GALAXIES: THE LONG WAVELENGTH VIEW

J. Fischer
Naval Research Laboratory, Remote Sensing Division, Washington, DC, USA

ABSTRACT
Far-infrared spectroscopy obtained with the ISO LWS has shown that there is strong variation (more than 2 orders of magnitude) in the [CII]/FIR ratios in galaxies extending from blue compact dwarfs, to normal and starburst galaxies, down to elliptical and ultraluminous galaxies (ULIGs). The variation in the relative [CII] 158 μm line strength has been attributed to low metallicity in blue compact dwarfs, high $G_0/n$ for normal galaxies and ULIGs, soft radiation fields in ellipticals, and extinction or enhanced abundance of dust in ionized regions in ULIGs.

Full ISO/LWS far-infrared (43 - 197 μm) spectra of six nearby IR-bright galaxies reveal a dramatic progression of decreasing fine-structure line emission from ionized species to molecular (OH and H$_2$O) absorption line dominated. The archetypical ULIG, Arp 220, lies at the absorption line dominated end of this sequence. For Arp 220, radiative transfer models indicate that it is optically thick in the FIR and that the water molecules observed in absorption are radiatively excited. If extinction plays a role in the sequence it appears from this analysis that the affected regions are heavily obscured even in the far-infrared, while the detected line emission is not more obscured in ULIGs than in starbursts. Linear correlation between polycyclic aromatic hydrocarbon (PAH) 6.2 μm feature strength and the [CII] 158 μm line strength in starbursts and ULIGs suggests a similar effect for these emitting species, and that the detected PAH emission is not more obscured in ULIGs than in lower luminosity starbursts.

Key words: galaxies: starburst – galaxies: ultraluminous – galaxies: ISM – infrared: galaxies – infrared: spectra

1. INTRODUCTION
Far-infrared spectroscopy obtained with ISO's Long Wavelength Spectrometer (LWS) probes the global conditions in the ionized, molecular, and dust components of the interstellar medium in galaxies. Indeed, the great diversity in the FIR spectra of galaxies is indicative of varying gas and dust content, location, and excitation along the line of sight. Far-infrared spectroscopy is not a sensitive probe of the hard radiation fields characteristic of AGN. Instead, the far-infrared spectra of galaxies are often dominated by emission from the strongest cooling lines (i.e. [CII] 158 μm and [O I]63,146 μm) of the photodissociation regions (PDRs) from which the far-infrared continuum emission is thought to arise and by the forbidden fine-structure lines from H II regions. Because it is much less affected by extinction due to dust than spectroscopy at shorter wavelengths, FIR spectroscopy can be an important tool in probing the starburst properties of the highly obscured regions often inferred to be present in infrared-bright galaxies.

In the first part of this review, I will describe the results of far-infrared spectroscopic surveys of a variety of morphological types of galaxies, including dwarf, normal, starburst, and ultraluminous galaxies (ULIGs). The far-infrared spectra of active galactic nuclei are discussed by Spinoglio et al. elsewhere in these proceedings. I will then discuss the still uncertain physical conditions and evolutionary effects responsible for the weak emission line galaxies, many of which are ULIGs. Where possible I will discuss cross-instrument studies and compare the results of mid- and far-infrared spectroscopic surveys.

2. H II REGION AND PDR DIAGNOSTICS
The LWS range includes seven diagnostic fine-structure lines: [CII] 158 μm, [O I] 63 and 146 μm, [N II] 122 μm, [O III] 52 and 88 μm, and [N III] 57 μm. The [N III] 57 μm /[N II] 122 μm line intensity ratio is a sensitive indicator of the hardness of the UV radiation field when T(\text{eff}) $\sim$ 33,000 K. This pair thus indicates the upper mass limit (or, age) of any purported starburst. The [O III] 52,88 μm lines can be used to derive the density for moderate densities of the ionized gas and together with the [N III] 57 μm and [N II] 122 μm lines can be used to estimate the average O/N abundance ratio, and hence, star formation history in the galaxy. The [N II] 122 μm line can also be used to discern the fraction of [CII] emission which arises from low density ionized gas.

