( p_i(I(x, y)) \equiv p(I(x, y)|I(x, y) \in I_i) \) for supervised segmentation model. The conditional PDF \( p_i(\cdot) \) could be either a parametric expression or a non-parametric expression. We propose to use a mixture of multivariate density functions as shown in equation 6.3 for supervised segmentation model. More detail will be discussed in chapter 9 and 10. We also propose to use a histogram density function as shown in equation 6.24 and 6.25 for unsupervised segmentation model. More detail will be discussed in chapter 8. The actual level set evolution equations for the case of two subsets and four subsets are respectively given by

\[
\frac{\partial \phi(x, y)}{\partial t} = \delta(\phi(x, y)) \left[ \nu \kappa(\phi(x, y)) \right.
\]

\[
+ \{ \log p_1(I(x, y)) - \log p_0(I(x, y)) \} ]
\]

and

\[
\frac{\partial \phi_1(x, y)}{\partial t} = \delta_1 \left[ \nu \kappa_1 + \left\{ \frac{(\log p_3 - \log p_2)H_2 + (\log p_1 - \log p_0)(1 - H_2)}{(\log p_3 - \log p_2)H_2 + (\log p_1 - \log p_0)(1 - H_2)} \right\} \right]
\]

\[
\frac{\partial \phi_2(x, y)}{\partial t} = \delta_2 \left[ \nu \kappa_2 + \left\{ \frac{(\log p_3 - \log p_1)H_1 + (\log p_2 - \log p_0)(1 - H_1)}{(\log p_3 - \log p_1)H_1 + (\log p_2 - \log p_0)(1 - H_1)} \right\} \right],
\]

where \( \log p_i \equiv \log p_i(I(x, y)) \). \( \delta_j \equiv \delta(\phi_j(x, y)) \) is not necessarily a Dirac delta function, but it performs a role of window like a bandpass filter which controls the width \( \varepsilon \) to update \( \phi_j(x, y) \). The level set function \( \phi_j(x, y) \) only where \( |\phi(x, y)| < \varepsilon \), i.e. around corresponding contours \( C_j \), are updated and the rest of area is ignored. The curvature term \( \kappa_j \) keeps \( C_j \) in a smooth shape. During the the contour evolution, \( p_i(I(x, y)) \) for supervised segmentation methods returns the probability of \( I(x, y) \) under the condition that \( I(x, y) \) is an element of given training samples \( I_i \), while \( p_i(I(x, y)) \) for unsupervised segmentation methods returns the probability of \( I(x, y) \) under the condition that \( I(x, y) \) is an element of the subset \( \Omega_i \). These conditional probabilities provide a force which changes the corresponding level set functions, i.e. propagates the corresponding active contours, and consequently partitions the given image satisfying the desired property, which is either uniformity of \( I \) within \( \Omega_i \) or similarity between the statistics of \( I \) and \( I_i \). The terms inside of \{ \cdot \} in above expressions provide segmentation force, while the curvature terms provide a regularity force. Constant \( \nu \) controls the balance between these two forces.
In this chapter, we propose an unsupervised active contour model using the non-parametric density estimation method introduced in section 6.2.1. The proposed active contour model measures a non-parametric PDF expression of each subset at each iteration, and updates level set functions based on the measured PDF expressions. Section 8.1 discusses the proposed unsupervised image segmentation model. We propose to use a multi-dimensional histogram density function as a discrete non-parametric density function of image intensity within each subset. The detail of this approach is discussed in section 8.2. Section 8.3 discusses the implementation of active contours using level set. Section 8.4 shows the numerical algorithm of the proposed method, and section 8.5 shows the experimental results applied on synthetic and real images.

8.1 Unsupervised Image Segmentation

The proposed method follows the classical role of image segmentation, which partitions an image without any prior knowledge or training samples, using a global energy minimization. The global energy function is given by

\[ E(\{p_i\}, C) = \sum_i \int_{\Omega_i} e(x, y|p_i) dxdy + \nu |C|, \quad (8.1) \]

and the global energy \( E \) is minimized with respect to two expressions: \( \{p_i\} \), i.e. the statistical representation of the image within a subset \( \Omega_i \), and the variational contours \( C \). First, the minimum \( E \) with respect to \( \{p_i\} \) is achieved while \( C \) is fixed. Then, the minimum \( E \) with respect to \( C \) is achieved while \( \{p_i\} \) are fixed. An objective function

\[ e(x, y|p_i) = -\log p_i, \quad \forall (x, y) \in \Omega, \quad \forall i, \quad (8.2) \]

determines the region-based segmentation criteria based on the statistical distribution of image intensity within each subset \( \Omega_i \). As \( e(\cdot) \) has the minimum value where \( p_i \) has the maximum value, the minimum \( E \) with respect to \( \{p_i\} \) is achieved where every \( p_i \) has the maximum. This is done by a similar way to the simplified Mumford-Shah segmentation model introduced in section 4.2 except that \( p_i \) is a statistical distribution of image intensity here, instead of a simple
expression $f_i$. The best $p_i$ satisfying the segmentation criteria is a conditional PDF of image intensity on the condition that the image pixel is an element of $\Omega_i$, given by

$$p_i \equiv p(I(x, y) | (x, y) \in \Omega_i), \quad \forall i,$$

(8.3)

where $I(x, y) : \Omega \rightarrow \mathbb{R}^B$ denotes a vector-valued image pixel. The estimated $p_i$ provides a force to propagate the variational contours $C$ to the proper position where $C$ divides the entire domain $\Omega$ of the image $I(x, y)$ into multiple subsets $\{\Omega_i\}$. This performs an unsupervised image segmentation. Then, the minimization of $E$ with respect to $C$ smoothes the variational boundaries $C$ minimizing $|C|$. As the proposed method does not require any prior knowledge or training samples, the use of proposed method is convenient and flexible, so it can be used in any kinds of images as the first choice. However, the performance of segmentation tends to be limited depending on the character of the given images. It is particularly limited if the image has significant non-uniform subsets. Supervised segmentation methods introduced in the next two chapters may show better performance in those non-uniform images.

8.2 Multi-dimensional Histogram Density Function

We have proposed to use a multivariate mixture density function as the statistical distribution of image intensity within a subset. In the proposed method, we propose to use a normalized multi-dimensional histogram, which is also introduced as a multi-dimensional histogram density function in section 6.2.1, as a non-parametric and discrete expression of the multivariate mixture density function.

Let $\mathcal{I} = \{I(1), I(2), \ldots, I(N)\}$ be the $N$ observed data samples, and $I \in \mathbb{R}^B$ be the vector-valued image intensity. The histogram density function of given data samples is given by

$$h(I) \equiv \left\{ \frac{1}{N} \text{hist}[\mathcal{I}] \right\} : \mathbb{R}^B \rightarrow \mathbb{R},$$

(8.4)

where hist$[\mathcal{I}]$ denotes a multi-dimensional histogram of $\mathcal{I}$, and $\Delta I$ denotes the volume of a histogram bin. If the histogram density function $h(I)$ is normalized as

$$\sum_I h(I) = 1$$

(8.5)

with unlimited number of data samples, i.e. $N \rightarrow \infty$, and infinitely narrow histogram bins, i.e. $\Delta I \rightarrow 0$, the discrete $h(I)$ ideally approximates a continuous PDF, given by

$$p(I) \approx \lim_{\Delta I \rightarrow 0} \lim_{N \rightarrow \infty} h(I).$$

(8.6)

In the proposed active contour model, $h(I)$ substitutes the $p_i$ in equation 8.1 and 11.8 as a discrete non-parametric form of a multivariate mixture density function.

In practical image processing problems, the number of data samples is limited and the width of a histogram bin cannot be zero. However, the native data is already in a sampled discrete
form in digital image processing, so the quantization error caused by $h(I)$ is reasonably low if $\Delta I = 1$. The simple computation of a histogram is another advantage. Although there are many non-parametric density estimation methods, e.g. $k$-nearest neighborhood, Parzen window, histogram provides fairly reasonable information with a short computation time. However, the required amount of memory significantly increases depending on the number of bands $B$ and the resolution of image intensity $\Delta I$. For example, a 24bit RGB image requires $2^{24} \times 8 = 128$ Mbytes, while a gray image requires only $2^8 \times 8 = 2$ Kbytes.

The statistics of image intensity in an image is not always representable as a simple parametric expression, such as a Gaussian distribution. Since the proposed method does not rely on a particular stochastic model, the use of the proposed method is more flexible and robust than other methods using simple parametric expressions. Figure 8.1 shows an example of non-uniform images whose statistical distribution is unrepresentable with a simple parametric expression. The wood pattern shown in figure 8.1(a) shows a non-uniform texture, and

![Figure 8.1: Statistical distribution of image intensity: (a) a wood pattern, (b) the histogram](image)

Figure 8.1: Statistical distribution of image intensity: (a) a wood pattern, (b) the histogram

the statistical distribution, i.e. a histogram, of image intensity shown in figure 8.1(b) shows a high peak in the range of high intensity and a low and wide distribution along the range of low intensity. The statistics of these data samples are not easily representable with a simple Gaussian or other parametric distributions though it is trivial for a non-parametric method.

### 8.3 Contour Evolution

The implementation of proposed active contour model is done using the multi-phase active contour model introduced in section 7.2. We define multiple level set functions $\Phi = \{\phi_1, \ldots, \phi_J\}$ on the spatial domain, and each level set function represents a set of contours $C_j$. $J$ level set functions can partition an image up to $2^J$ subsets as shown in chapter 7.

The Euler-Lagrange equation obtained by minimizing the energy function $E$ with respect to level set functions $\Phi = \{\phi_1, \ldots, \phi_J\}$ is given by

$$
\frac{\partial \phi_j(x, y)}{\partial t} = \delta_j \left[ \nu \kappa_j + \sum_{i=1}^{2^J} \log h(I(x, y) | (x, y) \in \Omega_i) \frac{\partial \chi_i}{\partial H_j} \right], \quad \forall j,
$$

(8.7)
where \( \chi_i(x, y) : \Omega \rightarrow \{0, 1\} \) denotes the binary identity functions introduced in equation 7.4 and 7.5, and \( H_j \equiv H_\epsilon(\phi_j(x, y)) : \Omega \rightarrow \mathbb{R} \) denotes the regularized unit step function of \( \phi_j(x, y) \), introduced in equation 7.3. \( h(I(x, y)|(x, y) \in \Omega_i) \) denotes the histogram density function measured within \( \Omega_i \), and it determines the amount of update in \( \phi_j(x, y) \). \( \delta_j \equiv \delta_\epsilon(\phi_j(x, y)) : \Omega \rightarrow \mathbb{R} \) performs a function of a window, which updates \( \phi_j(x, y) \) only around the contours where \( |\phi_j(x, y)| < \epsilon \). The curvature term \( \kappa_j \equiv \kappa(\phi_j(x, y)) : \Omega \rightarrow \mathbb{R} \), introduced in equation 3.10, keeps the regularity of contours, and \( \nu \) controls the relative weight between the segmentation force and regularity force.

