Abstract

This paper presents multi-conditional learning (MCL), a training criterion based on a product of multiple conditional likelihoods. When combining the traditional conditional probability of “label given input” with a generative probability of “input given label,” the later acts as a surprisingly effective regularizer. When applied to models with latent variables, MCL combines the structure-discovery capabilities of generative topic models, such as latent Dirichlet allocation and the exponential family harmonium, with the accuracy and robustness of discriminative classifiers, such as logistic regression and conditional random fields. We present results on several standard data sets showing significant reductions in classification error due to MCL regularization, and substantial gains in precision and recall due to the latent structure discovered under MCL.

Introduction

Conditional-probability training, in the form of maximum entropy classifiers (Berger et al., 1996) and conditional random fields (CRFs) (Lafferty et al., 2001; Sutton & McCallum, 2006), has had dramatic and growing impact on natural language processing, information retrieval, computer vision, bioinformatics, and other related fields. However, discriminative models tend to overfit the training data, and a prior on parameters typically provides limited relief. In fact, it has been shown that in some cases generative naïve Bayes classifiers provide higher accuracy than conditional maximum entropy classifiers (Ng & Jordan, 2002). We thus consider alternative training criteria with reduced reliance on parameter priors, which also combine generative and discriminative learning.

This paper presents multi-conditional learning, a family of parameter estimation objective functions based on a product of multiple conditional likelihoods. In one configuration of this approach, the objective function is the (weighted) product of the “discriminative” probability of label given input, and the “generative” probability of the input given label. The former aims to find a good decision boundary, the later aims to model the density of the input, and the single set of parameters in our naïve-Bayes-structured model thus strives for both. All regularizers provide some additional constraints on parameter estimation. Our experimental results on a variety of standard text data sets show that this density-estimation constraint is a more effective regularizer than “shrinkage toward zero,” which is the basis of traditional regularizers, such as the Gaussian prior—reducing error by nearly 50% in some cases. As well as improving accuracy, the inclusion of a density estimation criterion helps improve confidence prediction.

In addition to simple conditional models, there has been growing interest in conditionally-trained models with latent variables (Jебara & Pentland, 1998; McCallum et al., 2005; Quattoni et al., 2004). Simultaneously there is immense interest in generative “topic models,” such as latent Dirichlet allocation, and its progeny, as well as their directed analogues, including the harmonium models (Welling et al., 2005; Xing et al., 2005; Smolensky, 1986).

In this paper we also demonstrate multi-conditional learning applied to latent-variable models. MCL discovers a latent space projection that captures not only the co-occurrence of features in input (as in generative models), but also provides the ability to accurately predict designated outputs (as in discriminative models). We find that MCL is more robust than the conditional criterion alone, while also being more purposeful than generative latent variable models. On the document retrieval task introduced in Welling et al. (2005), we find that MCL more than doubles precision and recall in comparison with the generative harmonium.

In latent variable models, MCL can be seen as a form of semi-supervised clustering—with the flexibility to operate on relational, structured, CRF-like models in a principled way. MCL here aims to combine the strengths of CRFs (handling auto-correlation and non-independent input features in making predictions), with the strengths of topic models (discovering co-occurrence patterns and useful latent projections). This paper sets the stage for various interesting future work in multi-conditional learning. Many configurations of multi-conditional learning are possible, including ones with more than two conditional probabilities. For example, transfer learning could naturally be configured as the product of conditional probabilities for the labels of each task, with some latent variables and parameters shared. Semi-supervised learning could be configured as the product of conditional probabilities for predicting the label, as well as predicting each input given the others. These configurations are the subject of ongoing work.
Multi-Conditional Learning: Generative/Discriminative Training for Clustering and Classification
Multi-Conditional Learning and MRFs

In the following exposition we first present the general framework of multi-conditional learning. We then derive the equations used for multi-conditional learning in several structured Markov Random Field (MRF) models. We introduce discrete hidden (sub-class) variables into naïve MRF models, creating multi-conditional mixtures, and discuss how multi-conditional methods are derived. We then construct binary word occurrence models coupled with hidden continuous variables, as in the exponential family harmonic, demonstrating the advantages of multi-conditional learning for these models also.

