**14. ABSTRACT**
The factors driving resistance to antiestrogens are unknown. Comparing the transcriptomes of antiestrogen responsive and resistant MCF-7 variants by serial analysis of gene expression, we have implicated several genes, including the human X-box binding protein-1 (XBP-1). XBP-1 is a cAMP response element (CRE) binding protein associated with estrogen receptor (ER) expression in gene expression profiles of human breast cancers. We hypothesize that overexpression of XBP-1 and/or activation of CRE contribute functionally to the ability of responsive cells to survive the metabolic stresses induced by exposure to antiestrogens. We also hypothesize that measuring expression of the XBP-1 protein will assist in better identifying antiestrogen resistant and/or responsive tumors. Aim 1: We will further study the likely functional role of XBP-1/CRE by overexpression through transfection into responsive cells, and inhibiting expression in resistant cells. Effects of these molecular manipulations on responsiveness to antiestrogens will be studied. We will; also identify signaling downstream of XBP1 that may explain how XBP1 modifies responsiveness to endocrine treatments in breast cancer cells. Aim 2: We will explore the prognostic and predictive significance of XBP-1 expression in a unique series of human breast cancer biopsies. Thus, we will begin to assess the extent to which XBP-1 is a candidate prognostic factor.

INTRODUCTION
Antiestrogens are effective in premenopausal and postmenopausal patients, and in the chemopreventive, adjuvant and metastatic settings (1), probably through the induction of growth arrest/apoptosis (1). The triphenylethylene TAM, a partial agonist, is the most widely used antiestrogen. Long term TAM use reduces the incidence of contralateral breast cancer (antagonist) and primary breast cancer in high risk women (antagonist), maintains bone density (agonist) and increases the risk of endometrial carcinomas (agonist) (2). Newer antiestrogens include the “pure antagonist” ICI 182,780 (Faslodex; no agonist activity). In patients that had previously shown a response to TAM but recurred, Faslodex produces a response rate significantly higher than the response rate for crossover to another triphenylethylene (Toremifene) following TAM failure (3).

Antiestrogen Resistance. Most breast tumors that initially respond to TAM recur and require other endocrine or cytotoxic therapies (4). Despite over 10 million patient years of experience with TAM, the precise mechanisms that confer acquired resistance are unknown (1). Absence of ER expression is clearly important for de novo resistance (1). ER expression is not lost in most breast tumors that acquire antiestrogen resistance (5). Currently, there is little compelling evidence that expression of ER splice variants and mutant ER contribute significantly to antiestrogen resistance in patients (1;6). While the importance of wild type ERα is established as a mediator/predictor of antiestrogen responsiveness, that of ERβ remains unclear. ERα may be the predominant species in most ER+ breast tumors (7;8), and is associated with a better prognosis (9). ERβ is associated with a poorer prognosis, absence of PgR, and lymph node involvement (8;10). One small study reported higher ERβ mRNA levels in resistant tumors (11). However, this association could not be separated from that between ERβ and a more aggressive phenotype (8;10). Some studies report activities independent of ER function, which may initiate events that are necessary but not sufficient for antiestrogen-induced effects (1). Our research team has recently reviewed in detail the potential mechanisms of antiestrogen resistance in ER+ tumors (12).

Implicating XBP-1 in Antiestrogen Resistance. Initially, we explored differences in the transcriptomes of the MCF7/LCC1 (antiestrogen sensitive) and MCF7/LCC9 cells (antiestrogen resistant – resistant to both TAM and Faslodex) by serial analysis of gene expression (SAGE) as previously described (13), using the "SAGE" software (Dr. Kinzler, Johns Hopkins University). Most genes identified are not differentially expressed between MCF7/LCC1 and MCF7/LCC9 cells. Differentially expressed genes were selected by (a) the Tags compared represent ≤2 genes, (b) a Tag found in either the MCF7/LCC1 or MCF7/LCC9 SAGE library must represent 0.10% of the database, and (c) fold difference ~2-fold. Evidence that a gene is expressed in breast cancers also was considered. No single criterion was considered an absolute requirement for selection. Among the genes we identified were cathepsin D, nucleophosmin (NPM), tumor necrosis factor (TNF) and XBP-1 (14).

