Composite Materials and Naval Surface Combatants: The Integrated Technology Deckhouse Project
Pat Cahill, Associate Member, Bath Iron Works

ABSTRACT

Composite materials, particularly fiberglass, have created a revolution in commercial marine design and construction over the past 20-30 years. The U.S. Navy, however, has been slow in recognizing the value of composite materials and implementing their use. The current construction of a fiberglass minesweeper will introduce composites into the auxiliary Navy, but major surface combatants have yet to take advantage of their unique material properties.

The Integrated Technology Deckhouse (ITD) Project has been steadily progressing toward the goal of constructing Naval combatant deckhouses out of an integrated system of steel and composites. The approach of the ITD Project has resolved problems and issues in phases, with each phase becoming progressively narrower in scope and greater in detail. The first phase of the project was primarily a materials and structural concepts trade-off study. Material properties were reviewed for a variety of fiberglass composites and design concepts, resulting in a trade-off matrix. The second phase included a shipyard producibility study. Issues associated with working with composites in a modular, steel construction environment were addressed. Recommendations from this study were then addressed in detail in a follow-on producibility study.

In the most recently completed study, the producibility issues associated with the design and construction of the DDG-51 Class forward Close In Weapons System (CIWS) maintenance enclosure were addressed. This paper reviews the progress to date in the ITD project, highlighting the significant issues and explaining why some of the major decisions were made. Emphasis is placed on the most recent phase of the project, which concentrated on a specific ship unit.

INTRODUCTION

The continuing efforts of the U.S. Navy to reduce weight and increase survivability of Naval combatants has led to the serious development of composite technology for use on combatant ships. Composites, especially fiberglass, have revolutionized design and construction in the commercial marine industry. Until recently the impact has been primarily on pleasure craft and other small boats. Technological advances in materials and construction processes have led to larger composite boat designs as well as an increased interest in the use of composites by the U.S. Navy.

Although large combatant hulls will most likely continue to be constructed of steel, polymer composites may be integrated with more traditional ship building materials to form hybrid structures. Because of their high strength to weight ratios, composites are particularly attractive for weight critical areas. In the past, aluminum has been used to keep weights and centers of gravity down, but has proven to be a less than ideal material for combatant deckhouses. In the future, polymer composites may be the material of choice for deckhouse structures. The U.S. Navy's Integrated Technology Deckhouse Project is steadily progressing toward making this a reality.

BACKGROUND

The objective of the Integrated Technology Deckhouse (ITD) Project is to enhance the survivability of U.S. Navy combatant surface ships. Composite materials have been chosen as a means to achieve this enhanced survivability because of several factors. Composites allow an integration of a number of survivability requirements, have beneficial material characteristics and may reduce maintenance requirements. One of the major advantages over steel or aluminum is in fire containment. Although composites will burn at high temperatures, the thermal conductivity is considerably less than metals. A fire occurring in a composite space will not transmit significant heat through the bulkheads to adjacent spaces. Spontaneous combustion in spaces adjacent to the fire, such as that experienced on the U.S.S. Stark, should be prevented.

Polymer composites also have excellent ballistic properties, yet are considerably lighter than equivalent steel armor plate. Reduction of topside weight, although not yet an issue on the newest Navy destroyers, is an additional advantage of composite deckhouses. Because of their high strength to weight ratios, composite materials can result in a 25%-30% reduction in structural weight. Finally, properly prepared composite materials are nearly impervious to the corrosive effects of the ocean environment, resulting in reduced maintenance.

The ITD Project has been on-going since 1987, with sponsorship by Operational Navy (OPNAV) Code 03C2,
program management by Naval Sea Systems Command (SEA) Code 5112 and technical management and coordination by SEA55Y. David Taylor Research Center in Carderock and Annapolis, Maryland has played a key role in resolving technical problems. The Navy has used a design agent as prime contractor to complete much of the design and engineering work and to subcontract work out to shipyards and composite manufacturers. Additionally, there has been active participation since the inception of the project by three major surface combatant construction shipyards. The early involvement of the shipyards has been extremely valuable in ensuring that technical concepts developed in the labs and by the design firm can actually be built in a shipyard.