The MCL Framework

Consider a data set consisting of \( i = 1, \ldots, N \) instances. We will construct probabilistic models consisting of discrete observed random variables \( \{ x \} \), discrete hidden variables \( \{ z \} \) and continuous hidden variables \( z \). Denote an outcome of a random variable as \( \tilde{x} \). Define \( j = 1, \ldots, N_y \) pairs of disjoint subsets of observations \( \{ \tilde{x}_A \}_j \) and \( \{ \tilde{x}_B \}_j \), where our indices denote the \( i \)th instance of the variables subset \( j \). We will construct a multi-conditional objective by taking the product of different conditional probabilities involving these subsets and we will use \( \alpha_i \) to weight the contributions of the different conditionals. Using these definitions the optimal parameter settings under our multi-conditional criterion are given by

\[
\arg\max_{\theta} \prod_{i,j} \sum_{\{x\}, \{z\}} P(\{\tilde{x}_A\}_i, \{z\}_i, \{\tilde{x}_B\}_j, \theta) \alpha_i d_{ij},
\]

where we derive these marginal conditional likelihoods from a single underlying joint probability model with parameters \( \theta \). Our underlying joint probability model may itself be normalized locally, globally or using some combination of the two.

For the experiments in this paper we will partition observed variables into a set of “labels” \( y \) and a set of “features” \( x \). We define two pairs of subsets: \( \{ x_A, x_B \}_1 = \{ y, x \} \) and \( \{ x_A, x_B \}_2 = \{ x, y \} \). We then construct multi-conditional objective functions \( L_{MC} \) with the following form

\[
L_{MC} = \log \left( P(y|x)^{\alpha} \right) - \alpha \log \left( P(x|y) \right) + \beta \log \left( P_x|y \right).
\]

In this configuration one can think of our objective as having a generative component \( P(x|y) \) and a discriminative component \( P(y|x) \). Another attractive definition using two pairs is: \( \{ x_A, x_B \}_1 = \{ y, x \} \) and \( \{ x_A, x_B \}_2 = \{ x, \theta \} \), giving rise to objectives of the following form

\[
L = \log(P(y|x)^{\alpha} P(x|y)^{\beta}),
\]

which represents a way of restructuring a joint likelihood to concentrate modeling power on a conditional distribution of interest. This objective is similar to the approach advocated in Minka (2005).

Naïve MRFs for Documents

The graphical descriptions of the naïve Bayes model for text documents (Nigam et al., 2000) and the multinomial logistic regression or maximum entropy (Berger et al., 1996) model can be written with similar naïve graphical structures. Here we consider naïve MRFs which can also be represented by a similar graphical structure but define a joint distribution in terms of unnormalized potential functions.

Consider data \( D = \{ (\tilde{y}_n, \tilde{x}_{j,n}) : n = 1, \ldots, N, j = 1 \ldots M_n \} \) where there are \( N \) instances and within each instance there are \( M_n \) realizations of discrete random variables \( \{ x \} \). We will use \( y_n \) to denote a single discrete random variable for a class label. Model parameters are denoted by \( \theta \).

For a collection of \( N \) documents we thus have \( M_n \) word events for each document. The joint distribution of the data can be modeled using a set of naïve MRFs, one for each observation such that

\[
P(x_1, \ldots, x_{M_n}, y|\theta) = \frac{1}{Z} \phi(y|\theta) \prod_{j=1}^{M_n} \phi(x_j, y|x_{\theta,y})
\]

where

\[
Z = \sum_y \sum_{x_1} \ldots \sum_{x_{M_n}} \phi(y|\theta) \prod_{j=1}^{M_n} \phi(x_j, y|x_{\theta,y}).
\]

If we define potential functions \( \phi(\cdot) \) to consist of exponentiated linear functions of multinomial variables (sparse vectors with a single 1 in one of the dimensions), \( y \) for labels and \( w_j \) for each word, a naïve MRF can be written as

\[
P(y, \{ w \}) = \frac{1}{Z} \exp \left( \sum_{j=1}^{M_n} \phi(y|\theta) \prod_{j=1}^{M_n} \phi(x_j, y|x_{\theta,y}) \right).
\]

To simplify our presentation, consider now combining our multinomial word variables \( \{ w \} \) such that \( x = \sum_{j=1}^{M_n} w_j \). One can also combine \( \theta_y \) and \( \theta_{x,y} \) into \( \theta \) such that

\[
P(y, x) = \frac{1}{Z} \exp(y^T \theta^T x)
\]