By definition, only photons less energetic than those capable of ionizing hydrogen (i.e. with energies less than 13.6 eV) pass the ionization boundary of an HII region and heat the gas within PDRs. The most energetic of these, the far ultraviolet photons with energies of $\sim$ 6 – 13.6 eV are absorbed by dust followed by the ejection of energetic photoelectrons which then heat the gas in the ensuing layers of

Figure 1. A comparison of low-metallicity galaxies with galactic star-forming regions and normal and starburst galaxies. Lines of constant $I(C \text{ II})/I(CO)$ ratios are shown and range from 2000 up to 70,000 for some dwarf galaxies. The ratios of both axes are normalized to the local interstellar radiation field ($1.3 \times 10^{-4} \text{ erg s}^{-1} \text{ cm}^{-2} \text{ sr}^{-1}$). From Madden (2000).

H I, [C II] (ionization energy 11.3 eV), [O I] and molecules. Models of the heating and cooling of the gas and dust, including polycyclic aromatic hydrocarbon (PAH) heating, have produced diagnostic diagrams relating the strong cooling line emission and the total far-infrared dust emission to the average radiation density and hydrogen density in the PDR (Wolfire et al. 1990; Kaufman et al. 1999). These models can be applied directly if both the total FIR and the line emission come from the PDR and if the line emission is not affected by absorption due to foreground gas and dust. Since the [C II]158 $\mu$m and [O I]63, 145 $\mu$m, lines from these regions are very strong, they can be used to trace the conditions in dusty star forming regions, even in elliptical and blue compact dwarfs where the amount of dust is relatively low.

3. THE EFFECTS OF METALLICITY

The metallicity of a galaxy provides information about its star formation history. Moreover, the measurement of the metallicities of galaxies at high-$z$ will provide clues to the star formation history of the early universe. Thus the development and understanding of infrared metallicity diagnostics are important for future missions such as SIRTF, NGST, and FIRST.

Madden (2000) has analyzed ISO and KAO (Keck Airborne Observatory) observations of the [C II] 158 $\mu$m line in a sample of 15 dwarf galaxies with metallicities ranging from 0.1 to 0.5 solar. She finds very high values of [C II]/[O I] and somewhat higher [C II]/FIR (Figure 1) in these low metallicity systems relative to other galaxies discussed in Stacey et al. (1999), but does not find an unambiguous direct correlation of the [C II]/[O I] ratio with metallicity within her sample. She interprets the enhanced [C II]/[O I] to be the result of reduced dust abundance, which allows the UV radiation to penetrate further into the molecular core (Maloney & Black 1988; Israel et al. 1996), producing a geometric dilution effect.

4. NORMAL GALAXIES

Maihotta et al. (1997; 2000a,b) have analyzed their survey of a diverse sample of normal galaxies in the [C II]158, [O I]63, 145, [N II]122, and [O III]88, 52 $\mu$m far-infrared fine-structure lines. Since these galaxies are relatively faint in the far-infrared continuum and fine-structure lines, their work concentrates on the analysis of the

Figure 2. The [C II]158/FIR flux ratio versus $F_{60}/F_{100}$ from IRAS. Early-type galaxies are denoted by bullseye symbols. From Maihotta et al. (2000a).

Figure 3. The [C II]158/FIR flux ratio versus $F_{FIR}/F_B$. Early-type galaxies are denoted by bullseye symbols. From Maihotta et al. (2000a).
strong [CII]158 and [O I]63 μm PDR cooling lines. Using $F_{90}/F_{900}$ and $F_{FIR}/F_B$ as measures of the dust heating radiation density and star formation activity respectively, they argue that the inverse correlation of [CII]/FIR with both of these (Figure 2 and Figure 3) is evidence that the low values of [CII]/FIR found for warm, infrared-bright galaxies such as IC 860 ($< 1.96 \times 10^{-4}$) and NGC 4418 ($< 1.53 \times 10^{-4}$) can be attributed to lower gas heating efficiency arising from positively charged grains for high values of $(G_o)/n$. They suggest that this effect is also responsible for the low [CII]/FIR found in 11 out of 12 ULIRGs by Luhan et al. (1998; 2000) (see Section ). This is further substantiated by a positive correlation between the ratio of the two strong PDR cooling lines [O I]125/[CII]158 and dust temperature (Figure 4), as is predicted by theoretical PDR models.