The update of level set functions is performed as an iterative processing. At each iteration, we measure \( h(I(x, y)|(x, y) \in \Omega_i) \) of each subset, and update each level set function \( \phi_j(x, y) \) according to the update function shown above until the active contours finally converge to the position of desired boundaries.

### 8.4 Algorithm

Table 8.1: The input and output variables used in the unsupervised multi-dimensional histogram method

<table>
<thead>
<tr>
<th>Input</th>
<th>Output</th>
</tr>
</thead>
<tbody>
<tr>
<td>( - I(x, y) : \Omega \rightarrow \mathbb{R}^L ), a multispectral image. ( - \langle x \rangle ) ( J ), the number of level set functions ( {\phi_j(x, y)} = ) the number of active contours ( {C_j} ). ( - \nu ), a parameter to control the regularity of contours. ( - \Delta t ), the time step of iterative processing.</td>
<td>( - S(x, y) : \Omega \rightarrow {1, \ldots, 2^J} ), the segmented image</td>
</tr>
</tbody>
</table>

Table 8.1 shows the input and output variables used in the proposed method. A multispectral image \( I(x, y) \) is given as the input data. The number of level set functions, which is equivalent to the number of contours, is set as \( J \). \( \nu \) controls the regularity of contour evolution by controlling the relative balance between segmentation force and regularity force. \( \Delta t \) determines the convergence speed. After the proposed active contours converge, the algorithm produces the segmented image \( S(x, y) \) indicating each subset with different numbers.

As shown in algorithm 1, the proposed active contour algorithm consists of two stages: initialization and contour evolution. During the initialization stage, \( J \) sets of initial contours \( \{C_j\} \) are given either manually or from a defined set, and corresponding level set functions are initialized as the signed distance from each \( (x, y) \) to the closest contours. During the iterative contour evolution, the mean curvature \( \kappa_j(x, y) \) and the unit step function \( H_j(x, y) \) are computed from each level set function \( \phi_j(x, y) \). The mathematical description of function \( \text{meanCurvature}(\cdot) \) and \( \text{unitStep}(\cdot) \) are described respectively in equations 3.10 and 7.3. Then, binary identity functions \( \chi_i(x, y) \) and the histogram density functions \( h_i(I) \) for each subset \( \Omega_i \) are measured.
The mathematical description of functions `identityFunction(·)` and `histogramDensity(·)` are introduced respectively in equations 7.4 and 8.4. The measured $h_i(I)$ updates objective functions $e_i(x, y)$ for $\Omega_i$, and finally level set functions $\{\phi_j(x, y)\}$ are updated.

$e_i(x, y) = -\log h_i(I(x, y))$

Update level set function

for $j = 1 \cdots J$ do

$\phi_j(x, y) = \phi_j(x, y) + \Delta t\delta(\phi_j(x, y)) \left[ \nu\kappa(\phi_j(x, y)) - \sum_{i=1}^{2^J} e_i(x, y) \frac{\partial \chi_i}{\partial H_j} \right]$

$t = t + \Delta t$

until until the evolution of contour converges

**Segmentation result**

$S(x, y) = \sum_{i=1}^{2^J} \chi_i(x, y)$

Table 8.2 shows the input and output variables used in the histogram density function `histogramDensity(I)`. The density function takes three inputs: data samples $I$, the dynamic range of image intensity, and the size of histogram bins $\Delta I$. The dynamic range and $\Delta I$ determines the resolution of the histogram. After computation, the density function produces a normalized multi-dimensional histogram as a non-parametric and discrete density function. As shown in algorithm 2, the estimation of a histogram density function consists of two stages: initialization and computation. The mathematical model of this method was introduced in equation 8.4. First, the initial histogram is defined based on the dimension of the vector-valued image intensity $I \in \mathbb{R}^B$ and the given dynamic range. Then, the corresponding histogram bin for each data sample is accumulated, and the whole histogram is normalized in the final stage.
Table 8.2: The input and output variables used in the multi-dimensional histogram density function

Figure 8.2 shows the iterative contour evolution of the proposed active contour model. The figures on the top show the contour evolution, and the figures on the bottom show the corresponding segments. At the initial stage, a set of initial contours are given from a predefined shape as shown in the left figures. The contours move separating the given image, and finally converge to the boundary of the small rectangle.
8.5 Experiments

In this section, we apply the proposed segmentation method to three different images, and compare the results of the proposed method to the results of other active contour models. Two active contour models, which share the same region-based segmentation principle, were used as benchmarks: a piecewise-constant active contour model proposed by Sandberg and Chan [5, 123, 140] and another active contour model proposed by Rousson and Deriche [10, 117]. Sandberg’s method will be referred to method 1, and Rousson’s method will be referred to method 2. All three methods including the proposed method determine the segmentation criteria based on the statistical property of image intensity measured within a subset. Method 1 represents each subset as a vector-valued constant number. Method 2 represents each subset as a multivariate Gaussian density function. Both methods 1 and 2 use parameters to represent each subset. Method 1 uses the mean of image intensity measured within the subset, while method 2 uses the mean and covariance of image intensity measured within the subset. The detail of mathematical and analytical descriptions of both methods are presented in section 3.4.

Figure 8.3(a) shows an example of synthetic gray images with textures. There is a small rectangle in the image, and both the rectangle and the background have their own texture pattern. The object of this experiment is to separate the rectangle from the background. Figure 8.3(b) shows the ground truth image, the ideal result of segmentation, of the given image. The dark part presents the background, class 1, while the bright part presents the rectangle, class 2.

Figure 8.3: Synthetic textured image: (a) a textured gray image, (b) the ground truth image

Figure 8.4 shows the result of method 1 applied on figure 8.3(a). Figure 8.4(a) shows the final stage of contour evolution, and figure 8.4(b) shows the corresponding segmentation result. Method 1 cannot partition the rectangle as a single object as it separates the rectangle as dark sub-regions and bright sub-regions, and the same effect also appears on the background. Method 1 fails in this problem because the dark intensity and the bright intensity of the rectangle stay too far away in the image intensity space, so it cannot represent the subset with the average value of the intensity.

Figure 8.5 shows the result of method 2 applied on figure 8.3(a). Figure 8.5(a) shows the final stage of contour evolution, and figure 8.5(b) shows the corresponding segmentation result.
Figure 8.4: Method 1 applied to a synthetic textured image: (a) the final stage of contour evolution, (b) the segmented subsets

Figure 8.5: Method 2 applied to a synthetic textured image: (a) the final stage of contour evolution, (b) the segmented subsets

Method 2 shows a better segmentation result than method 1. It successfully separates the rectangle from the background, but there are still a few artifacts in the background.

Figure 8.6 shows the result of the proposed method applied on the same image. Figure 8.6(a) shows the final stage of contour evolution, and figure 8.6(b) shows the corresponding segmentation result. The proposed method successfully separates the rectangle from the background without significant artifacts, which were observed in the cases of other two methods.

For more precise comparison, we measure the statistical distribution of image intensity within class 2, which is supposed to be the small rectangle in the segmentation result. Figure 8.7(a), 8.7(b), and 8.7(c) respectively present the results of method 1, method 2, and the proposed method. The blue solid line of all three graphs presents the statistical distribution of image intensity within the rectangle in the ground truth image. Because of the wood pattern, the statistical distribution of the rectangle is not simple. There is a high peak at the region of high intensity in the graph, and there are multiple low peaks at the region of dark intensity in the graph.
Figure 8.6: Proposed method applied to a synthetic textured image: (a) the final stage of contour evolution, (b) the segmented subsets

Figure 8.7: Statistical distribution of image intensity within class 2, the small rectangle: (a) method 1, (b) method 2, (c) proposed method

The green solid line of all three graphs presents the same statistics measured within class 2 in the segmentation result. As the green solid line exists closer to the blue solid line, it presents better result. In figure 8.7(a), the dotted green line with a circle presents the representation of the subset used in method 1, i.e. the mean of green solid line. The green line is very different from the ground truth because the constant representation is not sufficient to represent the
complicated ground truth. In figure 8.7(b), the dotted green line presents the representation of the subset used in method 2, i.e. the Gaussian density function of image intensity measured. Although the green solid line stays close to the blue line, the dotted line seems quite different from the actual distribution, and it consequently results in the artifacts shown in figure 8.5. In figure 8.7(c), the result of the proposed method and the ground truth data is almost identical.

Figure 8.8(a) shows another example of gray images with textures. There are five objects

![Figure 8.8: Synthetic textured image: (a) a textured gray image, (b) the ground truth image](image)

in a synthetic gray image: a circle, a rectangle, a horizontal ellipse, a vertical ellipse, and a triangle. The circle and vertical ellipse have uniform image intensity, but the triangle and the horizontal ellipse have textured pattern. The rectangle has a gradient intensity. The overall image has some noise, so the edges between each object and the background are not clear. The object of this experiment is to separate all objects from the background forming two classes, i.e. background and objects. Figure 8.8(b) shows the ground truth of this experiment. Class 1, i.e. background, appears as a bright sub-region, while class 2, i.e. objects, appear as dark sub-regions.

Figure 8.9 shows the result of method 1 applied on figure 8.8(a). Figure 8.9(a) shows the final stage of contour evolution, and figure 8.9(b) shows the corresponding segmentation result. Although method 1 successfully partitions the circle and vertical ellipse as class 2, it completely fails to separate the horizontal ellipse from the background. Also, only some portions of the rectangle and triangle appear as class 2 in the final result due to their textured pattern and gradient intensity. Since method 1 represents two classes as two constant numbers, it cannot recognize an object if the image intensity of the object is not uniform.

Figure 8.10 shows the result of method 2 applied on figure 8.8(a). Figure 8.10(a) shows the final stage of contour evolution, and figure 8.10(b) shows the corresponding segmentation result. Method 2 shows a better segmentation result than method 1 successfully separating the circle, vertical ellipse, triangle, and rectangle from the background. However, there are still a few artifacts on the horizontal ellipse due to the textured pattern because the statistical distribution of the texture pattern stays out of the Gaussian density function of class 2.