Under this model, to optimize \( L_{MC} \) from (2) we have

\[
P(y|x) = \frac{\exp(y^T \theta^T x)}{\sum_y \exp(y^T \theta^T x)} \quad \text{and} \quad P(x|y) = \frac{\exp(y^T \theta^T x)}{Z(y)}
\]

where

\[
Z(y) = \sum_{w_1} \ldots \sum_{w_{M_n}} \prod_{j=1}^{M_n} \exp(y^T \theta_{w_j}^T \theta_{x,y}) \exp(y^T \theta_y).
\]

The gradients of the log conditional likelihoods contained in our objective can then be computed using:

\[
\nabla L_{y|x} = \sum_{n=1}^{N} \left( x_n y_n^T - \sum_y \frac{\exp(y^T \theta^T x_n) y_n^T x_n^T}{\sum_y \exp(y^T \theta^T x_n^T)} \right)
\]

\[
= N \left( (xy^T) \tilde{P}(y|x) - \langle (xy^T) \tilde{P}(y|x) \rangle \tilde{P}(x) \right)
\]

where \( \langle \cdot \rangle \) denotes the expectation with respect to distribution \( P(x) \) and we use \( \tilde{P}(x) \) to denote the empirical distribution of the data, the distribution obtained placing a delta
function on each data point and normalized by \( N \). To compute \( \nabla L_{x|y}(\theta_{x,y}) \), we observe that
\[
P(x|y) = \prod_{j=1}^{M_n} P(w_j|y) = \prod_{j=1}^{M_n} \left( \frac{\exp(y^T \theta_{x,y}^T w_j)}{\sum_{w_j} \exp(y^T \theta_{x,y}^T w_j)} \right),
\]
and therefore
\[
\nabla L_{x|y}(\theta_{x,y}) = \sum_{y=1}^{N} \sum_{j=1}^{M_n} \left( \tilde{w}_{j,n} y_n^T \tilde{\theta}_{x,y}^T - \sum_{y=1}^{N} \tilde{w}_{j,n} y_n^T P(w_j|y) \right).
\]

### Mixtures of Naïve MRFs

We can extend the basic naïve MRF model shown in Figure 1 (Left) by adding a hidden subclass variable as illustrated (Right). In a mixture of naïve MRFs the joint distribution of the data for each observation can be modeled using
\[
P\{x\}, y, z|\theta = \frac{1}{2} \phi(y|\theta_y) \phi(y, z|\theta_{y,z}) \prod_{j=1}^{M_n} \phi(x_j, z|x, z),
\]
where the \( \phi(y, z|\theta_{y,z}) \) potential encodes a sparse compatibility function relating labels or classes to a subset of states of the hidden discrete variable \( z \).

To optimize a mixture of naïve MRFs, we use the expected gradient algorithm (Salakhutdinov et al., 2003). In this model we can compute the gradient of the complete log likelihood and this gradient decomposes with respect to our expectation such that the following computation can be efficiently performed,
\[
\nabla L_{x|y}(\theta) = \frac{\partial}{\partial \theta} \ln P\{x\}|y; \theta) = \sum_{z} P(z|\{x\}, y; \theta) \frac{\partial}{\partial \theta} \ln P\{\{x\}, z|y; \theta\}.
\]

For example, the gradient for the “weights” \( \theta_{x,z} \), comprising the elements of the potential function parameters \( \theta_{x,z} \) are computed from
\[
\frac{\partial L_{x|y}(\theta)}{\partial \theta_{x,z}} = \sum_{n=1}^{N} \sum_{j=1}^{M_n} \left[ \sum_{z} P(z_n|\{\tilde{x}\}_n, \tilde{y}_n; \theta) f_{x,z}(\tilde{x}_j, z_n) \right.
\]
\[
- \sum_{z} P(\{x\}_n, z_n|\tilde{y}_n; \theta) f_{x,z}(x_j, z_n, z_n) \left. \right],
\]
where \( f_{x,z}(x, z) \) are binary feature functions evaluating to one when the state of \( x = x_e \) and the state of \( z = z_s \). The updates for the potentials function parameters using \( \hat{L}_{y|x} \) take a form similar to the standard “maximum entropy” gradient computations, augmented with a hidden variable. We term mixture models trained using multi-conditional learning multi-conditional mixtures (MCM).