In order to obtain quantitative agreement with the PDR models of Kaufman et al. (1999), they find that it is necessary to significantly correct the observed [CII] fluxes for a contribution from diffuse ionized gas based on measured [N II] line fluxes (Figure 5). With this correction they find that their data is best fit by $(G_o) \propto n^{1.4}$ and conclude that this can be explained if the PDRs in high $(G_o)/n$ galaxies are associated with embedded H II regions and larger giant molecular clouds.

5. INFRARED-BRIGHT GALAXIES

Population synthesis and photoionization models of dusty, infrared-bright galaxies such as Arp 299, M 82, and NGC 4038/39, indicate that short-lived bursts of star formation with ages of $3-7 \times 10^7$ years, can best explain the LWS spectra of these galaxies (Satyapal et al. 2000, Colbert et al. 1999, and Fischer et al. 1996). Thornley et al. (2000) find similar results from an analysis of their [Ne III] 15.6 μm, [Ne II] 12.8 μm survey of 27 starburst galaxies. Satyapal et al. show that the models derived from LWS measurements including all of the individual components of Arp 299 are indeed consistent with the ensemble of model fits to high spatial resolution Brackett γ images of individual components of this galaxy. Unger et al. (2000) find that even in Cen A, the extended far-infrared emission is powered primarily by star formation rather than by the central obscured AGN. Fischer et al. (1999) have presented a sequence of full, high signal-to-noise LWS spectra of six infrared bright galaxies (see Figure 6) in order of the relative strength of the [O III] 52, 88 μm fine-structure lines. The spectral sequence extends from the strong emission line galaxies Arp 299 (Satyapal et al. 2000) and M 82 (Colbert et al. 1999) to the ULIG Arp 220, whose spectrum is dominated by absorption lines of OH, H$_2$O, CH, and [O I], with only very weak [C II] 158 μm and OH 163 μm line emission. Intermediate in the sequence are Cen A (Unger et al. 2000), NGC 253 (Bradford et al. 1999) and NGC 4945 (Lord et al. 2000), showing weak [O III] and [N III] lines while their PDR emission lines remain moderately strong. In this sequence, the strength and richness of the molecular absorption spectra are anti-correlated with the equivalent widths of the fine-structure emission lines. For example, M 82 shows faint OH absorption from the ground level at 119 μm, while NGC 253 shows absorption from the ground-state in three cross-ladder transitions and an emission line cascade in the 79 μm and 163 μm lines. In Arp 220, absorption from rotational levels as high as 416 K and 305 K above the ground state is present for OH and H$_2$O respectively, and the [O I]63 μm line is seen in absorption.
it appears from this analysis that the affected regions are very heavily obscured even in the far-infrared, while the detected line emission is relatively unobscured. In this case, the progression to low excitation could be a result of total obscuration of the youngest starburst population and/or the central AGN.

6. ULIGS AND WEAK EMISSION-LINE GALAXIES

The full LWS spectrum of the second brightest ultraluminous galaxy Mrk 231 (Harvey et al. 1999) is similar to that of Arp 220 (to within the achieved signal-to-noise ratio). It is dominated by OH absorption, with similar OH absorption line ratios, and only faint [C II]158 μm line emission is present. Based on the mid-infrared spectra of a sample of nearby ULIGs, Genzel et al. (1998) infer that Mrk 231 has a strong AGN component while the far-infrared luminosity of Arp 220 is powered by a starburst. Thus the similarity of the far-infrared spectra of these two ultraluminous galaxies is surprising. Indeed, Luhman et al. (1998; 2000) find that the [C II]158/FIR ratio in ULIGs is typically an order of magnitude fainter than in lower luminosity starburst and normal galaxies (Figure 7).

Figure 6. The full ISO Long Wavelength Spectrometer spectra of six IR-bright galaxies. The spectra have been shifted and ordered vertically according to the equivalent width of the [O III]88 μm line. The excitation potential, the energy required to create the species, is given in eV at the bottom of the figure. From Fischer et al. (1999).