Figure 8.11 shows the result of the proposed method applied on the same image. Figure 8.11(a) shows the final stage of contour evolution, and figure 8.11(b) shows the corresponding segmenta-
Figure 8.9: Method 1 applied to a synthetic textured image: (a) the final stage of contour evolution, (b) the segmented subsets

Figure 8.10: Method 2 applied to a synthetic textured image: (a) the final stage of contour evolution, (b) the segmented subsets

The proposed method successfully separates all five objects, even the horizontal ellipse with texture pattern, from the background without significant artifacts. This experiment shows how robust the proposed method is in the segmentation problems of non-uniform images.

Figure 8.12 shows an example of outdoor RGB images. This color image consists of three bands: red, green, blue. In the picture, there is a gray squirrel in the green grass field. The back of the squirrel shows a mix of gray color, the stomach side of the squirrel shows a mix of pink, and the tail shows a mix of pink and brown. Due to the texture of fur, there are a significant number of narrow shadows and sharp edges along the whole body of the squirrel as well as the grass field. The object of this experiment is to separate the squirrel from the grass field, i.e. background. This is a difficult segmentation problem because the color of neither squirrel or grass field is uniform. Although this non-uniform texture is a common problem found in any outdoor color images, it makes image segmentation very difficult.

Figure 8.13 shows the result of method 1 applied on figure 8.12. Figure 8.13(a) shows the
Figure 8.11: Proposed method applied to a synthetic textured image: (a) the final stage of contour evolution, (b) the segmented subsets

Figure 8.12: An outdoor RGB image

Figure 8.13: Method 1 applied to an outdoor RGB image: (a) the final stage of contour evolution, (b) the segmented subsets

final stage of contour evolution, and figure 8.13(b) shows the corresponding segmentation result. Because of the strong sharp texture pattern on the squirrel and the grass field, method 1 produces a lot of noise-like artifacts but cannot properly separate the squirrel from the background. Both the grass field and the squirrel are too complicated to be represented as a constant number
due to the presence of many small edges and shadows.

Figure 8.14 shows the result of method 2 applied on figure 8.12. Figure 8.14(a) shows the

(a)  
(b)

Figure 8.14: Method 2 applied to an outdoor RGB image: (a) the final stage of contour evolution, (b) the segmented subsets

final stage of contour evolution, and figure 8.14(b) shows the corresponding segmentation result. Method 2 shows a better segmentation result than method 1 successfully separating the squirrel from the grass field. However, there are still a few artifacts on the background due to the small edges and shadows of grass field.

Figure 8.15 shows the result of the proposed method applied on the same image. Figure 8.15(a)

(a)  
(b)

Figure 8.15: Proposed method applied to an outdoor RGB image: (a) the final stage of contour evolution, (b) the segmented subsets

shows the final stage of contour evolution, and figure 8.15(b) shows the corresponding segmentation result. The proposed method successfully separates the squirrel from the grass field, and the number of noise-like artifacts is much lower than method 2 as well as method 1. This experiment shows that the proposed method is robust in the segmentation problems of multispectral images with non-uniform subsets, which is common in outdoor color images.
Chapter 9

Half-supervised Active Contour Model using Multivariate Gaussian Mixture Density Functions

In this chapter, we propose a half-supervised active contour model using a parametric density estimation method introduced in section 6.1.1. The proposed method follows the same region-based segmentation principle introduced in chapter 8 except for two major modifications. First, a supervised estimation method, instead of an unsupervised method, estimates the conditional PDF $p_i$ from prior knowledge. Second, $p_i$ is estimated as a mixture of parametric continuous functions instead of a non-parametric discrete function. Section 9.1 discusses the parametric density estimation method, and section 9.2 discusses the half-supervised image segmentation model. Section 9.3 presents the numerical algorithms of the proposed method, and section 9.4 presents the experimental results applied on synthetic and real images.

9.1 Multivariate Gaussian Mixture Density Function Estimated by EM

In chapter 8, we proposed to estimate the conditional PDF $p_i$ of image intensity within a subset $\Omega_i$ as a non-parametric discrete function. In this chapter, we propose to estimate $p_i$ as a mixture of continuous parametric density functions

$$p_i \equiv \sum_{k=1}^{K} \alpha_k p(I|\theta_k),$$

(9.1)

where the number of sub-classes $K$ and the weight of each sub-class $\{\alpha_k\}$ determine the global statistical property of a mixture density function $p_i$, and the parameter set $\theta_k$ determines the local statistical property of a sub-class $k$. The PDF of each sub-class is represented as a multivariate Gaussian density function

$$p(I|\theta_k) = p(I|\mu_k, \Sigma_k), \forall k,$$

(9.2)

$\overset{1}{\text{Although there is no such term as } \text{half-supervised, we refer to the proposed method as a half-supervised method because it requires relatively lower level of prior knowledge compared to the supervised method introduced in the next chapter.}}$
where $\mu_k$ and $\Sigma_k$ respectively denote the mean vector and the covariance matrix of data belong to the sub-class $k$. A global PDF can be estimated as a mixture of $K$ Gaussian density functions by estimating these four sets of parameters: $K$, $\{\alpha_k\}$, $\{\mu_k\}$, and $\{\Sigma_k\}$.

The proposed method uses the classic EM method, introduced in section 6.1.1, to estimate the mixture density function $p_i$ from given data samples $I$, such as

$$p_i \approx \sum_{k=1}^{K} \hat{\alpha}_k p(I|\hat{\mu}_k, \hat{\Sigma}_k). \quad (9.3)$$

As mentioned in section 6.1, there are two problems to estimate a mixture density function using the classic EM method. First, classic EM method cannot estimate $K$. Second, the result of classic EM method highly depends on the initial values of the parameters to be estimated: $\{\alpha_k(t = 0)\}$, $\{\mu_k(t = 0)\}$, and $\{\Sigma_k(t = 0)\}$. In the proposed method, we solve these problems by providing partial information of $p_i$ as a prior knowledge, and then estimate the rest of information from the given data samples and the prior knowledge. Thus, the parameters are estimated by a supervised method instead of an unsupervised method as chapter 8.

A total of four sets of parameters are required to present $p_i$ as a mixture of Gaussian density functions: the number of sub-classes $K$, the weight of each sub-class $\{\alpha_k\}$, the mean vector of each sub-class $\{\mu_k\}$, and the covariance matrix of each sub-class $\{\Sigma_k\}$. Let us assume that some training samples are available and the statistical properties of both the training samples and test data are similar. We can find the expected values of $K$ and $\{\mu_k\}$ from training samples and provide them as the prior knowledge of supervised density estimation. Then, the proposed EM method needs to estimate only $\{\alpha_k\}$ and $\{\Sigma_k\}$ from the test data. Figure 9.1 shows an example of mixture density estimation using the proposed method. The blue solid line presents the histogram of data samples, i.e. the true statistical distribution of the given data. There are three peaks in the histogram, thus the PDF of the given data should be represented as a mixture of at least three Gaussian density functions. Let us assume that two information are available: the expected number of sub-classes $K = 3$ and the expected values of the mean of each sub-class $\{\mu_1, \mu_2, \mu_3\}$ shown as the three red circles. Then, the classic EM method can estimate the weights of each sub-class $\{\hat{\alpha}_1, \hat{\alpha}_2, \hat{\alpha}_3\}$ and the covariance matrix of each sub-class $\{\hat{\sigma}_1, \hat{\sigma}_2, \hat{\sigma}_3\}$ from the given data. The red dotted line presents the estimated parametric mixture density function. The mathematic description of the general EM method was
described in section 6.1.1, and the algorithm of the proposed method is presented in section 9.3.

## 9.2 Half-supervised Image Segmentation

The proposed segmentation method consists of two stages: training and test. During the training stage, a low level of prior knowledge is provided. The test stage consists of two procedures. First, we estimate the statistical distribution of image intensity within each subset as a mixture of continuous parametric density functions. Then, we partition an image using the same energy minimization based image segmentation principle used in the unsupervised multi-dimensional histogram method.

The same global energy function introduced in section 8.1

\[
E(\{p_i\}, C) \equiv \sum_i \int_{\Omega_i} e(x, y|p_i)dx\,dy + \nu|C| \tag{9.4}
\]

is minimized with respect to two expressions: \(p_i\), i.e. the representation of the image within a subset \(\Omega_i\), and the variational contours \(C\). The objective function \(e(x, y|p_i)\) determines the region-based segmentation criteria based on \(p_i\), and the best \(p_i\) satisfying the segmentation criteria is a conditional PDF of image intensity on the condition that the image pixel is an element of \(\Omega_i\), i.e. \(p(I(x, y)|x, y \in \Omega_i)\).

In the proposed method, \(p_i\) is represented by four sets of parameters: the number of sub-classes \(K\), the weight of each sub-class \(\{\alpha_k\}\), the mean vector of each sub-class \(\{\mu_k\}\), and the covariance matrix of each sub-class \(\{\Sigma_k\}\). Before the image segmentation, i.e. during the training stage, the expected values of \(K\) and \(\{\mu_k\}\) are provided from training samples. During image segmentation, i.e. the test stage, \(\{\alpha_k\}\) and \(\{\Sigma_k\}\) of image intensity within \(\Omega_i\) are estimated by the classic EM method as described in the previous section. The given parameters, \(\hat{K}\) and \(\{\hat{\mu}_k\}\), and the estimated parameters, \(\{\hat{\alpha}_k\}\) and \(\{\hat{\Sigma}_k\}\), represent the conditional PDF \(p_i\) of image intensity at each subset, and the estimated \(p_i\) provides a force to propagate the variational contours \(C\) to the proper position where \(C\) divides the entire domain \(\Omega\) of the image \(I(x, y)\) into multiple subsets \(\{\Omega_i\}\). Figure 9.2 and 9.3 show an example of the proposed half-supervised segmentation. Figure 9.2(a) shows an RGB image consisting of two military camouflage patterns where each of the pattern consists of at least three different paints, and figure 9.2(b) shows the two subsets of the given image as \(\{\Omega_1, \Omega_2\}\). Since both camouflage patterns consist of three different paints, the PDF of image intensity for each subset should be a mixture of at least three sub-classes. Figure 9.3 shows the example of training stage of the proposed method. The vector-valued image intensities at six points are measured from training samples, and assigned as \(\{\mu_1, \mu_2, \mu_3, \mu_4, \mu_5, \mu_6\}\) for the background \(\Omega_1\) in figure 9.3(a). Three samples are measured from training samples, and assigned as \(\{\mu_1, \mu_2, \mu_3\}\) for the rectangle \(\Omega_2\) in figure 9.3(b). During the image segmentation, \(\{\hat{\alpha}_k\}\) and \(\{\hat{\Sigma}_k\}\) are estimated for both subsets \(\{\Omega_1, \Omega_2\}\) from the given expected values of \(\hat{K}\) and \(\{\hat{\mu}_k\}\) and the image intensity of each subset \(I(x, y)|\forall(x, y) \in \Omega_i\).

