**14. ABSTRACT**

The Air Vehicles Unstructured Solver (AVUS) is a three-dimensional (3-D) flow simulator running on unstructured grids. Embedded in the simulator is a sparse matrix package for solving coupled partial differential equations. Unstructured grid solvers usually do not exhibit optimal computer memory access patterns. The purpose of this report is to detail the memory access patterns and provide a roadmap for improving it.

1 Task Objective
The objective of this delivery order is to improve the cache performance of the computer code AVUS.

1.1 Background
AVUS is a three-dimensional (3-D) flow simulator running on unstructured grids. Embedded in the simulator is a sparse matrix package for solving coupled partial differential equations. Unstructured grid solvers usually do not exhibit optimal computer memory access patterns. This project will determine the memory access patterns and provide a roadmap for improving it.
2 Description of Work

The following summarizes the activity/work accomplished during the period of January 1 to August 31, 2005 by the principal investigator Dr. Craig C. Douglas and his graduate student Adam Zornes.

A tutorial, Cache-aware Algorithms and PDE Libraries, on using computer cache memory subsystems was presented by Craig Douglas on May 18, 2005 at Wright-Patterson Air Force Base to the Computational Sciences Branch of the Air Vehicles Directorate. The presentation covers how the caches are organized and what is required to use caches effectively.

Years ago, knowledge of the number of floating point multiplies used in a given algorithm (or code) provided a good measure of the running time of a program. This was a good measure for comparing different algorithms to solve the same problem. This is no longer true. Many current computer designs, including the node architecture of most parallel supercomputers, employ caches and hierarchical memory architecture. Therefore, the speed of a code (e.g., multigrid) depends increasingly on how well the cache structure is exploited. The number of cache misses provides a better measure for comparing algorithms than the number of multiplies. Unfortunately, estimating cache misses is difficult to model a priori and only somewhat easier to do a posteriori.

Typical multigrid applications are running on data sets that are much too large to fit into the caches. Thus, copies of the data that are once brought into the cache should be reused as often as possible. For multigrid, the possible number of reuses is always at least as great as the number of iterations of the smoother (or rougher), plus the residual correction before correction steps. Suitable fixed and adaptive blocking strategies for both structured and unstructured grids must be introduced. Both types of cache-aware algorithms use a fixed, given percentage of the cache.

Fixed algorithms use fixed blocks of the unknowns (or subdomains) that are determined in a preprocessing step. Adaptive algorithms use a moving active set of unknowns that should be in cache and can be reused. Once an unknown has been completely updated for \( k \) iterations, it leaves the active set.

The cache-aware algorithms improve the cache usage without changing the underlying algorithm. In particular, bitwise compatibility is guaranteed between the standard and the high-performance implementations of the algorithms. This is illustrated by comparisons for various multigrid algorithms on a selection of different computers for problems in two and three dimensions.

To apply cache-aware principles to the code AVUS, it is first necessary to read the actual code, find the relevant parts, and start profiling running examples once the code has been built on suitable platforms. The techniques we intend to introduce should be fairly portable. One aspect that we had not expected is that AVUS is built using a pair of scripts that are tied to certain commercial compilers on specific platforms. We do not
have access to these compilers and have had to produce variants of the scripts just to get started on compiling and running AVUS.

We have successfully built and run AVUS on two platforms: a Xeon 64-EMT-based PC cluster and an Itanium 2-based shared-memory HP Integrity Superdome. The code was profiled to find the routines that need to be considered for cache-aware algorithms.

The compilation is driven by the script make_avus. One must configure options for the platform on which compilation is to be done. The script then builds and links executables for the desired platform and options. The main option is single or double precision. Double precision in the default. The make_avus script first checks to see if the ParMetis library has been built for the desired platform. If not, it calls another script, make_metis, to build the desired library. After the library has been established, the make_avus script checks to see if the .f sources have been built for the desired platform and are up to date. If not, they are built and saved in the objects directory en mass. When the .f sources have been built, a few other sources are built and then all are linked together with the ParMetis library to create the executable, which is saved in the bin directory.

The compilation scripts must be modified to allow for profiling. This involves adding the correct options for compilation (specific to each compiler) for producing profiling output. This must be done both in the make_avus and make_metis scripts, and sources must be rebuilt accordingly.

Execution is generally done through a .job file. This file sets several environment variables (including executable location and calling sequence), creates and input file for the program, and calls the program execution script. The execution script is AvusRUN. This first moves various files to the correct locations as set by the .job file. The script then runs the executable and tidies up by moving output files to a location set by the .job file and destroying temporary files.

To correctly collect profiling data, some aspects of the execution process must be modified. This may include altering the AvusRUN script to not remove temporary files and may also entail some other changes to the script.

The first step in profiling was to run AVUS under gprof, a relatively simple profiler. We then had statistics on how much time was spent in each of the routines in the overall code. This is helpful in determining where the code spends most of its time on a single processor. A complete gprof output for one of examples starts at about 70 pages of text, which we omit and will provide to the program manager electronically.

The top 15 routines are shown in Table 1.

Ucm6 constructs left and right face values of primitives. Poogrd compute a mask array for the one-sided least-squares gradient construction at each face. The mask array is ‘good’ and it is initialized to true in subroutine zero. A neighbor cell not truly one-sided will cause a false entry in the appropriate location in the array. Orderpt removes redundant points from each face to ensure that each edge is composed of two points and is shared by two faces of any given cell in three dimensions. It also orders points around the perimeter of each face.

Karl6sc is the parallel symmetric Gauss-Seidel iterative solver. It communicates twice per iteration with neighbors. Riemann solves a Riemann problem at every face using the exact Riemann solver of Gottlieb and Groth.