Using the temperature-insensitive [O III] 52 μm/[O III] 88 μm line ratio as a probe of density, Fischer et al. find no clear dependence of the [O III]88/F FIR ratio on electron density and all of the measured [O III] line ratios were found to fall within the range 0.6 - 1.2, consistent with electron densities between 100 - 500 cm⁻³. From this they infer that neither density nor far-infrared differential extinction (between 52 - 88 μm) to the ionized gas appears to be the single dominant parameter in the observed sequence. Rather, since both of the line ratios [N III]57/[N II]122 and [O III]52/[N III]57 increase as a function of the [O III]88/F FIR ratio, they infer that [O III]88/F FIR correlates with excitation. They suggest that progression to soft radiation fields or dusty H II regions may explain these effects and that the absorbing molecules may be located in dense photodissociation regions, where they could be excited radiatively by the far-infrared emission from warm dust. If extinction plays a role in this sequence

Based on single dust temperature fits and measured millimeter size constraints the far-infrared dust emission of the nearest ULIG, Arp 220, is thought to be optically thick (Scoville et al. 1991; Fischer et al. 1997) throughout most of the LWS range. Single dust temperature models that fit our LWS spectrum with optical depth τ(100 μm) ≤ 1, would imply dust emission regions 3-4 times larger in angular area than what is measured at 1.3-mm by Sanders & Mirabel (1996), and more detailed radiative transfer models assuming central, spherical geometry, Draine & Lee (1984) dust, and power law density point toward high optical depth even in the far infrared (Fischer et al. 1997; 2000). Indeed, non-local radiative transfer models of Eduardo Gonzalez-Alfonse and Pepe Cernicharo using identical ensembles of clouds with radii of 10¹⁸ - 2 x 10¹⁹ cm and densities of 10⁵ - 10⁷ cm⁻³ can best explain the H₂O absorption lines in Arp 220 for τ_FIR ≥ 1 (Fischer et al. 2000). These model fits indicate that the levels are populated by absorption of photons emitted by warm dust. This suggests that the excited molecules may be located in PDRs associated with H II regions or an AGN, where the infrared radiation field would be particularly intense.

Genzel et al. (1998) find that for Arp 220 a screen model with A_v = 45 best fits the SWS mid-infrared recombination line fluxes, but point out that a mixed gas and dust model with A_v = 1000 would provide moderate agreement in the near- and mid-IR. If indeed τ(150 μm) = 1 and A_v ~ 1000 for Draine & Lee dust (Fischer et al. 1997), a purely mixed extinction model predicts an extinction correction of (1 - e^−τ)/τ = 0.33 for the [O III]88 μm line. Even with τ(150 μm) = 10, the 88 μm line should have been detected at the 3σ level for the pure mixed case.
While in the galaxies M 82 and Arp 299 the [O III] 88 μm line is about 1% of the LWS far-infrared luminosity, it is < 0.1% (3σ) in Arp 220. Thus, the extinction estimated from the mid-infrared lines is not enough to explain the lack of [O III] 88 μm line emission in Arp 220 if its intrinsic spectrum looks like that of M 82.

Can low photoelectric heating efficiency in high \( G_o/n \) PDRs, as proposed by Malhotra et al. (1997; 2000), explain the low [C II] emission in ULIGs and other [C II] deficient galaxies? The [O I] 63 μm/[C II] 158 μm line ratio found in the two ULIGs where [O I] 63 μm is detected is consistent with higher \( G_o/n \) (Luhman et al. 2000). On the other hand, the upper limit on the [O I] 145 μm/[C II] 158 μm line ratio found in Arp 220 (Fischer et al. 1997) is inconsistent with high \( G_o/n \), unless there is foreground absorption the [O I] 145 μm line, or if almost all of the [C II] line emission in Arp 220 originates in the diffuse ionized medium, as suggested may be the case for many galaxies by Malhotra et al. (2000b). Comparing their observations of the ground state fine-structure line of atomic carbon to the [C II] 158 μm line, CO rotational lines, and the FIR flux, Gerin & Phillips (1998; 2000) find evidence for high \( G_o \) and high \( n \) in the ULIGs Arp 220 and Mrk 231, but suggest that dust absorption and or [C II] line opacity must also play a role.