The minimization of \(E\) with respect to \(C\) smooths the variational boundaries \(C\) minimizing the length \(|C|\). We use the same level set theory introduced in section 8.3 to implement the
The proposed half-supervised image segmentation method performs better than the unsupervised image segmentation method introduced in the last chapter particularly if the image has distinctive non-uniform sub-regions as shown in figure 9.3. Since the statistical property of each subset must be represented as a mixture density function, the segmentation of the images like figure 9.3 is extremely difficult for unsupervised segmentation methods. The supervised density estimation improves the classic EM method providing more robust segmentation capability, and the parametric mixture density function provides more flexibility than the histogram density function.

9.3 Algorithm

Table 9.1 shows the input and output variables used in the proposed segmentation method. A multispectral image $I(x, y)$ is given as the input data. The number of level set functions,

</tbody>
</table>

which is equivalent to the number of contours, is set as $J$. $\nu$ controls the regularity of contour evolution by controlling the relative balance between segmentation force and regularity force. $\Delta t$ determines the convergence speed. The expected number $\hat{K}$ of sub-classes and the expected mean vectors $\{\hat{\mu}_k\}$ of sub-classes for each subset is measured from the training samples $I_i$ for each subset $\Omega_i$, and they provide prior information on supervised density estimation for $\{\hat{\alpha}_k\}$ and $\{\hat{\Sigma}_k\}$. After the proposed active contours converge, the algorithm produces the segmented image $S(x, y)$ indicating each subset with different numbers.

The proposed active contour algorithm consists of three stages: training, initialization, and contour evolution (test). During the training stage, the expected number $\hat{K}$ of sub-classes and the expected mean vectors $\{\hat{\mu}_k\}$ of sub-classes are measured from the training samples $I_i$ and assigned for each subset $\Omega_i$. The description of function $\text{priorInfo}(\cdot)$ is presented in section 9.2. During the initialization stage, $J$ sets of initial contours $\{C_j\}$ are given either manually or from a defined set, and corresponding level set functions are initialized as the signed distance from each $(x, y)$ to the closest contours. During the iterative contour evolution, the mean curvature $\kappa_j(x, y)$ and the unit step function $H_j(x, y)$ are computed from each $\phi_j(x, y)$. The mathematical description of function $\text{meanCurvature}(\cdot)$ and $\text{unitStep}(\cdot)$ are introduced respectively in equation 3.10 and 7.3. Then, binary identity functions $\chi_i(x, y)$ for each subset $\Omega_i$ are computed. The mathematical description of function $\text{identityFunction}(\cdot)$ is introduced in equation 7.4. The weights $\{\hat{\alpha}_k\}$ and covariance matrix $\{\hat{\Sigma}_k\}$ of sub-classes are estimated from the given $\{\hat{\mu}_k\}$ and the image intensity measured within each subset $I(x, y)\chi_i(x, y)$ using the classic EM method. The mathematical description of function $\text{EM}(\cdot)$ is introduced in section 6.1.1, and the numerical algorithm is presented in algorithm 4. The estimated $\{\hat{\alpha}_k\}$ and $\{\hat{\Sigma}_k\}$ and the given $\{\hat{\mu}_k\}$ determine the conditional PDF of image intensity $p_i$, and $p_i$ updates the objective function $e_i(x, y)$ for $\Omega_i$. The level set functions $\{\phi_j(x, y)\}$ are finally updated based on $\chi_i(x, y)$ and $e_i(x, y)$.

supervised EM method takes three inputs, data samples $I$, the number of sub-classes $K$, and the mean vector of each sub-class $\{\mu_k\}$, and produces two outputs, the estimated weight $\{\hat{\alpha}_k\}$ and covariance matrix $\{\hat{\Sigma}_k\}$ of each sub-class.

The proposed EM method estimates the output values through an iterative process consisting of three steps: expectation (E-step), maximization (M-step), and evaluation. During E-step, the expected posterior probabilities of the given data samples based on the current $\hat{\Sigma}_k$ and given $\mu_k$ for each sub-class $k$ are estimated and updated. During M-step, two output parameters, $\hat{\alpha}_k$ and $\hat{\Sigma}_k$, which maximize the likelihood function $Q(t)$, are estimated for each sub-class $k$. During the evaluation step, we check the value of $Q(t)$, and stop the iteration if $Q(t)$ has converged.

\subsection*{9.4 Experiments}

In this section, we apply the proposed segmentation method to four different images, and compare the results of the proposed method to the results of other active contour models. The same region-based active contour models used in the last chapter were used as benchmarks. All three methods including the proposed method determine the segmentation criteria based on the statistical property of image intensity measured within a subset. Method 1 and 2 are unsupervised methods, while the proposed method uses prior knowledge from the given training samples. The experiments of all three methods use the same pre-defined initial contours. The
Figure 9.4 shows an example of synthetic RGB images with complicated non-uniform patterns. There is a rectangle in the middle of the image in figure 9.4(a). Figure 9.4(b) shows the ground truth information of the given image. The object of this experiment is to separate the rectangle, class 2, from the background, class 1. This is a difficult segmentation problem because the statistical distribution of both the rectangle and the background are complicated due to the military camouflage patterns consisting of multiple paints. Also, the image is manipulated, so the mean vectors of both interior and exterior are identical as \([R, G, B] = [163, 164, 77]\).

Figure 9.5 shows the result of method 1 applied on figure 9.4. Figure 9.5(a) shows the final stage of contour evolution, and figure 9.5(b) shows the corresponding segmentation result. Method 1 cannot separate the rectangle as a single object because it separates the rectangle as two sub-regions, bright and dark, and the same effect also appears on the background. The
dark sub-class and the bright sub-class of the rectangle stay too far sway in the image intensity space, so the average value of the intensity cannot represent the subset. The same problem appears on the background.

Figure 9.6 shows the result of method 2 applied on figure 9.4. Figure 9.6(a) shows the

![Figure 9.6](image1)

(a)  
(b)

Figure 9.6: Method 2 applied to a complicated synthetic RGB image: (a) the final stage of contour evolution, (b) the segmented subsets

final stage of contour evolution, and figure 9.6(b) shows the corresponding segmentation result. Method 2 cannot separate the rectangle as a single object because of the same reason that method 1 fails. Experiments shown in figure 9.5 and 9.6 show the limitation of unsupervised segmentation methods on the images with non-uniform sub-regions.

We applied the proposed half-supervised segmentation method on the same image. Figure 9.7 shows the training stage of the proposed method. Training samples for both the

![Figure 9.7](image2)

(a)  
(b)

Figure 9.7: Training stage of the proposed method: (a) 6 samples measured for background, (b) 3 samples measured for the core

rectangle and the background are provided. Six vector-valued image intensities are measured from the training samples and assigned as \( \{ \hat{\mu}_1, \hat{\mu}_2, \ldots, \hat{\mu}_6 \} \) for the background in figure 9.7(a).
Three vector-valued image intensities are measured from the training samples and assigned as \( \{ \hat{\mu}_1, \hat{\mu}_2, \hat{\mu}_3 \} \) for the rectangle in figure 9.7(b). Figure 9.8 shows the result of the proposed method. Figure 9.8(a) shows the final stage of contour evolution, and figure 9.8(b) shows the corresponding segmentation result. The proposed method successfully separates the rectangle from the background without any significant artifact.

For more precise comparison, the statistical distribution of image intensity within both class 1 and 2 are measured. Figure 9.9 shows the statistical distribution of image intensity measured at green channel within class 1, which is supposed to be the background in the segmentation result. Figure 9.9(a), 9.9(b), and 9.9(c) respectively present the results of method 1, method 2, and the proposed method. The blue solid lines of all three graphs present the statistical distribution of image intensity measured at the background, and it shows that the camouflage pattern of background consists of at least three different paints. The green solid lines of all three graphs present the same statistics measured within class 1 in the segmentation results. As the green solid line exists closer to the blue solid line, it presents better result. In figure 9.9(a), the dotted red line with a circle presents the representation of the subset used in method 1, i.e. the mean of green solid line. The measured statistics are very different from the ground truth because the constant representation is not sufficient to represent the non-uniform sub-region consisting of three different paints. In figure 9.9(b), the dotted red line presents the representation of the subset used in method 2, i.e. the Gaussian density function of image intensity measured. The measured statistics is very different from the ground truth because of the same reason as figure 9.9(a). The red circles in figure 9.9(c) present \( \{ \hat{\mu}_1, \hat{\mu}_2, \ldots, \hat{\mu}_6 \} \) measured from training samples. They are the centers of each sub-class. The dotted red line presents the estimated parametric mixture density function at the final stage of contour evolution. Although the estimated mixture density function is not identical to the true statistical distribution, i.e. the blue solid line, it successfully finds the position of peaks producing a good segmentation result. The estimated weights \( \{ \hat{\alpha}_1, \hat{\alpha}_2, \ldots, \hat{\alpha}_6 \} \) help to ignore insignificant sub-classes and to emphasize significant sub-classes. The measured statistics and the ground truth are almost identical. Figure 9.10 shows the same measure for class 2, the rectangle. Both method 1 and 2 cannot produce satisfying results, while the proposed method successfully estimates a mixture density function, which is close to the true statistical distribution of image intensity.
Figure 9.9: Statistical distribution of image intensity within the background measured at green channel: (a) method 1, (b) method 2, (c) proposed method

intensity, from \( \{\hat{\mu}_1, \hat{\mu}_2, \hat{\mu}_3\} \). The measured statistics and the ground truth are almost identical.

Figure 9.11 shows an RGB image captured from a virtual 3D scene generated by an ATR simulator. The background is reconstructed from an air-borne range data, and the corresponding color picture is put on the reconstructed surface as texture. We also reconstruct a tank model, and put the camouflage pattern shown in figure 9.7(b) on its surface. The object of this experiment is to extract the shape of the tank from the scene as a target. This image is another difficult problem because there are a lot of shades on the surface of both the tank and the background as well as the complicated camouflage pattern.

Figure 9.12 shows the result of method 1 applied on figure 9.11. Figure 9.12(a) shows the final stage of contour evolution, and figure 9.12(b) shows the corresponding segmentation result. Method 1 identifies the sky as the target, the white subset. Also, method 1 cannot extract the whole body of the tank from the scene because of the complicated camouflage pattern. Method 2 also produces an undesirable result as shown in figure 9.13. The mountains and other areas in the background are identified as target, the dark subset.