To confirm the altered expression of XBP-1, we first performed Western analysis on proteins from MCF7/LCC1 and MCF7/LCC9 cells. We initially detected a ~5-fold induction of XBP-1 protein in MCF7/LCC9 cells, comparable with the 4-fold induction in mRNA levels (14). Measuring protein levels and/or protein bound to responsive elements can be poor indicators of the functional activation of transcription factors. Since XBP-1 activates CREs, we measured directly CRE transcriptional activation using a CRE promoter-firefly luciferase reporter assay.
(PathDetect \textit{in vivo} signal transduction pathway \textit{cis}-reporting system; Stratagene). Cells were transiently transfected with the appropriate plasmids using Qiagen’s Superfect reagent. Normalization of transfection efficiency was made to a \textit{Renilla} luciferase reporter driven by the constitutive cytomegalovirus promoter (Promega’s Dual-luciferase reporter assay). The basal CRE activity is significantly increased in MCF7/LCC9 cells compared with MCF7/LCC1 cells (14).

Upregulation of CRE activation would be of limited use to cells if it could be inhibited by Faslodex-occupied ERs. Thus, we assessed the ability of Faslodex to affect CRE activation using the promoter-reporter assay. Faslodex treatments (10 nM) were administered for 48 hrs post-transfection. Faslodex treatment does not alter the transcriptional regulatory activities of the CRE promoter in either responsive MCF7/LCC1 or resistant MCF7/LCC9 cells (14). These data further imply a functional role for XBP-1 in acquired resistance to Faslodex. In responsive cells, the inability to induce CRE in the presence of Faslodex allows for the dominance of growth inhibitory signals leading to growth arrest/apoptosis. Resistant cells may survive growth inhibition/apoptosis by upregulating signaling through CREs. Since CRE-activation is required for MCF-7 cell proliferation (15), some breast cancer cells may survive antiestrogen treatment by upregulating factors that are not affected by ER-mediated signaling, e.g., XBP-1/CRE.

\section*{BODY}

This is a final addendum report. In this report, we present primarily the work completed during the no-cost extension.

\section*{KEY RESEARCH ACCOMPLISHMENTS}

We have continued to make good progress and have nearly completed most of the Tasks as proposed. We have made changes to Task 3 to change the direction in a more productive manner and obtained significant new data from gene expression microarray studies. These new studies provide powerful mechanistic insights not initially envisioned in the application. We are on target to complete most of the unfinished work and have requested a no-cost extension to help us do so.

\section*{Bulleted List of Research Accomplishments (this reporting period)}

- Completed analyses of microarray data and identified genes implicated in driving XBP-1’s effects on cell cycle and apoptosis
- Selected second round of candidate genes for validation
- Validated differential expression of candidate genes from the second round of analysis by quantitative real-time PCR (qPCR)
- Generated new signal transduction pathway for XBP-1 based on validated genes from first and second round of microarray validation studies

\textit{Nota Bene:} Please note that we changed the emphasis for Task 3 in the SOW in the prior report.
RESEARCH ACCOMPLISHMENTS

TASK 1: Overexpress XBP-1 in antiestrogen sensitive cells

This aim has been essentially completed. As previously reported, a small preliminary experiment was inconclusive with respect to XBP-1 conferring full estrogen-independence in vivo in MCF7/XBP-1 cells. As also indicated in the prior report, we chose to use the remaining resources to explore the cellular signaling data we had begun to generate last year (see Task 3; below).

TASK 2: Inhibit XBP-1 expression in antiestrogen resistant cells

We had some difficulty with the reproducibility of the siRNA. While our initial studies were promising (some were reported in an earlier report), we could not get readily interpretable data. We could not exclude some “off-target” effects, and so we chose not to pursue further these studies. Since we were quite successful with the other aims, included additional studies in Task 3, and the amount of work proposed here represented a relatively modest proportion of the overall proposal, we do not consider this problematic.