The project has been established as a three phase effort. Phase A, from FY87 to 1st quarter FY89, was a concept development and material characterization stage. Phase B, dedicated to technical development and validation of design details and structural elements, is scheduled through FY91. During this phase the efforts of the project were, and continue to be, focused on the construction of a Close In Weapons System (CIWS) maintenance enclosure for DDG51 Class destroyers. Phase C, scheduled for FY92-FY94, is planned to be the full scale deckhouse unit fabrication, erection and evaluation.

The project is currently on schedule and well into Phase B. The CIWS structural design is nearly complete, and the testing of design details will occur during the summer of 1991.

**PHASE A**

Phase A consisted of a number of paper studies and small scale testing. The paper studies included identification of technology areas and definition of design criteria. Phase A culminated in an overall Material Systems and Structural Concepts Trade-off Study. A number of different material systems were considered for use in the ITD Project. Five major factors were used as evaluation criteria in deciding which material was best suited for the project. These factors were:

- specific strength
- fire resistance
- environmental suitability
- fragmentation protection
- acquisition cost and availability

Using these evaluation criteria a fiberglass composite made from a woven roving E-glass solid laminate vinylester resin system was chosen as the primary material. The additional strength characteristics of a 70% glass (70% glass to resin weight ratio) system made it the primary choice for exterior and structural bulkheads, while a 50% system was recommended for non-structural and joiner bulkheads.

The second part of the study evaluated a number of different structural concepts for composite deckhouse construction. Molded construction and modular construction using a framework and panels were both considered, with modular construction chosen for the project. Modular construction eliminates the need for molds, does not require extensive facility upgrades by shipyards building primarily steel combatants, incorporates construction techniques familiar to most shipyards and may reduce the risk and costs associated with repairs and rework. Composite panels are also easier to ship from the fabrication facility to the shipyard than large molded structures.

Once this decision was made a number of new issues arose, including composite versus steel framework, single bay versus multi bay panels, integral versus non-integral stiffeners and adhesive versus mechanical fastening. Candidates were evaluated using the following criteria:

- structural weight
- ballistic performance
- fire containment
- electromagnetic properties
- producibility, repairability and maintainability

At this stage of the program a matrix of concepts and their advantages and disadvantages was developed rather than selecting a specific concept, as the optimum structural concept will be dependent on the actual deckhouse configuration.

**PHASE B**

Phase B of the ITD Project concentrated initially on solving the air blast and fire issues, as well as continued shipyard support. A simulated nuclear air blast test was performed on a small (2.44m (8') by 2.44m (8') by 4.88m (16')) composite module. In addition, a series of fire tests, including a large scale “Stark” fire simulation, were conducted on a similar sized module. The results of these tests supported the choice of materials.

An in depth shipyard producibility study was also conducted during this phase. The study identified and resolved producibility issues associated with the design and construction of a generic composite deckhouse structure. Significant contributions were made to the ITD Project in the areas of fabrication, safety and non-destructive testing and evaluation techniques. Methods of construction were reviewed and several alternatives identified for most production tasks.

The study made a number of recommendations pertaining to panel fabrication and storage. Composite panels will be manufactured by a vendor contracted through the shipyard, as the yards currently involved in major naval combatant construction have limited capability for large scale fiberglass panel fabrication. The shipyard or design agent will provide the manufacturer with the necessary design information to fabricate either custom or standard panels. Gel-coat will be applied by the panel manufacturer to prevent environmental damage to the panels during construction. Panels must be carefully handled and stored, preferably in a vertical racking system.

The design of the deckhouse panels should minimize the requirement for cutting and trimming of the panels by the
shipyard. This will reduce construction time and cost by eliminating some of the Occupational Safety and Health Administration (OSHA) requirements and safety measures that must be taken when working with fiberglass. Manual methods were evaluated and will be used where cutting is necessary, eliminating the need for shipyards to invest in automated fiberglass panel line equipment. Panel fastening will be accomplished with a combination of adhesives and mechanical fasteners. Although sole use of adhesives and fiberglass bonding methods is more appealing for both strength and reduction of topside clutter, the difficulty in integrating steel and composites and the requirement for controlled conditions for fiberglass layup mandates the use of bolts at panel joints and attachment points. The use of steel transition pieces (similar to the bimetallic strips used on aluminum deckhouses) and welding near panels was ruled out by the study due to potential damage from the weld heat.