We applied the proposed half-supervised segmentation method on the same image. Figure 9.14 shows the training stage of the proposed method. We used the same image as the training samples for this experiment. Three vector-valued image intensities are measured from a mountain, sky and the field, and assigned for the background. Six vector-valued image in-
Figure 9.10: Statistical distribution of image intensity within the core measured at green channel: (a) method 1, (b) method 2, (c) proposed method

Figure 9.11: A complicated synthetic RGB image

tensities are measured from the tank, and assigned for the tank. After applying the proposed method on the same image, we successfully extract the almost perfect shape of the tank from the background as shown in figure 9.15. Figure 9.15(a) shows the final stage of contour evolution, and figure 9.15(b) shows the corresponding segmentation result. In figure 9.15(b), we can see very sophisticated detail of the tank. This experiment shows the robustness of the proposed method in ATR problems.

Figure 9.16 shows an example of outdoor gray scale images with texture. There are two
Figure 9.12: Method 1 applied to a complicated synthetic RGB image: (a) the final stage of contour evolution, (b) the segmented subsets

Figure 9.13: Method 2 applied to a complicated synthetic RGB image: (a) the final stage of contour evolution, (b) the segmented subsets

Figure 9.14: Training stage of the proposed method: (a) 3 samples measured for background, (b) 6 samples measured for the tank

zebras standing close on the field. The zebras consist of white and black stripes, while the background is textured gray. The object of this experiment is to extract the shape of zebras from the background. This is a difficult segmentation problem because of the complicated patterns of zebras. The white stripes of zebras are brighter than the background, while the
Figure 9.15: Proposed method applied to a complicated synthetic RGB image: (a) the final stage of contour evolution, (b) the segmented subsets

Figure 9.16: A complicated outdoor gray image; two zebras

black stripes of zebras are darker than the background. Also, some portions of zebras, e.g. white stripes under the shade, have similar intensity to the background. The statistical distribution of image intensity within the zebras must be represented as a mixture of more than two sub-classes.

Figure 9.17 shows the result of method 1 applied on figure 9.16. Figure 9.17(a) shows the final stage of contour evolution, and figure 9.17(b) shows the corresponding segmentation result. Although method 1 identifies the whole background as a subset, it separates the zebras into two parts: bright sub-regions and dark sub-regions. Also, method 1 identifies the bright sub-regions of zebras as the background.

Figure 9.18 shows the result of method 2 applied on figure 9.16. Figure 9.18(a) shows the final stage of contour evolution, and figure 9.18(b) shows the corresponding segmentation result. Although method 2 produces better segmentation result than method 1, there are many artifacts on both zebras and background. The sub-regions of zebras whose intensity is similar to the background are identified as background, the white subset, while the sub-regions of background whose intensity is darker than the other parts of background are identified as zebras, the black subset.
Figure 9.17: Method 1 applied to the zebra image: (a) the final stage of contour evolution, (b) the segmented subsets

Figure 9.18: Method 2 applied to the zebra image: (a) the final stage of contour evolution, (b) the segmented subsets

Figure 9.19 shows the training stage of the proposed segmentation method. We used the same image as the training samples for this experiment. The image intensities of two samples are measured and assigned as \( \{ \hat{\mu}_1, \hat{\mu}_2 \} \) for the background. Four image intensities from bright white stripes, dark white stripes, bright black stripes, and dark black stripes are measured and assigned as \( \{ \hat{\mu}_1, \hat{\mu}_2, \hat{\mu}_3, \hat{\mu}_4 \} \) for the zebras. After applying the proposed method on the same image, the proposed method successfully extracts the shape of two zebras from the background as shown in figure 9.20. Figure 9.20(a) shows the final stage of contour evolution, and figure 9.20(b) shows the corresponding segmentation result. Although there are still a few artifacts on the zebras, the number of artifacts has been significantly reduced, and there are no artifacts in the background. The artifacts found within zebras appear because the image intensity of those sub-regions is identical to the background. This experiment shows the robustness and the limitation of the proposed segmentation method.

Figure 9.21 shows an example of indoor RGB images with a strong texture. There is a
Figure 9.19: Training stage of the proposed method: (a) 2 samples measured for background, (b) 4 samples measured for zebras

Figure 9.20: Proposed method applied to the zebra image: (a) the final stage of contour evolution, (b) the segmented subsets

Figure 9.21: A complicated indoor RGB image; hand
human hand and a donut-shaped object on the texture background. The object of this experiment is to extract the hand and the donut-shaped object from the background and to identify them as different subsets. Thus, the ideal segmentation result should have three subsets as \( \{ \Omega_{\text{hand}}, \Omega_{\text{object}}, \Omega_{\text{background}} \} \). This is a difficult segmentation problem because it requires not only segmentation but also pattern classification. The textured background is another difficult problem. In order to partition the given image into three subsets, all three active contour models use two level set functions \( \{ \phi_1(x, y), \phi_2(x, y) \} \). The mathematical description of 4-phase active contour is presented in chapter 7.

Figure 9.22 shows the result of method 1 applied on figure 9.21. Figure 9.22(a) shows the

![Figure 9.22](image)

(a) (b)

Figure 9.22: Method 1 applied to the hand image: (a) the final stage of contour evolution, (b) the segmented subsets

Figure 9.23 shows the result of method 2 applied on figure 9.21. Figure 9.23(a) shows the final stage of contour evolution, and figure 9.23(b) shows the corresponding segmentation result. Method 1 produces a very poor segmentation result in this case. Because of the texture, a lot of artifacts appear on the background. Also, the use of two level set functions produces undesired local minima resulting in a lot of artifacts on the hand.

Figure 9.23 shows the result of method 2 applied on figure 9.21. Figure 9.23(a) shows the final stage of contour evolution, and figure 9.23(b) shows the corresponding segmentation result.
Although method 2 produces a relatively cleaner segmentation on the textured background, it generates a lot of artifacts on the background, which is the local minima of two level set functions. Method 2 also identifies the hand and the donut-shaped object as the same subset. A smart choice of initial contours may avoid the artifacts caused by local minima of two level set functions, but it requires prior knowledge of given image.

Figure 9.24 shows the training step of the proposed segmentation method. We used the same image as the training samples for this experiment. The vector-valued image intensities of three samples are measured from hand and assigned as \( \hat{\mu}_1, \hat{\mu}_2, \hat{\mu}_3 \) for the hand. Two samples are measured from the donut-shaped object, and assigned as \( \hat{\mu}_1, \hat{\mu}_2 \) for the object. For the background, we did not provide any information, but assumed the background can be represented as a multivariate Gaussian density function. After applying the proposed method on the same image, the proposed method successfully extracts the shape of hand and the donut-shaped object from the background, and identifies them as three different subsets \( \{ \Omega_{\text{hand}}, \Omega_{\text{object}}, \Omega_{\text{background}} \} \) as shown in figure 9.25. Although there are still a few artifacts, identified as \( \Omega_{\text{unknown}} \), the proposed method shows the best result compared to the benchmarks. This experiment shows

![Figure 9.24](image1.png)  
**Figure 9.24:** Training stage of the proposed method: (a) 3 samples measured for hand, (b) 2 samples measured for the donut shaped object

![Figure 9.25](image2.png)  
**Figure 9.25:** Proposed method applied to the hand image: (a) the final stage of contour evolution, (b) the segmented subsets
that the proposed method can be used for not only image segmentation but also pattern classification.
Chapter 10

Supervised Active Contour Model using Multivariate Gaussian Mixture Density Functions

In this chapter, we propose a supervised active contour model using the parametric density estimation method introduced in section 6.1.2. The proposed active contour model estimates the statistical information of training samples for each subset, and applies the pre-estimated information into image segmentation without iterative density estimation during contour evolution. Section 10.1 discusses the supervised image segmentation model, and section 10.2 discusses the parametric density estimation method. Section 10.3 presents the numerical algorithms of the proposed method, and section 10.4 presents the experimental results applied on synthetic and real images.

10.1 Supervised Image Segmentation

The proposed segmentation method consists of two stages: training and test stages. During the training stage, an advanced EM method with MML estimates the PDF of training samples as a mixture of multivariate Gaussian density functions. During the test stage, the proposed segmentation method assigns the pre-estimated density functions as the conditional PDF of image intensity for each subset, and partitions the given image without any density estimation process.

Let us assume that training samples for each subset are available and the statistical distribution of training samples is similar to the statistical distribution of image intensity within each subset in the image. Then, we can estimate the conditional PDF of image intensity from the training samples, such as

\[ p(I(x,y)|x,y) \in \Omega_i) \approx p(I|I \in I_i), \quad \forall i \] (10.1)

where \( I_i = \{I_1, \ldots, I_n, \ldots, I_N\} \) denotes the ideally sampled training samples or a statistical template of the object, which is supposed to be isolated as a subset \( \Omega_i \) in the result of the segmentation. \( p(I|I \in I_i) : \mathbb{R}^B \rightarrow \mathbb{R} \) denotes a multivariate conditional PDF of a vector-valued image intensity \( I \) on the condition that the multispectral image pixel is an element of training samples \( I_i \). The detail on the density estimation of \( p(I|I \in I_i) \) will be discussed in the next
The proposed segmentation method uses the same global energy minimization scheme as the other two methods introduced in chapter 8 and 9. However, the minimization of the global energy function $E$ with respect to the statistical representation $p_i$ in equation 9.4 and 8.1 of each subset is not necessary in the proposed method because the best fitting $p_i$ is already given as $p(I|I \in I_i)$ from training samples instead of the given image. The global energy function can be simplified as a function of variational contours $C$ only, such as

$$E(C) \equiv \sum_i \int_{\Omega_i} -\log p(I(x, y)|I(x, y) \in I_i)dxdy + \nu |C|,$$

(10.2)

where the pre-estimated $p(I(x, y)|I(x, y) \in I_i)$ determines the segmentation criteria and provides a force to propagate the variational contours $C$ to the proper position where $C$ divides the entire domain $\Omega$ of the image $I(x, y)$ into multiple subsets $\{\Omega_i\}$. This is a supervised image segmentation. Then, the minimization of $E$ with respect to $C$ smoothes the variational boundaries $C$ minimizing the length $|C|$.

The Euler-Lagrange equation obtained by minimizing the energy function $E$ with respect to level set functions $\Phi = \{\phi_1, \ldots, \phi_j, \ldots, \phi_J\}$ is given by

$$\frac{\partial \phi_j(x, y)}{\partial t} = \delta_j \left[ \nu \kappa_j + \sum_{i=1}^{2J} \log p(I(x, y)|I(x, y) \in I_i) \frac{\partial \chi_i}{\partial H_j} \right], \quad \forall j,$$

(10.3)

where $\delta_j \equiv \delta_t(\phi_j(x, y))$ controls the width of update $\partial \phi_j/\partial t$, $p(I(x, y)|I(x, y) \in I_i)$ provides a force to propagate contours $C_j$, and $\partial \chi_i/\partial H_j$ determines the region where $\phi_j$ updates. The implementation of the proposed active contour model is identical to the two other proposed active contour models except that the proposed method does not need to compute $p(I(x, y)|I(x, y) \in I_i)$ at each iteration.