TASK 3: Explore the molecular events that confer XBP-1’s ability to affect endocrine responsiveness (modified Task for Statement of Work)

In the prior report, we presented the results of some preliminary gene expression microarray studies comparing the MCF7/XBP-1 and control cells. Our primary focus for this final period of investigation was to continue working on this data set. Thus, we completed analysis of the data by performing a second run of analysis to finalize the gene list related to apoptosis and cell proliferation, and performed qPCR validation studies.

The experimental design for the microarray studies was provided in the prior report. We first reran the analysis to obtain a more robust assessment of differentially expressed genes, this time we included a more detailed in silico search of promoters of those genes selected from Bin 1 (we looked only in Bin 1). These searches were done only for those differentially expressed genes associated with apoptosis and cell cycle distribution, since these are the functions of primary interest to this research project. Table 1 shows the final list of differentially expressed genes that also contain at least one XBP-1 responsive element (CRE with ACGT core sequence) in their upstream regions; Fig 1 shows the results of the dimension reduction analysis and Bin 1 from within which these genes were identified. Previously, we had validated only three genes/proteins, Bcl2 (protein), ERα (protein), and aromatase (mRNA).

To study further the data on aromatase transcription, we established a new collaboration with Dr. Angela Brodie at the University of Maryland. Dr. Brodie is a world expert in the study of aromatase and she tested the cell lines for increased aromatase activity. Despite the significant
induction of aromatase mRNA as confirmed by quantitative real-time PCR (MCF7/XBP-1 cells; 8-fold; p<0.05), Dr. Brodie was not able to detect increased enzyme activity. We then looked for protein by Western but we could not detect increased protein by Western. It is not clear if the increased transcription in the absence of translation or activation is unique to MCF-7 cells but it is interesting that we did not detect increased aromatase transcription in the T47D/XBP-1 cells. The aromatase gene has several promoters that contain XBP-1 responsive elements; promoters 1.3, 1.4, 1.7, and II are used in breast tissues and each contain at least one CRE-ACGT. Thus, the potential remains for XBP-1 to affect aromatase expression in other breast cancer cells or other estrogen-responsive tissues.

\(^{b}\)Fold Change in MCF7/XBP-1 cells relative to MCF7/c (control cells)

XBP-1 mediated antiestrogen resistance is characterized by increased cell cycle progression and reduced levels of apoptosis. As a transcription factor, it is likely that XBP-1 controls the resistant phenotype by regulating the transcription of cell cycle- and apoptosis-associated genes. In our gene expression microarray studies, we found several genes annotated with these functions, that contain ACGT CREs in their 5’ sequences, and that are likely to be significantly altered by XBP-1 overexpression (based on simple univariate analysis). For example, IL24 is strongly downregulated by XBP-1 overexpression (-2.68 fold by microarray, and -9.7 fold by qPCR). Also known as melanoma differentiation-associated gene 7 (mda-7), IL24 is an established inducer of apoptosis in breast cancer cell lines (16). While this gene has not been previously associated with estrogen or antiestrogen responsiveness, downregulation of proapoptotic molecules like IL24/mda-7 may play a functional role in endocrine resistance. Similarly, PHLDA2 (also known as IPL or TSSC3) is significantly downregulated in MCF7/XBP-1 cells (-1.8 fold by microarray, and -3.3 fold by qPCR). PHLDA2 is one of the only apoptosis-associated genes known to be imprinted. Moreover, PHLDA2 is located on chromosome 11p15, a region thought to harbor tumor suppressor activities and that also is altered in several cancers including breast cancer (17). In the mouse, where expression of maternal PHLDA2 is highest in extraembryonic structures, knockout of this gene leads to overgrowth of the placenta (18), suggesting that dysregulation of PHLDA2 can promote hyperproliferation.