**CIWS MAINTENANCE ENCLOSURE**

During the latter part of Phase B, the forward CIWS maintenance enclosure of the DDG-51 Class destroyer was chosen as the first actual ship’s structure to be constructed under the project. The CIWS enclosure was chosen for several reasons. Its size approximates that of the air blast and fire test modules, allowing the use of experimental data in the development of the unit design. It was anticipated that the deck and bulkhead connections could be easily accomplished as it is a relatively small unit with straight edges. Changing the CIWS enclosure structure will also have minimal impact on the overall ship design and construction due to its isolated location and small level of outfitting. It should be noted that the Vulcan Phalanx CIWS gun mount foundation is actually on the structural unit below the maintenance enclosure, so that the issues associated with mounting large, heavy items on a composite deck are not addressed. The unit will be used to test key issues such as EMX, fire protection, producibility, shock and fatigue. Finally, the design can be incorporated as either a forward or back fit into both the DDG-51 Class destroyers and aircraft carriers. Figures 1 and 2 show the relative location and configuration of the enclosure.

The decision to construct a CIWS enclosure led to an additional producibility study by the lead shipbuilder of the DDG-51 Class, as well as the development of detailed test plans and schedules for implementation of the project.

![Figure 2](image)

**PRELIMINARY DESIGN DATA**

Prior to tasking the producibility study of the CIWS enclosure, the structural concepts to be used were chosen from those identified in the previous studies. Preliminary structural drawings were developed by the design agent and provided as a baseline for the CIWS producibility study. The unusual geometry of the enclosure dictates the use of large custom built panels rather than standard size panels. These panels will be...
fabricated using the 70% E-glass/vinylester resins in system. The initial design called for one half inch solid laminate panels, thickening to three-quarters inch at the edges to provide a stronger faying surface. The design had foam or balsa cored hat stiffeners integrated into the panels during layup, a steel framework consisting of angles at the joints, and a steel flat bar at the deck and bulkhead connections. The angles were connected to the panels using steel bolts and the edges sealed with the same vinylester resin used in the panel fabrication.

It was anticipated that the assembled unit will be temporarily erected on the ship, and the deck and bulkhead edge locations scribed onto the adjoining units. The enclosure will then be removed and the flatbar (with pre-drilled bolt holes) welded in place and straightened as necessary. The fully assembled enclosure is then lifted back onto the ship and bolted in place, applying a resin sealer to the joints. This preliminary construction method was later modified during the shipyard study.

A small number of outfitting details, based primarily on techniques developed during design of the MHC-51 Class Coastal Minehunters, were also provided with the preliminary design. These included methods for installing pipe and vent hangers, electrical cableways and foundations.

CONSTRUCTION PHILOSOPHY

Previous studies recommended the continued use of modern modular construction and zone outfitting methods currently in use in many shipyards. The CIWS study concurred with the recommendations and identified construction approaches that will result in as little deviation as possible from present shipbuilding practices.

STORAGE AND HANDLING

One of the initial steps in the construction process is the receipt and storage of construction materials. The expense and long lead times associated with composite panels requires a more careful process than that used with steel plate. To prevent environmental damage prior to erection on the ship the panels should be stored inside. A vertical racking system is the preferred method of storage, particularly for custom panels, as the panels will only have to be moved once during each construction phase. Each panel will also be readily accessible when needed.

Several methods of handling the composite panels were recommended by the various shipyard studies. The use of vacuum cups appears to be the best method as no modifications to the panels are required. Other methods include the use of slings, which is labor intensive; holes drilled in the panels, which will require later rework; and laminated fiberglass padeyes. An advantage of laminated padeyes is that, if properly designed and located, they may be left in place and used for unit lifting and erection of temporary scaffolding.

PANEL DESIGN

The next step to consider was the design of the panels themselves. Earlier studies had considered both custom made and standard panels, with custom panels as the final recommendation. For a DDG-51 Class deckhouse this is the only logical choice due to its unusual configuration and varied geometry, as shown in Figure 3.