The proposed active contour model estimates the PDF of training samples prior to the contour evolution, and does not estimate the PDF from the image but only apply the pre-estimated PDF for image segmentation. This supervised approach simplifies the segmentation procedure reducing the convergence time of active contours. As long as the training samples are reliable, the segmentation results will be also more robust than the results of the two methods introduced in chapter 8 and 9 as well as traditional segmentation methods. However, the results will not consistent or robust if the training samples are unreliable.

### 10.2 Multivariate Gaussian Mixture Density Function Estimated by EM with MML

In this chapter, we represent the conditional PDF of vector-valued image intensity for being an element of a subset $p(I(x, y)|x, y) \in \Omega_i)$ in the same way that we estimate $p_i$ in chapter 9, i.e. a mixture of multivariate Gaussian density functions

$$p(I(x, y)|x, y) \in \Omega_i) \equiv \sum_{k=1}^{K} \alpha_k p(I(x, y)|\mu_k, \Sigma_k), \quad \forall i,$$

(10.4)
except that the mixture density function is estimated from training samples $I_i$ given by

$$p(I(x, y)|(x, y) \in \Omega_i) \approx \sum_{k=1}^{K} \hat{\alpha}_k p(I_i|\hat{\mu}_k, \hat{\Sigma}_k), \quad \forall i. \quad (10.5)$$

The estimation above is done by estimating four sets of parameters: the number of sub-classes $K$, the weight $\{\alpha_k\}$, the mean vector $\{\mu_k\}$, and the covariance matrix $\{\Sigma_k\}$.

Since classic EM method cannot estimate the number of sub-classes $K$, the proposed method uses an advanced EM method proposed by Figueiredo and Jain [144] to estimate a mixture density function from given data samples, i.e. training samples. The advanced EM method based on the minimum encoding length criteria initiates a high number of sub-classes, and eliminates the weakest sub-class one by one, so it can automatically select the number of sub-classes $K$. Therefore, all four sets of parameters, $\hat{K}$, $\{\hat{\alpha}_k\}$, $\{\hat{\mu}_k\}$, $\{\hat{\Sigma}_k\}$, can be estimated from given data samples without any prior knowledge on the data. That is an unsupervised density estimation method estimates parameters, and a supervised segmentation method partitions an image based on the estimated parameters. The detail of mathematic description of this density estimation method is presented in section 6.1.2, and the numerical algorithm is presented in the next section.

### 10.3 Algorithm

Table 10.1 shows the input and output variables used in the proposed segmentation method. A multispectral image $I(x, y)$ is given as the input data. The number of level set functions, which is equivalent to the number of contours, is set as $J$. $\nu$ controls the regularity of contour evolution by controlling the relative balance between segmentation force and regularity force. $\Delta t$ determines the convergence speed. The parameters representing each subset $\Omega_i$ are estimated from the corresponding training samples $I_i$. After the proposed active contours converge, the algorithm produces the segmented image $S(x, y)$ indicating each subset with different
The proposed active contour algorithm consists of three stages: training, initialization, and contour evolution (test). During the training stage, the four sets of parameters representing the PDF of training samples $I_i$ are estimated for each subset $\Omega_i$: the mean vector $\{\hat{\mu}_k\}$, the weight $\{\hat{\alpha}_k\}$, and the covariance matrix $\{\hat{\Sigma}_k\}$ of each sub-class, and the number $\hat{K}$ of sub-classes. The mathematical description of density estimation method $\text{EMwMML}(\cdot)$ is presented in section 6.1.2, and the algorithm is presented in algorithm 6.

**Algorithm 5: Supervised Active Contour Model using Multivariate Gaussian Mixture Density Functions**

Training
\[
\text{for } i = 1 \cdots 2^J \text{ do} \\
\quad [\hat{K}, \{\hat{\alpha}_k\}, \{\hat{\mu}_k\}, \{\hat{\Sigma}_k\}]_i = \text{EMwMML}(I_i)
\]

Initialization
\[
t = 0. \\
\text{for } j = 1 \cdots J \text{ do} \\
\quad C_j(x(s), y(s), t = 0): \text{Initialize contours.} \\
\quad \phi_j(x, y, t = 0) = \pm D((x, y), N(x, y)(C_j)): \text{Initialize level set functions.}
\]

Contour evolution
\[
\text{repeat} \\
\quad \text{for } j = 1 \cdots J \text{ do} \\
\quad \quad \kappa_j(x, y) = \text{meanCurvature}(\phi_j(x, y)) \\
\quad \quad H_j(x, y) = \text{unitStep}(\phi_j(x, y)) \\
\quad \text{Supervised region-based segmentation} \\
\quad \text{for } i = 1 \cdots 2^J \text{ do} \\
\quad \quad \chi_i(x, y) = \text{identityFunction}([H_j(x, y), \forall j]) \\
\quad \quad e_i(x, y) = -\log p(I(x, y)|[\hat{K}, \{\hat{\alpha}_k\}, \{\hat{\mu}_k\}, \{\hat{\Sigma}_k\}]_i) \\
\quad \text{Update level set function} \\
\quad \text{for } j = 1 \cdots J \text{ do} \\
\quad \quad \phi_j(x, y) = \phi_j(x, y) + \Delta t \delta(\phi_j(x, y)) [\nu \kappa(\phi_j(x, y)) - \sum_{i=1}^{2^J} e_i(x, y) \frac{\partial \psi_i}{\partial H_j}] \\
\quad t = t + \Delta t \\
\text{until until the evolution of contour converges}
\]

Segmentation result
\[
S(x, y) = \sum_{i=1}^{2^J} \chi_i(x, y)
\]

During the initialization stage, $J$ sets of initial contours $\{C_j\}$ are given either manually or from a defined set, and corresponding level set functions are initialized as the signed distance from each $(x, y)$ to the closest contours. During the iterative contour evolution, the mean curvature $\kappa_j(x, y)$ and the unit step function $H_j(x, y)$ are computed from each level set function $\phi_j(x, y)$. The mathematical description of function $\text{meanCurvature}(\cdot)$ and $\text{unitStep}(\cdot)$ are introduced respectively in equation 3.10 and 7.3. Then, binary identity functions $\chi_i(x, y)$ for each subset $\Omega_i$ are computed. The mathematical description of function $\text{identityFunction}(\cdot)$

81
is given in equation 7.4. There is no density estimation procedure during the contour evolution as the required parameters are already estimated from training samples $I_i$. Instead, the proposed method just assigns the pre-estimated parametric mixture density functions $p(I(x, y)|[\hat{K}, \{\hat{\alpha}_k\}, \{\hat{\mu}_k\}, \{\hat{\Sigma}_k\}]_i)$ to each subset $\Omega_i$ on the image, and the density functions perform the role of conditional PDF of image intensity. $p(I(x, y)|[\hat{K}, \{\hat{\alpha}_k\}, \{\hat{\mu}_k\}, \{\hat{\Sigma}_k\}]_i)$ updates the objective function $e_i(x, y)$ for $\Omega_i$, consequently updates the level set functions $\{\phi_j(x, y)\}$ based on $\chi_i(x, y)$ and $e_i(x, y)$.

Table 10.2 shows the input and output variables used in the function EMwMML($\cdot$) [144]. The advanced unsupervised EM method takes data samples $I$ and the maximum and minimum possible number of sub-classes $\{K_{max}, K_{min}\}$ as input, and produces the four sets of parameters representing a mixture of multivariate Gaussian density functions: the mean vectors $\{\hat{\mu}_k\}$, the weights $\{\hat{\alpha}_k\}$, and the covariance matrix $\{\hat{\Sigma}_k\}$ of each sub-class, and the number $\hat{K}$ of sub-classes.

The advanced EM method used in the proposed active contour model estimates the output values through an iterative process consisting of four steps: expectation (E-step), maximization (M-step), evaluation, and annihilation. At the initialization stage, the number of sub-classes is initialized as $K_{max}$. The three other parameters, $\{\hat{\alpha}_k\}, \{\hat{\mu}_k\}, \{\hat{\Sigma}_k\}$, are also initialized as appropriate values. During E-step, the expected posterior probabilities of the given data samples based on the current status of parameters $[\hat{\alpha}_k, \hat{\mu}_k, \hat{\Sigma}_k]$ are estimated and updated for each sub-class $k$. During M-step, four output parameters, $[\hat{K}, \{\hat{\alpha}_k\}, \{\hat{\mu}_k\}, \{\hat{\Sigma}_k\}]$, are estimated. Function eliminate($\cdot$) eliminates the sub-class with zero weight $\hat{\alpha}_k = 0$, adjusts the number of sub-classes $\hat{K} = \hat{K} - 1$, and rearranges the parameters of remained sub-classes. During the evaluation step, we check the value of metric function $\mathcal{L}$, and stop the iteration if $\mathcal{L}(t)$ has converged. During the annihilation step, we eliminate the sub-class with the lowest weight.
10.4 Experiments

In this section, we apply the proposed segmentation method to three different images, and compare the results of the proposed method to the results of other active contour models. The same
region-based active contour models used in the last two chapters were used as benchmarks. All three methods including the proposed method preform the segmentation based on the statistical property of image intensity measured within a subset. Method 1 and 2 are unsupervised methods, while the proposed method determines the statistical information from training samples. The experiments of all three methods use the same pre-defined initial contours. The detail of mathematical and analytical descriptions of both benchmarks methods are presented in section 3.4.

Figure 10.1 shows an example of synthetic gray images with textures. There is a small rectangle in figure 10.1(a), and both the rectangle and the background have their own texture pattern. The object of this experiment is to separate the rectangle from the background. Figure 10.1(b) shows the ground truth of the given image. The dark part presents the background, class 1, while the bright part presents the rectangle, class 2.

Figure 10.2 shows the result of method 1 applied on figure 10.1. Figure 10.2(a) shows the final stage of contour evolution, and figure 10.2(b) shows the corresponding segmentation result.
Method 1 produces extremely many artifacts on both the background and the rectangle because of the complicated texture patterns. Method 1 partitions the image into dark sub-regions and bright sub-regions, but they are not equivalent to the two texture patterns.