### Harmonium Structured Models

A harmonium model (Smolensky, 1986) is a two layer Markov Random Field (MRF) consisting of observed variables and hidden variables. Like all MRFs, the model we present here will be defined in terms of a globally normalized product of (unnormalized) potential functions defined upon subsets of variables. A harmonium can also be described as a type of restricted Boltzmann machine (Hinton, 2002). In the following we present a new type of exponential family multi-attribute harmonium, extending the models used in Welling et al. (2005) and the dual-wing harmonium work of Xing et al. (2005).

Our exponential family harmonium structured model can be written as
\[
P(x, z|\Theta) = \exp \left\{ \sum_{i} \theta_{i} f_i(x_i) + \sum_{j} \theta_{i} f_j(z_j) \right. \]
\[
+ \sum_{i} \sum_{j} \theta_{ij} f_{ij}(x_i, z_j) - A(\Theta) \right\},
\]
where \( z \) is a vector of continuous valued hidden variables, \( x \) is a vector of observations, \( \Theta \) represents parameter vectors (or weights), \( \theta_{ij} \) represents a parameter vector on a cross product of states, \( f \) denotes feature functions, \( \Theta = \{ \theta_{ij}, \theta_{i}, \theta_{j} \} \) is the set of all parameters and \( A \) is the log-partition function or normalization constant. A harmonium model factorizes the third term of (16) into \( \theta_{ij} f_{ij}(x_i, z_j) \) = \( f_i(x_i)^T \theta_{ij} f_j(z_j) \), where \( \theta_{ij} \) is a parameter matrix with dimensions \( a \times b \), i.e., with rows equal to the number of states of \( f_i(x_i) \) and columns equal to the number of states of \( f_j(z_j) \). In the models we construct here we will use binary word occurrence vectors that have dimension \( M_n \), the size of our vocabulary. This is in contrast to our models in the previous section where we had a different number of discrete word events \( M_n \) for each document \( n \). We will denote one of the observed input variables \( x_d \) as a discrete label denoted as \( y \) in Figure 2.

Figure 2 illustrates a multi-attribute harmonium model as a factor graph. A harmonium represents the factorization of a joint distribution for observed and hidden variables using
a globally normalized product of local functions. In our experiments here we shall use the harmonium’s factorization structure to define an MRF and we will then define sets of marginal conditionals distributions of some observed variables given others that are of particular interest so as to form our multi-conditional objective.

Importantly, using a globally normalized joint distribution with this construction it is also possible to derive two consistent conditional models, one for hidden variables given observed variables and one for observed variables given hidden variables (Welling et al., 2005). The conditional distributions defined by these models can also be used to implement sampling schemes for various probabilities in the underlying joint model. However, it is important to remember that the original model parameterization is not defined in terms of these conditional distributions. In our experiments below we use a joint model with a form defined by (16) with $W^T = [W_b^T W_d^T]$ such that the (exponential family) conditional distributions consistent with the joint model are

$$P(z_n|x) = N(z_n; \mu, \Sigma), \quad \mu = \mu + W^T \hat{x} \quad (17)$$

$$P(x_b|z) = \mathcal{B}(x_b; \theta_b), \quad \theta_b = \theta_b + W_b \hat{z} \quad (18)$$

$$P(x_d|z) = \mathcal{D}(x_d; \theta_d), \quad \theta_d = \theta_d + W_d \hat{z} \quad (19)$$

where $\mathcal{N}()$, $\mathcal{B}()$ and $\mathcal{D}()$ represent Normal, Bernoulli and Discrete distributions respectively. The following equation can be used to represent the marginal distribution of $x$,

$$P(x; \theta, \Lambda) = \exp \{ \theta^T x + x^T \Lambda x - A(\theta, \Lambda) \}, \quad (20)$$

where $\Lambda = \frac{1}{2} W W^T$ and $\theta$ combines $\theta_d$ and $\theta_b$. The labels for this model are the discrete random variable (i.e. $y = x_d$) and the features are the binary variables.