The use of standardization during custom panel design and fabrication should, however, result in lower shipbuilding costs. Maintaining a degree of consistency between panels allows the shipbuilder to fabricate connection and mounting parts on a large scale, rather than designing and fabricating completely unique pieces for each panel. It also allows the tradesmen to develop a familiarity with the product, which eventually results in reduced production manhours. Stiffener spacings and dimensions, panel thicknesses and faying surface widths are some of the items that, if held to a strict standard, will reduce overall costs.

An additional consideration is the amount of pre-outfitting to be accomplished by the panel vendor. By working with the shipyards on a jointly developed design the panel manufacturers should be able to fabricate panels that incorporate a number of attachment points for outfit items, resulting in a shorter production cycle in the shipyard and fewer opportunities to damage the panels during the production process. The disadvantage to this is the possibility of improperly located attachment points resulting in rework and delays. Strict quality assurance procedures and accurate, fixed designs will prevent this problem.

FRAME DESIGN

The next major design consideration was the type of framing system to use. It was decided relatively early in the ITD project to use a steel or composite frame system to hold the panels together. Several factors must be considered in the design of a framing system. It must be adaptable to several types of composite joints, all of which will be addressed by the CIWS maintenance enclosure. These include:

-GRP deck to GRP bulkhead
-GRP deck to steel bulkhead
-GRP bulkhead to steel bulkhead
-GRP bulkhead to steel deck

Panels and their connections must be designed for nuclear air blast loading, meeting strict requirements for panel deflection, sheer and bending moments. The framing system should minimize weight, but not at the expense of producibility. Finally, the unique configuration of the DDG-51 deckhouse units will require the use of non-standard shapes.

Two types of framing systems were considered as candidates for the CIWS enclosure. Each has its merits and its disadvantages. The first type, with framing members located only at the panel edges, is shown in Figure 4.

The panels are bolted to the frame members and act together to provide the structural strength and stiffness of the unit. This type of framing system will allow the use of composite framing members and offers the minimum structural weight. Construction using this framing method will
require the panels to be erected one at a time, bolting them to the frame pieces in sequence while supporting the partially finished structure with a mock or jig.

The other option considered for a framing system was a free standing structural frame constructed of steel. The framework is welded together and has some inherent structural strength prior to bolting the panels onto the frame. This method is obviously heavier, but provides additional points for joining to ships structure and attaching distributed systems. It may also help support distributed systems in the event of catastrophic fire damage. This type of frame is shown in Figure 5. The final choice for the project is a combination of the two systems; a steel panel boundary frame with some additional steel members at critical points.

One of the greatest challenges during this study was to develop a method of connecting the composite panels to steel plate bulkheads and decks. The connection must be air and water tight and able to meet all compartment test requirements. It must be resistant to corrosion, cracking and pitting. It must also be lightweight and producible. Various connection methods were considered, including mechanical fasten-
ing, adhesives and welding, as well as combinations of the aforementioned. The early ITD studies considered steel plates embedded in the edges of the panels and then welded to the adjacent deck or bulkhead. This was ruled out because it was assumed that the high heat from welding would cause significant damage to the composite panels.

The suggested method was to weld the steel coaming to the adjacent structure and then bolt the composite panels to the coaming. The problem with this method is that difficulties in obtaining alignment within tolerances are anticipated when erecting the assembled composite unit onto the ship. An alternative method that will prevent alignment problems by allowing welding near the panels needed to be developed.

The CIWS study proposed that the transition pieces be temporarily bolted to the panels until the unit is erected and supported by temporary jacking stools. Once proper alignment is obtained the transition pieces will be welded to the adjacent steel plate and the permanent bolts installed and torqued down. This method still left the heat damage issue open.

In order to verify the practicality of the proposed construction method a welding heat experiment was conducted. Steel flatbars of varying thickness and width were welded into a tee shape with temperature probes attached to the vertical member of the tee as shown in Figure 6.

The critical temperatures for the E-glass/vinylester resin panels are shown in Table I.

Table II shows the test results. The results of this test demonstrate that depending on the type of plate used it may be possible to weld as close as one inch to the composite panels without significant damage, validating the proposed construction method. Several types of connections using this method were designed, with the preferred option shown in Figure 7.