Figure 10.3 shows the result of method 2 applied on figure 10.1. Figure 10.3(a) shows the final stage of contour evolution, and figure 10.3(b) shows the corresponding segmentation result. Method 2 does not show many artifacts on the background, but cannot extract the shape of the rectangle. Figure 10.2 and 10.3 show that the performance of unsupervised segmentation methods is limited if the image has non-uniform subsets and different subsets show similar image intensities.

We applied the proposed supervised segmentation method on the same image. Figure 9.7 shows the training samples used for the proposed method. Two reference images of the texture patterns are given as training samples. Figure 10.4(a) shows the training samples for the background, and figure 10.4(b) shows the training samples for the rectangle. The proposed
method estimates the PDF of both images as a mixture of Gaussian density functions, and assign them as the conditional PDF of image intensity for each subset. Figure 10.5 shows the result of the proposed method. Figure 10.5(a) shows the final stage of contour evolution, and

![Figure 10.5: Proposed method applied to a synthetic textured image: (a) the final stage of contour evolution, (b) the segmented subsets](image)

figure 10.5(b) shows the corresponding segmentation result. The proposed method successfully separates the rectangle from the background without any significant artifact.

For more precise comparison, the statistical distribution of image intensity within both the background and the rectangle are measured. Figure 10.6 shows the statistical distribution of image intensity within class 1, which is supposed to be the background in the segmentation result. Figure 10.6(a), 10.6(b), and 10.6(c) respectively present the results of method 1, method 2, and the proposed method. The blue solid lines of all three graphs present the statistical distribution of image intensity measured at the background, which is a mixture of at least three sub-classes. The green solid lines of all three graphs present the same statistics measured within class 1 in the segmentation results. As the green solid line exists closer to the blue solid line, it presents better result. In figure 10.6(a), the dotted red line with a circle presents the representation of the subset used in method 1, i.e. the mean of green solid line. The measured statistics is very different from the ground truth because the constant representation is not sufficient to represent the non-uniform sub-region consisting of many sub-classes. In figure 10.6(b), the dotted red line presents the representation of the subset used in method 2, i.e. the Gaussian density function of image intensity measured. The measured statistics is similar to the ground truth though the representation is quite different from the true statistics. In figure 10.6(c), the dotted red line presents the estimated parametric mixture density function from training samples. The estimated density function is very similar to the true statistics, and the measured statistics is almost identical to the ground truth. Figure 9.10 shows the same measure for class 2, the rectangle. Although the ground truth looks like a simple Gaussian distribution, neither method 1 or 2 can produce reasonable results, as shown in figure 10.7(a) and 10.7(b), because the non-uniform statistics in the other subset was too complicated for them. In figure 10.7(c), the proposed method estimates very accurate statistics from training samples, and it leads to a very successful segmentation result.

Figure 10.8 shows an example of outdoor gray images with texture. There is a zebra stand-
The zebra consists of white and black stripes, while the background is uniformly gray. The object of this experiment is to extract the shape of zebra from the background. This is a difficult segmentation problem because of the complicated patterns of the zebra and the shade under the zebra. The white stripes of zebra are brighter than the background, while the black stripes of zebra are darker than the background. Also, some portions of zebras, e.g. white stripes under the shade, have similar intensity to the background. The shade under the zebra is as dark as the black stripes though it is not part of the zebra. The statistical distribution of image intensity within the zebra must be represented as a mixture of more than at least two sub-classes.

Figure 10.9 shows the result of method 1 applied on figure 10.8. Figure 10.9(a) shows the final stage of contour evolution, and figure 10.9(b) shows the corresponding segmentation result. Method 1 separates the zebra into two parts, i.e. bright sub-regions and dark sub-regions, but identifies the bright sub-regions of the zebra as the background.

Figure 10.10 shows the result of method 2 applied on figure 10.8. Figure 10.10(a) shows the final stage of contour evolution, and figure 10.10(b) shows the corresponding segmentation result. Although method 2 produces better segmentation result than method 1, there are still many artifacts on both zebras and background. The sub-regions of zebras whose intensity is similar to the background are identified as background, i.e. the white subset, while the sub-regions of background whose intensity is darker than the other parts of background are
Figure 10.7: Statistical distribution of image intensity within the small rectangle: (a) method 1, (b) method 2, (c) proposed method

Figure 10.8: A complicated outdoor image: (a) a zebra, (b) the ground truth image identified as zebras, i.e. the black subset.

Figure 10.11 shows the training stage of the proposed segmentation method. We used the same image as the training samples for this experiment. The yellow rectangles indicate the regions used as training samples. The statistical distribution of image intensity within those sampled regions \( \{ p(I \mid I \in I_i) \} \) is estimated as a mixture of Gaussian density functions, and assigned as the conditional PDF of image intensity as the background \( p(I(x, y))(x, y) \in \Omega_1 \) and the zebra \( p(I(x, y))(x, y) \in \Omega_2 \). Figure 10.12(a) shows the final stage of contour evolution, and figure 10.12(b) shows the corresponding segmentation result. Although there are still a few artifacts on the zebra, the number has been significantly reduced. There are no artifacts in the
Figure 10.9: Method 1 applied to a complicated outdoor image: (a) the final stage of contour evolution, (b) the segmented subsets

Figure 10.10: Method 2 applied to a complicated outdoor image: (a) the final stage of contour evolution, (b) the segmented subsets

Figure 10.11: Training stage of the proposed method: (a) training samples for background, (b) training samples for the zebra

background. The artifacts found within the zebra appear because the image intensity of those sub-regions is identical to the background. This experiment shows how robust the proposed method using mixture density functions is compared to traditional methods using unimodal density functions, and it also shows the limitation of the image segmentation method based on image intensity as it cannot separate two objects with identical image intensities.
Figure 10.12: Proposed method applied to a complicated outdoor image: (a) the final stage of contour evolution, (b) the segmented subsets

Figure 10.13 shows an example of applications using the proposed method on indoor RGB images. The object of this experiment is to simulate ATR problems with real RGB images instead of synthetic images. We measure training samples from a reference image, and apply the proposed method with the training samples into other images taken under different light condition and angle. We applied them into the images with even unknown objects. Figure 10.13(a) shows the reference image. There is a toy tank on the carpet, and the carpet has a wool pattern. This image simulates a miniature version of a tank on the grass field. Figure 10.13(b) and 10.13(c) show the two test images. The reference image figure 10.13(a) is taken from directly above the target simulating a view from satellite or high-altitude reconnaissance flight, while the first test image figure 10.13(b) is taken from a diagonal view and the focus is little bit blurred simulating a view from a missile or a jet fighter. The second test image figure 10.13(c) shows another target, a humvee, as well as the tank shown in the reference image. There is also
a gray painted vehicle in the figure 10.13(c), which simulates a non-target object. This is the most difficult problem among the experiments shown in this document because the reference image and test images were taken from different views, and we do not have information for all objects appeared in the test images, i.e. the humvee and the gray painted vehicle.

Figure 10.11 shows the training stage of the proposed segmentation method. We obtain some training samples from the reference image. The yellow rectangles indicate the regions used as training samples. The statistical distribution of image intensity within those sampled regions \( \{ p(I_I I_I \in I_I) \} \) is estimated as a mixture of multivariate Gaussian density functions, and assigned as the conditional PDF of image intensity as the background \( p(I(x, y) | (x, y) \in \Omega_1) \) and the target \( p(I(x, y) | (x, y) \in \Omega_2) \).

Figure 10.15 shows the result of the proposed method applied on figure 10.13(b). Figure 10.15(a) shows the final stage of contour evolution, and figure 10.16(b) shows the corresponding segmentation result. The object of this experiment is to extract the shape of the tank from the background, and the proposed method produces a reasonable result. Although there are a few small artifacts on the result, a smarter choice of training samples may solve the problem.
Figure 10.16 shows the result of the proposed method applied on figure 10.13(c). Figure 10.16(a) shows the final stage of contour evolution, and figure 10.16(b) shows the corresponding segmentation result. The object of this experiment is to extract the shape of the tank and the humvee, but to ignore the non-target object, i.e. the gray painted car. There was no such information on the non-target object in the reference image. The proposed method successfully extracts the shape of the tank and the humvee, while it ignores the non-target object. There is an artifact on the hood of the humvee because the white star did not appear in the reference image. The segmentation result is little bit affected by shading and different light condition. The shadows of the gray painted vehicle are recognized as targets, and a bright portion of the tank is recognized as the background. This experiment shows the potential use of the proposed method in real ATR problems and the possible problems that should be improved by future research.
Chapter 11

Improvements in Unsupervised Active Contour Model using an Expanded Feature Space

In this chapter, we propose some improvements over the unsupervised image segmentation method using Multi-dimensional Histograms introduced in chapter 8. The feature space is expanded to include 3 more features apart from image intensity. These are then non-linearly diffused before using them to measure a PDF expression for each subset in the image at each iteration and update the level set function. Section 11.1 discusses feature extraction procedure to compute the new expanded set of features. Section 11.2 discusses the PDF modeling of the new feature set for improved unsupervised image segmentation. Section 11.3 shows the numerical algorithm and section 11.4 shows results on some real images.

11.1 Feature Extraction

The proposed improvement is based on expanding the feature set to include features from the modified classical structure tensor as proposed in Rousson and Derichel [164]. The classical structure tensor is defined below:

\[ J_\rho = K_\rho * (\nabla I \nabla I^T) = \begin{pmatrix} K_\rho * I_x^2 & K_\rho * I_x I_y \\ K_\rho * I_x I_y & K_\rho * I_y^2 \end{pmatrix} \] (11.1)

where \( K_\rho \) is a Gaussian kernel with standard deviation \( \rho \) and the subscripts denote partial derivatives of the image. We replace the convolution with the Gaussian kernel with non-linear diffusion as proposed in [164]. Using a Gaussian kernel results in the smoothing of the edges and thus, leads to inaccurate segmentation near the boundaries. Non-linear diffusion avoids the problem by reducing the smoothening near the edges.

Thus, our feature space is given by the non-linearly diffused version of:

\[ u = \begin{bmatrix} I & I_x^2 & I_y^2 & I_x I_y \end{bmatrix}^T \] (11.2)

Note that \( u \) is a vector valued image.

We use the vector valued non-linear diffusion scheme as proposed in [164],

\[ \partial_t u_i = div \left( g(\sum_{k=1}^{N} |\nabla u_k|^2) \nabla u_i \right) \quad \forall i \] (11.3)
All the channels are coupled in the diffusivity function \( g(s) \). Therefore, an edge in one channel inhibits smoothing in the others. The diffusivity function \( g(s) \) is defined as:

\[
g(s) = \frac{1}{s + \epsilon}
\]  

(11.4)

where \( \epsilon \) is a small constant to avoid division by zero.