In an exponential family model with exponential function $F(x; \theta)$, it is easy to verify that the gradient of the log marginal likelihood $\log P(x)$ of the observed data $x$, can be expressed

$$\frac{\partial \mathcal{L}(\theta; x)}{\partial \theta} = N \left[ \left\langle \frac{\partial F(x; \theta)}{\partial \theta} \right\rangle_{P(x)} - \left\langle \frac{\partial F(x; \theta)}{\partial \theta} \right\rangle_{P(x; \theta)} \right], \quad (21)$$

where $\left\langle \cdot \right\rangle_{P(x)}$ denotes the expectation under the empirical distribution, $\left\langle \cdot \right\rangle_{P(x; \theta)}$ is an expectation under the models marginal distribution and $N$ is the number of data elements. We can thus compute the gradient of the log-likelihood with respect to the weight matrix $W$ using

$$\frac{\partial \mathcal{L}}{\partial W^T} = \frac{1}{N_s} \sum_{s=1}^{N_s} \left( W^T \tilde{x}_s \tilde{x}_s^T - \frac{1}{N_s} \sum_{j=1}^{N_s} W^T \tilde{x}_{s(j)} \tilde{x}_{s(j)}^T \right), \quad (22)$$

where $N_d$ are the number of vectors of observed data, $\tilde{x}_{s(j)}$ are samples indexed by $j$ and $N_s$ are the number of samples used per data vector, computed using Gibbs sampling with conditionals (17), (18) and (19). In our experiments here we have found it possible to use either one or a small number of Markov Chain Monte Carlo (MCMC) (Andrieu et al., 2003) steps initialized from the data vector (the contrastive divergence approach (Hinton, 2002)). Standard MCMC approximations for expectations are also possible. We use straightforward gradient-based optimization for model parameters with a learning rate and a momentum term. Finally, for conditional likelihood and multi-conditional likelihood based learning, gradient values can be obtained from

$$\frac{\partial \mathcal{L}_{MC}}{\partial \theta} = N \left[ (\alpha + \beta) \left\langle \left\langle \frac{\partial F(x_s, x_d; \theta)}{\partial \theta} \right\rangle_{P(x_s, x_d)} \right\rangle_{P(x_s)} - \alpha \left\langle \left\langle \frac{\partial F(x_s, x_d; \theta)}{\partial \theta} \right\rangle_{P(x_s|x_d; \theta)} \right\rangle_{P(x_s)} \right] - \beta \left\langle \left\langle \frac{\partial F(x_s, x_d; \theta)}{\partial \theta} \right\rangle_{P(x_s,x_d; \theta)} \right\rangle_{P(x_d)}, \quad (23)$$

Relationships to Other Work

Theoretical and empirical results in Ng and Jordan (2002) have supported the notion that, while a discriminative model may have a lower asymptotic error (with more data), the error rate of classifications based on an analogous generative model can often approach an asymptotically higher error rate faster. Hybrids methods combining generative and discriminative methods are appealing in that they have the potential to draw upon the strengths of both approaches. For example, in Raina et al. (2003), a high dimensional subset of parameters are trained under a joint likelihood objective while another smaller subset of parameters are trained under a conditional likelihood objective. In contrast, in our approach all parameters are optimized under a number of conditional objectives.

In Corduneanu and Jaakkola (2003), a method characterized as information regularization is formulated for using information about the marginal density of unlabeled data to constrain an otherwise free conditional distribution. Their approach can be thought of as a method for penalizing decision boundaries that occur in areas of high marginal density. In terms of the regularization perspective, our multi-conditional approach uses additional or auxiliary conditional distributions derived from an underlying joint probability model as regularizers. Furthermore, our approach is defined within the context of an underlying joint model. It is our belief that these additional conditional distributions in our
The industry sector corpus is a collection of corporate webpages split into about 70 categories. We use the en-
viated as categorized test data set consists of 73,218 UseNet articles from four universities that are classified into
category: academic, real auto, and real aviation.

The results are presented in Table 1. The parenthesized values are the standard deviations of the test accuracy across
the cross validation folds. On 15 of 20 data sets, we show improvements over both maximum entropy and na¨ıve Bayes.
Although the differences in accuracy are small in some cases, the overall trend across data sets illustrates the potential
of MCL for regularization. In fact, the difference between the mean accuracy for maximum entropy and MCL
is larger than the difference between the mean accuracies of na¨ıve Bayes and maximum entropy. Across all data sets, the
mean MCL accuracy is significantly greater than the mean accuracy for maximum entropy and MCL.