In contrast to the suppression of tumor suppressor-like activities, we observe upregulation of pro-proliferative and/or prosurvival genes by XBP-1: c-Myc, XRCC6, and the calcium-binding protein S100A6 (calcyclin). Increased S100A6 expression has been demonstrated in several different cancerous versus normal tissues (19), and in 32% of breast tumors (20). In pulmonary fibroblasts, S100A6 antisense oligonucleotides inhibit cell proliferation, (21). In WI-38

![Fig 1.](image)

**Fig 1.** Error distribution graph for MCF7/XBP1 microarray data set. The reduced dimensional data set from which the genes in Table 1 were obtained is indicated as Bin 1. FDR = false discovery rate; MR = miss rate; p-value = univariate (uncorrected) T-test.
embryonic lung cells, any delay in the upregulation of S100A6 transcripts in late G1 is accompanied by a delay in S phase entry (22). The molecular mechanism(s) by which S100A6 regulates proliferation is unclear, but its calcium binding function may be important. XRCC6 (also known as the Ku70 autoantigen) is a DNA repair molecule essential to the end-joining process (reviewed in (23). Two single nucleotide polymorphisms (SNPs) in the XRCC6 gene are significantly associated with breast cancer risk (24), and XRCC6 overexpression has recently been implicated in acquired cisplatin resistance in ovarian cancer cells (25). Finally, c-Myc is a well-established pro-survival molecule in human breast cancer and mouse mammary tumorigenesis (26). Capable of modulating both cell growth and cell death, cMyc is overexpressed in 70% of breast tumors, and amplified at least 3-fold in 16% of breast tumors (27). Moreover, inducing c-Myc expression in MCF-7 cells can confer resistance to Faslodex (28). To our knowledge, this is the first report that XBP-1 can regulate c-Myc expression in breast cancer cells. Whether the regulation of cMyc signaling by XBP-1 contributes to the resistance phenotype in T47D cells is currently under investigation.

The signaling network predicted by these interactions is shown in Fig 2. We include ATF6 even though it is not differentially expressed because it can be activated by Myc and induce ER; both ER and Myc are upregulated in the MCF7/XBP-1 cells. XBP-1 and ER can interact to increase the transcriptional activation of ER (activation would not be detected by the microarrays); ER also is known to regulate Myc and Bcl2, so these may be affected directly by XBP-1 (through the CREs) and/or through XBP-1 increasing transcriptional activation of ER. In a recent collaborative study with colleagues in the U.K., we then showed how increased ER expression and phosphorylation is sufficient to confer antiestrogen resistance. Establishing the functional relevance of other nodes in this pathway and confirming the regulatory interactions will be used as the basis for a future application to NIH or another funding agency.

**TASK 4: Explore XBP-1 expression in clinical samples**

We have completed and published the first study on the clinical samples - a reprint will be forwarded to the DOD BCRP. We will continue with these studies in additional clinical material as it becomes available.
REPORTABLE OUTCOMES

We have now published some of our data and presented other data at meetings and in abstracts. Another paper has been submitted and this will be forwarded to the DOD BCRP once it has been accepted for publication. Publications in the past 12 months are listed below.

2. Kuske, B., Naughton, C., Moore, K., MacLeod, K.G., Miller, W.R., Clarke, R. Langdon, S.P. & Cameron, D.A. “Endocrine therapy resistance can be associated with high estrogen receptor alpha (ERα) expression and reduced ERα phosphorylation in breast cancer models.” Endocr Related Cancer, in press.

CONCLUSIONS
Our data confirm a potentially important role for XBP-1 in breast cancer. We have successfully overexpressed XBP-1 in MCF-7 cells, shown that XBP-1 binds to ERα, and induces estrogen-independence and antiestrogen resistance. We have optimized the use of tissue microarrays and demonstrated the detectable presence of XBP-1 protein in breast tumors. We have performed gene expression microarrays on XBP-1 transfected and control cells and identified several key leads to explain how XBP-1 may function. We have confirmed the differential expression of most of the selected genes and constructed a signaling pathway to explain how XBP-1 may act to affect breast cancer cell proliferation and cell survival.