### 11.2 Probability Density Estimation

The probability density function for the contour evolution is estimated using the expanded feature set rather than just the multi-dimensional histogram of the image intensity. The four feature vectors are assumed to be independent of each other. The feature vector \( I \) is estimated using a multi-dimensional histogram as proposed in chapter 8.

The other 3 feature vectors are approximated as a multidimensional-Gaussian distribution with parameters \( \{ \mu_i, \Sigma_i \} \) for each subset \( \Omega_i \) of the image. These are updated at every iteration during the evolution of the contour as follows:

\[
\begin{align*}
\mu_i &= \frac{\int_{\Omega} u(x) \chi_i dx}{\int_{\Omega} \chi_i dx} \\
\Sigma_i &= \frac{\int_{\Omega} (u(x) - \mu_i)(u(x) - \mu_i)^T \chi_i dx}{\int_{\Omega} \chi_i dx}
\end{align*}
\]  

(11.5)

where \( \chi_i \) is the binary identity function defined in chapter 7.

Note that the Covariance matrix \( \Sigma_i \) is diagonal because of the independence of each feature channel.

The total probability density function for each subset of the image \( \Omega_i \) is then estimated as follows:

\[
p_i(u(x)) = \prod_{k=1}^{4} p_i(u_k(x))
\]  

(11.6)

The proposed method uses the same global energy minimization scheme as proposed in chapter 8. The global energy function is given by:

\[
E(\{p_i\}, C) \equiv \sum_i \int_{\Omega_i} e(x, y|p_i)dx dy + \nu|C|,
\]  

(11.7)

and the global energy \( E \) is minimized with respect to two expressions: \( \{p_i\} \), i.e. the statistical representation of the image within a subset \( \Omega_i \), and the variational contours \( C \). First, the minimum \( E \) with respect to \( \{p_i\} \) is achieved while \( C \) is fixed. Then, the minimum \( E \) with respect to \( C \) is achieved while \( \{p_i\} \) are fixed. An objective function

\[
e(x, y|p_i) = -\log p_i, \quad \forall (x, y) \in \Omega_i
\]  

(11.8)

determines the region-based segmentation criteria. The probability density function \( p_i \) for each subset \( \Omega_i \) is estimated by using equation 11.6.
11.3 Algorithm

The contour evolution algorithm is similar to the one proposed in chapter 8. There are however, some differences. One is the feature extraction step and the other is in the computation of the objective function. Table 11.1 shows the input and output variables used in the algorithm and the modified algorithm is shown in algorithm 7.

Table 11.1: The input and output variables used in the unsupervised image segmentation with the expanded feature space

Because of the expanded feature, the probability density is estimated by a Multi-dimensional Histogram for feature \( u_1 \) which is the diffused version of the image intensity \( I \). The other features approximated by Gaussian distribution.
Algorithm 7: Unsupervised Active Contour Model using and Expanded Feature Space

Initialization
\[ t = 0. \]
\[ u = \text{FeatureExtract}(I(x, y)) \]
for \( j = 1 \cdots J \) do
\[ C_j(x(s), y(s), t = 0) \): Initialize contours.
\[ \phi_j(x, y, t = 0) = \pm D((x, y), N_{(x,y)}(C_j)) \): Initialize level set functions.

Contour evolution
repeat
for \( j = 1 \cdots J \) do
\[ \kappa_j(x, y) = \text{meanCurvature}(\phi_j(x, y)) \]
\[ H_j(x, y) = \text{unitStep}(\phi_j(x, y)) \]

Unsupervised region-based segmentation
for \( i = 1 \cdots 2^J \) do
\[ \chi_i(x, y) = \text{identityFunction}([H_j(x, y), \forall j]) \]
\[ p_i = \text{histogramDensity}(u_1(x, y) \chi_i(x, y)) \]
for \( k = 2 \cdots 4 \) do
\[ \mu_{i,k} = \text{mean}(u_k, \chi_i(x, y)) \]
\[ \Sigma_{i,k} = \text{Variance}(u_k, \chi_i(x, y)) \]
\[ e_i(x, y) = -\log p_i \]

Update level set function
for \( j = 1 \cdots J \) do
\[ \phi_j(x, y) = \phi_j(x, y) + \Delta t \delta(\phi_j(x, y)) \left[ \nu \kappa(\phi_j(x, y)) - \sum_{i=1}^{2^J} e_i(x, y) \frac{\partial \chi_i}{\partial H_j} \right] \]
\[ t = t + \Delta t \]
until until the evolution of contour converges

Segmentation result
\[ S(x, y) = \sum_{i=1}^{2^J} \chi_i(x, y) \]

Table 11.2 shows the input and output variables used in the feature extraction procedure and the actual algorithm is shown in algorithm 8.

The feature extraction procedure involves the computation of the image gradient. The gradients are then used to compute the feature channels \( (\mathbf{u}') \). \( \mathbf{u}' \) is finally, non-linearly diffused to obtain the desired feature vector(\( \mathbf{u} \)).
Algorithm 8: Feature Extraction

\[
[I_x, I_y] = \text{ComputeImageGradient}(I) \\
u' = [I, I_x^2, I_y^2, I_x I_y]^T \\
u = \text{NonLinearDiffusion}(u')
\]

11.4 Results

In this section, we apply the proposed method to the zebra image to highlight the significant improvements obtained over the method proposed in chapter 8.

Figure 11.1 shows the zebra image on which the proposed method was tested on. Feature extraction was performed on the above image by the algorithm proposed in section 11.1. Figure 11.2 shows the four feature channels obtained after feature extraction and non-linear diffusion. These form the feature vector \( u \).

Figure 11.1: The Zebra Test Image

Figure 11.2: The 4 smoothened feature channels \((I, I_x^2, I_y^2, I_x I_y)\)

Figure 11.3 shows the final stages of contour evolution.

As it can be seen, the proposed method successfully segments the zebra from the background. The results show a significant improvement over the previous methods. Furthermore, the new algorithm is unsupervised.
Thus, the expanded feature space coupled with the unsupervised segmentation algorithm proposed in chapter 8 overcomes the earlier drawback that it cannot separate objects with similar image intensities.

The current approach is, however, by no means complete and has been tested only on gray scale images. The proposed approach could be extended to multi-spectral images by future research.
Chapter 12

Conclusions

The proposed work has two main objects: robust image segmentation and the integration of image segmentation and pattern classification. Although image segmentation is a fundamental problem in image analysis, it has been difficult for traditional image segmentation methods to produce satisfying results on images with non-uniform sub-regions. We have developed robust image segmentation methods, which can produce good segmentation results on difficult image segmentation problems that traditional segmentation methods cannot produce reasonable results. In traditional image analysis, image segmentation performs a role of preprocessing for pattern classification providing the input data. We have integrated image segmentation and statistical pattern classification by using the statistical distribution of image intensity as the feature used in image segmentation. Thus, the proposed image segmentation methods produce the result of statistical pattern classification as well as image segmentation reducing the computation time and effort.

The proposed image segmentation methods use the framework of active contours. As active contours always provide continuous boundaries of sub-regions, they can produce more reasonable segmentation results than traditional segmentation methods, and consequently improve the final results of image analysis. The mathematical implementation of the proposed active contour models is accomplished using level set method. By presenting contours as a level of a topological function, we can merge multiple contours into one contour, or can split a contour into multiple contours, providing a good flexibility in the use of active contours.

Traditional image segmentation methods partition an image based on either discontinuity between sub-regions or uniformity within a sub-region of a desired feature, e.g. image intensity, texture. Instead of a simple feature, the proposed image segmentation methods use the statistical distribution of image intensity within a sub-region, in a form of conditional probability density functions, as the feature to determine the segmentation criteria. Since the segmentation criteria are determined by the statistics of large samples rather than a single image intensity at a pixel, the proposed image segmentation methods show robust performance on images with noise. The proposed image segmentation methods partition an image in two ways: unsupervised or supervised. The unsupervised method partitions an image based on the uniformity of the feature within a sub-region. The supervised method partitions an image based on the similarity of the feature within a sub-region to the feature provided from corresponding training samples. The unique character of the proposed methods, which helps them to outperform traditional methods, is the use of a mixture density function to represent the statistical distribution.
of image intensity within a subset. As the segmentation criteria is determined by a mixture of sub-probability density functions instead of a probability density function, the proposed methods are able to recognize subsets with non-uniform (multimodal) image intensity, such as zebras. For multispectral images, we use a mixture of multivariate density functions instead of a product of marginal mixture density functions to represent the statistics of complicated patterns. These methods recognize extremely non-uniform vector-valued image intensities, such as military camouflage patterns, very well.

As the application of the proposed segmentation principle, three image segmentation methods are proposed. First, we represent the statistics of image intensities within each subset during the contour evolution in a form of multi-dimensional histograms. The use of a non-parametric discrete function provides an improved segmentation results compared to traditional segmentation methods based on particular stochastic model because the statistics of image intensity can be hardly represented as a simple stochastic model. Second, we represent the same statistics as a mixture of multivariate Gaussian density functions during the contour evolution, using a prior knowledge provided from training samples. The use of supervised mixture density functions provides significant improvements on segmentation and classification results because proposed method can recognize extremely non-uniform subsets. This method provides reasonable results even on the images that the previous method cannot segment well. Third, instead of computing the statistics of image intensity during contour evolution, we compute the statistics of corresponding training samples in advance before image segmentation, and assign the pre-computed statistics as the conditional PDF of image intensities for each subset during image segmentation. This method provides reasonable results even on images that the two previous proposed methods cannot segment well. The Unsupervised method was further improved by expanding the feature space to include the image gradients. Non-linear diffusion was used to smoothen the feature vector and then used to evolve the contour. This method produces even better results than the previous three methods. The biggest advantage of this method is that it is unsupervised. However, the method has been tested only on grey scale images given the time. Future work would be extending this method to multi-spectral images.

In order to show the improved performance of the proposed methods, we have applied them to images that other segmentation methods cannot properly segment. As benchmarks, the segmentation results of proposed methods and the results of two more traditional active contour models, which share similar segmentation criteria, are compared. The proposed methods have shown very promising results outperforming the reference methods.

Although the proposed methods produce very robust and promising results, there are still a few aspects could be improved. Since the proposed methods represent the statistical distribution of image intensity in a complicated form, i.e. a mixture of multivariate density functions, the required computation is relatively larger than traditional methods increasing the convergence time. The fast advance of computer processor may solve this problem. Since supervised methods extract information from training samples, the performance may rely on the quality of training samples. A smart choice of training samples may reduce the effect of this problem.

The expanded feature space provides a significant improvement in performance. However, this method was not explored in detail given the time and can be the basis for future work.