We also find that in 10 of 15 data sets on which we also calculated the area under the accuracy/coverage curve, MCL
provided better confidence estimates.

Mixtures of Na¨ıve MRFs
In order to demonstrate the ability of multi-conditional mix-
tures to successfully classify data that is not linearly separ-
4
arable, we perform the following synthetic data experiments.
Four class labels are each associated with four 4-
dimensional Gaussians, having means and variances uni-
formly sampled between 0-100. Positions of data points
generated from the Gaussians are rounded to integer values.
For some samples of the Gaussian means and variances—
4
For example, an XOR configuration—a significant portion of the data
would be misclassified by the best linear separator.
MCMs, however, can learn and combine multiple linear de-
cision boundaries. A MCM with two hidden subclasses per class attains an accuracy of 75%, whereas na¨ıve Bayes,
maximum entropy, and non-mixture multi-conditional naïve
MRFs have accuracies of 54%, 52%, and 56%, respectively.

Running these MCMs on the talk data set yields “top-
ics” similar to latent Dirichlet allocation (LDA) (Blei et al.,
2003), except that parameter estimation is driven to discover
topics that not only re-generate the words, but also help pre-
dict the class label; (thus MCM can also be understood as a
“semi-supervised” topic model). Furthermore, MCM topics

Objective function can serve as a regularizer for the condi-
tional distributions we primarily care about, the probability of labels. As such, we weight the conditional distributions
differently in our objective.

With equal weighting of conditionals and an appropriate
definition of subsets of variables, the method can be seen
as a type of pseudo-likelihood (Besag, 1975). However, our
goals are quite different, in that we are not trying to approx-
imate a joint likelihood, but rather, we wish to explicitly op-
imize for the conditional distributions in our objective.

The mixtures of naïve MRFs we present resemble the multiple mixture components per class approach used in
Nigam et al. (2000). The conditional distributions arising
for our labels given our data are also related to mixtures of
experts (Jordan & Jacobs, 1994), conditional mixture mod-
els (Jebara & Pentland, 1998), simple mixtures of maximum
entropy models (Pavlov et al., 2002), and mixtures of condi-
tional random fields (McCallum et al., 2005; Quattoni et al.,
2004). The continuous latent variable model we present here
is similar to the dual wing harmonium or two layer random
field presented in Xing et al. (2005) for mining text and im-
ages. In that approach a lower dimensional representation of
image and text data is obtained by optimizing the joint
likelihood of a harmonium model.

Experimental Results
In this section, we present experimental results using multi-
conditional objective functions in the context of the models
described. First, we apply naïve Markov random fields to
document classification and show that the multi-conditional
training provides better regularization than the traditional
Gaussian prior. Next, we demonstrate mixture forms of the
model on both real and synthetic data, including an example
of topic discovery. Finally, we show that in harmonium-
structured models, the multi-conditional objective provides
a quantitatively better latent space.

Naïve MRFs and MCL as Regularization
We use the objective function $\alpha \mathcal{L}_{\theta|y}(y) + \beta \mathcal{L}_{\theta|x}(x)$ in naïve
MRFs and compare to the generative naïve Bayes model and
the discriminative maximum entropy model for document
classification. We present extensive experiments with com-
mon text data sets, which are briefly described below.

- 20 Newsgroups is a corpus of approximately 20,000
  newsgroup messages. We use the entire corpus (abbrevi-
  ated as news), as well as two subsets (talk and comp).

- The industry sector corpus is a collection of corporate
  webpages split into about 70 categories. We use the en-
  tire corpus (sector), as well as three subsets: healthcare,
  financial (finan), and technology.

- The movie review corpus (movie) is a collection of user
  movie reviews from the Internet Movie Database, com-
piled by Bo Pang at Cornell University. We used the po-
larity data set (v2.0), where the task is to classify the sen-
timent of each review as positive or negative.

- The sraa data set consists of 73,218 UseNet articles from
  four discussion groups: simulated auto racing, simulated
  aviation, real autos, and real aviation.

- The Web Knowledge Base (webkb) data set consists of
  webpages from four universities that are classified into
  faculty, student, course, and project (we discard the
categories of staff, department, and other).