Most of the rest of the routines are used to construct Jacobians by computing fluxes or enforcing boundary conditions or positivity requirements. Anything that passes through data once only is not a candidate for improving cache reuse unless the routines can be combined so that fewer passes are made through the same data. In particular, Poogrd, Orderpt, and Hunter are not candidates for improvement since on very large data sets they use relatively little time.

A more sophisticated profiler is the HPCToolkit developed at Rice University. It has the capability to profile multiple processor codes on platforms that are supported by the Performance Application Programming Interface (PAPI), which was developed at the University of Tennessee at Knoxville. We are in the process of building scripts that will allow us to extract highly detailed runtime statistics on the performance of AVUS. Unfortunately, writing the scripts is time consuming, tedious, and not automated. When completed, the scripts will be useful after the project as AVUS evolves over time.
In the case of multiple processors, the grid is automatically reordered to take advantage of locality. This is not done automatically in the single processor case. However, a program called Blacksmith may be run to reorder the grid before starting AVUS. This causes a significant drop in the time spent per iteration.

AVUS is spending most of its time generating the problems it has to solve, not on solving these problems. One of the principal iterative solvers, a block symmetric Gauss-Seidel, performs two major communications exchanges every iteration. This algorithm needs to be modified in order to be cache efficient. One possibility is to eliminate some of the communication by switching the algorithm to a more traditional Schwarz alternating method that runs multiple steps of Gauss-Seidel locally.

Schwarz procedures solve local (domain decomposed) sub-problems to some level of accuracy. There are two variants of interest:

1. Additive: all sub-problems are solved in parallel. Data is exchanged between sub-problems for overlapping data (if any) in parallel, too.
2. Multiplicative: each sub-problem is solved sequentially. Data is exchanged only between sub-problems that have an update pending.

The additive form is most suitable for parallel processing. There are multilevel variants as well, e.g., multigrid within each sub-problem versus domain decomposition within a global multigrid procedure. I prefer the latter, but the domain decomposition community prefers the former.

The advantage of an additive Schwarz procedure for AVUS is that the symmetric Gauss-Seidel procedure can be modified to be cache-aware. Currently, there are two parallel communications of sub-domain boundary data per iteration. Several complete iterations can be done instead before communication. Switching to a natural order Gauss-Seidel will make it even easier to add cache-aware algorithms devised either by my group or the one of Ulrich Ruede in Erlangen (both our groups have cooperated on a number of joint papers). Many papers can be found in the MGNet preprint web page.

Keeping the right-hand sides and the matrix values together in memory in one structure seems to make a modest improvement in cache locality. For 3-D problems, this is not always the case, however. In a large application, it may be better to have the right-hand side in two places depending on what it is needed for. Copying the data makes sense if there will be many iterations of the Gauss-Seidel solver.

Another approach is to do a domain decomposition style Gauss-Seidel solver within each Schwarz sub-problem, where the domains now are localized to the size of the usable part of cache. Jonathan Hu wrote a Ph.D. dissertation on how to do this for multigrid on a single processor for unstructured grids. Danny Thorne wrote a Ph.D. dissertation on how to do this for multigrid on a single processor for structured, adaptively refined grids. Both dissertations are available in the ML-DDDAS web page, http://www.mgnet.org/~douglas/ml-dddas.html. Codes can be provided as examples of how to develop such codes. Both students’ codes fall in the category of research codes. A newer, production level code that works well in both environments is slowly being
A significant idea in Hu’s dissertation is to study the adjacency matrix $C=(c_{ij})$ of cache-bound subdomains. These matrices are square and the size of the number of cache blocks used to solve a problem. If $c_{ij}=c_{ji}>0$, then cache blocks $i$ and $j$ transfer data between each other. Trying to minimize the number of nonzeros will reduce computational time. If the $c_{ij}$ represent how many pieces of data have to be transferred from block $i$ to $j$, minimizing the $c_{ij}$ as well will have an impact on cache reusability.

Studying the techniques employed by either Hu or Thorne will take a significant amount of time.
3 Profiling AVUS with the HPCToolkit

To simplify the process of profiling AVUS with the HPCToolkit, the .job files and the AvusRun script have been combined with other HPCToolkit commands and options in a single script, hpc_script.

At the beginning of the script, there are a number of variables that must be defined. These are listed and discussed Table 2. Below this, the input file is created and the AvusRun script is concatenated. Alterations have been made, and as of now there is support for Linux platforms only. Support for other platforms can be added as needed.

The process for analyzing AVUS with the HPCToolkit involves five steps. The first step is to determine the loop structure of the binary executable file using bloop. Next, the executable is run under hpcrun with various optional events defined in the variable HPCRUN_EVENTS. After this has been done, the output files produced by hpcrun are analyzed by hpcprof. These files are then all combined by hpcquick into a database viewable by either hpcviewer or a web browser. Finally, the results may be viewed.

A number of variables may be defined in the script. Table 2 lists those variables and a short description of each. For proper execution, all path names should be fully qualified, not relative.

4 Sources of Future Cooperation

The program manager has computer access to our work through accounts on www.mgnet.org (a Mac Mini running Mac OS X 10.4) and hpc1c.csr.uky.edu (a Centos 4.1 based Itanium 2 HP workstation). HPCToolkit is installed and functional on hpc1c. Should the program manager need to run simple examples in parallel in our environment, we will issue logins on hpc1d and hpc1e. I expect that the program manager will have questions about how to deal with Schwarz alternating procedures and some of the sophisticated cache-aware algorithms that Jonathan Hu and Danny Thorne devised as part of their Ph.D. dissertations. I expect to continue cooperating with the program manager after the formal end of the project on an informal basis, including answering questions related to this final report.