OUTFIT DESIGN

Outfitting methods to be employed are another major challenge of the project. Outfitting includes the installation of all piping and mechanical equipment, combat systems and equipment, electrical equipment and cableways, ventilation ductwork and hull outfit items such as doors, ladders, gratings and habitability components. A steel or aluminum deckhouse is typically outfitted by welding foundations or hangers onto the structure and attaching the system or outfit items to them. Obviously this cannot be done with a composite structure. In most cases the existing hanger designs can be used, but the method of attaching them to structure will be modified. A number of possible methods were developed as part of the CIWS study, including attachment with adhesives, laminated attachment points, through bolts on stiffeners and bolting through the panels. Tap screws and rivnets can also be used, provided shock requirements are met. Figures 5-11 show examples of the different types of methods that were conceived during the CIWS study.

![WELDING TEST SETUP](image)

Figure 6

Two different types of welders were used; a pulse gas metal arc welder and a flux core welder, which is the hotter of the two. Single and double passes were conducted, as well as several with a preheat to simulate summer conditions. The temperature of the plate was measured at one inch increments from the weld and recorded on a strip chart recorder for the duration of the weld.

The critical temperatures for the E-glass/vinylester resin panels are shown in Table I.

REWORK AND SHIPYARD REPAIRS

Rework during construction on a steel structure often requires cutting or burning off the incorrect component, grinding down the steel plate surface and welding a new component in place. Rework with composites may, however, result in a labor intensive sanding, patching and re-laminating process. It is anticipated that common fiberglass boat building technology will be used to accomplish any required repairs.
Since fiberglass resin layup normally requires an environment with controlled temperatures and humidity, rework will present some difficulties on the shipways, particularly during winter months. For the CIWS enclosure a temporary cover and space heaters will be adequate, but this problem must be addressed prior to construction of an entire deckhouse. The best solution is to avoid rework altogether, making it especially important to ensure that design and construction practices minimize the possibility of errors.

**PAINTING AND CORROSION CONTROL**

The use of an integrated system of steel and composites presents a unique challenge for corrosion control. Although the composites are not themselves susceptible to corrosion they are not impervious to environmental damage. If not properly coated the long term effects of ultraviolet radiation will cause material degradation. Long term exposure to the ocean environment will also result in water and mineral absorption problems. A gel coat applied by the panel manufacturer will discourage these problems, but touch-up will be required by the shipyard prior to final painting.

The design used to integrate the steel and composites may also create crevice corrosion problems on the steel members. Steel erection units are normally grit blasted and primed prior to accomplishing most pre-outfitting. A steel/composite unit can not be put through the normal blasting process, so the steel framing members must be prepared separately prior to bolting to the panels. Weldable primer will
Flexible caulking is required at the composite/steel interface to create an air and watertight seal. The seal must remain intact during normal expansion and contraction of the steel plate from ships motion and environmental heating and cooling.

Actually putting a unit to sea and exposing it to the rigors of the ocean environment will test the effectiveness of these protective measures. New inspection and underway painting procedures must be developed to counter corrosion problems that may occur.

MAINTENANCE REQUIREMENTS

Maintenance of a composite/steel structure by ship’s force will be far different than that required for an all steel or aluminum vessel. Maintenance must become more inspection oriented and conditional, fixing defects or problems as they are found rather than performing regular preventive maintenance. Training will be required to instruct crew members on how to detect damaged gel coat, blisters, delamination and corrosion at the steel/composite interface. Period checks on bolts and seals will be required and care must be taken when performing hot work in the vicinity of composites.
CONCLUSIONS

The use of composites on large naval combatants has the potential to be a cost effective means of increasing survivability and decreasing weight. The remaining milestones prior to erection of a CIWS maintenance enclosure aboard a DDG-51 class ship will continue to present challenges to those working on the project. The successful erection and subsequent trials of the unit may potentially open the door for a larger scale introduction of this technology into naval shipbuilding.

ACKNOWLEDGEMENTS

The author would like to thank Mr. Alan Kurzweil of Naval Sea Systems Command and Mr. Bill Gregory of CASDE Corp., two of the key players in the ITD Project, for their assistance in the preparation of this paper. Thanks also to Mr. Tim Tetu of BIW for the DDG 51 isometrics.