We determine $\alpha$ and $\beta$, the weights of each component of
our objective function, and the Gaussian prior variance $\sigma^2
using cross validation. Specifically, we use 10-fold cross-
validation, with 5 fold used for choosing these parameters
and 5 folds used for testing. The models tend to be quite
sensitive to the values of $\alpha$ and $\beta$. Additionally, because
there is no longer a guarantee of convexity, thoughtful ini-
tialization of parameters is sometimes required. In future
work, we hope to more thoroughly understand and control
for these engineering issues.

During preprocessing, we remove words that only occur
once in the each corpus, as well as stopwords, HTML, and
email message headers. We also test with small-vocabulary
versions of each data set in which the vocabulary size is re-
duced to 2000 using information gain.

The results are presented in Table 1. The parenthesized
values are the standard deviations of the test accuracy across
the cross validation folds. On 15 of 20 data sets, we show
improvements over both maximum entropy and naïve Bayes.
Although the differences in accuracy are small in some cases,
the overall trend across data sets illustrates the potential
of MCL for regularization. In fact, the difference be-
tween the mean accuracy for maximum entropy and MCL
is larger than the difference between the mean accuracies of
naïve Bayes and maximum entropy. Across all data sets, the
mean MCL accuracy is significantly greater than the mean
accuracies of naïve Bayes ($p = 0.001$) and maximum en-
tropy ($p = 0.0002$) under a one-tailed paired t-test.

We also found that in 10 of 15 data sets on which we also
calculated the area under the accuracy/coverage curve, MCL
provided better confidence estimates.

Table 2: Two MCM-discovered “topics” associated with the politics.guns label in a run on talk data set. On the left, discussion about gun control in Texas. The negatively-weighted words are prominent in other classes, including politics.misc. On the right, discussion about the gun rights of David Koresh when federal agents stormed their compound in Waco, TX. Aspects of the Davidian cult, however, were discussed in religion.misc.

Figure 3: (Left) Joint likelihood optimization. (Middle) One of the many near optimal solutions found by conditional likelihood optimization. (Right) An optimal solution found by our multi-conditional objective.

Multi-Conditional Harmoniums

We are interested in the quality of the latent representations obtained when optimizing multi-attribute harmony structured models under standard (joint) maximum likelihood (ML), conditional likelihood (CL) and multi-conditional likelihood (MCL) objectives. We use a similar testing strategy to Welling et al. (2005) but focus on comparing the different latent spaces obtained with the various optimization objectives. As in Welling et al. (2005), we used the reduced 20 newsgroups data set prepared in MATLAB by Sam Roweis. In this data set, 16242 documents are represented by 100 word vocabulary binary occurrences and are labeled as one of four domains.

To evaluate the quality of our latent space, we retrieve documents that have the same domain label as a test document based on their cosine coefficient in the latent space when observing only binary occurrences. We randomly split the data into a training set of 12,000 documents and a test set of 4242 documents. We use a joint model with a corresponding full rank multi-variate Bernoulli conditional for binary word occurrences and a discrete conditional for domains. Figure 4 shows the precision-recall results. ML-1 is our model with no domain label information. ML-2 is optimized with domain label information. CL is optimized to predict domains from words and MCL is optimized to predict both words from domains and domains from words. From Figure 4 we see that the latent space captured by the model is more relevant for domain classification when the model is optimized under the CL and MCL objectives. MCL more than doubles the precision and recall at reasonable values of the counterparts.

Discussion and Conclusions

We have presented multi-conditional learning in the context of naïve MRFs, mixtures of naïve MRFs and harmony-structured models. For Naïve MRFs, we show that multi-conditional learning provides improved regu-
Multi-conditional learning is well suited for multi-task and semi-supervised learning, since multiple prediction tasks are easily and naturally defined in the MCL framework. In recent work by Ando and Zhang (2005), semi-supervised and multi-task learning methods are combined. Their approach involves auxiliary prediction problems defined for unlabeled data such that model structures arising from these tasks are also useful for another classification problem of particular interest. Their approach involves finding the principal components of the parameters space for auxiliary tasks. One can similarly use the MCL approach to define auxiliary conditional distributions among features. In this way MCL is a natural framework for semi-supervised learning. We are presently exploring MCL in these multi-task and semi-supervised settings.