Luhman et al. (2000) have found that the average value and spread of the [C II] 158 μm line intensity to 6.2 μm PAH feature intensity ratio is similar in ULIGs and other IR-bright galaxies (Figure 8). The 6.2 μm feature was chosen because it is an isolated feature, well separated from other narrow PAH features and the 9.8 μm silicate absorption feature. The 6.2 μm PAH feature flux was measured from CAM CVF spectra, integrated over the full LWS beam for galaxies with extended emission, and from PHOT-S spectra for compact galaxies (Dudley et al. 2000). Black, filled symbols are ULIGs, while unfilled or grey filled symbols are lower luminosity galaxies. Dashed lines show a range of a factor of 10 in the flux ratio. From Luhman et al. (2000).

Figure 7. The [C II] 158 μm line flux versus FIR flux for 12 ULIGs observed with the LWS (Luhman et al. 1998; 2000) compared with a sample of normal and starburst galaxies (Luhman et al. 1998; Lord et al. 1996; Colbert et al. 1999; Stacey et al. 1999; Bradford et al. 1999). In the symbol key, the galaxies are listed in order of luminosity from top to bottom and the ULIG symbols are black filled, while the lower luminosity galaxies are unfilled. ULIGs are defined as in Sanders & Mirabel (1996). The dashed lines mark the regime typical of normal and starburst galaxies. From Luhman et al. (2000).

Figure 8. The 6.2 μm PAH feature versus versus [C II] 158 μm line flux for ULIGs and other IR-bright galaxies. The 6.2 μm PAH emission was measured from CAM CVF spectra (open symbols), integrated over the full LWS beam for galaxies with extended emission, and from PHOT-S spectra (filled symbols) for compact galaxies (Dudley et al. 2000). Black, filled symbols are ULIGs, while unfilled or grey filled symbols are lower luminosity galaxies. Dashed lines show a range of a factor of 10 in the flux ratio. From Luhman et al. (2000).
Lyman continuum photons. Comparison with CLOUDY (Ferland 1993) models indicates that this can explain the low intensity of the FIR fine-structure lines, but would not produce lower excitation if Draine & Lee (1984) dust is used. Further modeling is needed to determine whether increased dust opacity within ionized regions, due perhaps to increased metallicity or evolutionary effects, can quantitatively explain the low [C II] / FIR ratios, warmer dust temperatures, and OH and H$_2$O far-infrared absorption from excited levels.

7. SUMMARY

Far-infrared spectroscopy obtained with the ISO LWS has shown that there is strong variation (more than 2 orders of magnitude) in the [C II] / FIR ratios in galaxies extending from blue compact dwarfs, to normal and starburst galaxies, down to elliptical and ultraluminous galaxies. The variation in the relative [C II] line strength has been attributed to low metallicity (blue compact dwarfs), high ($G_n / n$) for normal galaxies and ULIGs, soft radiation fields in ellipticals, and extinction or enhanced abundance of dust in ionized regions in ULIGs.

Full ISO/LWS far-infrared (43 – 197 μm) spectra of six nearby IR-bright galaxies reveal a dramatic progression of decreasing fine-structure line emission from ionized species to molecular absorption line dominated. The archetypical ULIG, Arp 220 lies at the absorption line dominated end of this sequence. For Arp 220, radiative transfer models indicate that it is optically thick in the FIR and that the water molecules observed in absorption are radiatively excited. If extinction plays a role in the sequence it appears from this analysis that the affected regions are heavily obscured even in the far-infrared, while the detected line emission is not more obscured in ULIGs than in starbursts. Linear correlation between the PAH 6.2 μm feature strength and the [C II] 158 μm line strength in starbursts and ULIGs suggests a similar form for these emitting species, and that the detected PAH emission is not more obscured in ULIGs than in lower luminosity starbursts.

Ultimately many of these effects are related to geometry and the physical location of dust, for which more detailed models and SIRTF spectroscopy will be invaluable.

ACKNOWLEDGEMENTS

I would like to thank my collaborators on the LWS infrared-bright galaxies science team, M. Luhman, S. Satyapal, C. Dudley, E. Gonzalez, P. Cernicharo, M. Wolfire, P. Clegg, J. Colbert, P. Cox, M. A. Greenhouse, V. Harvey, C. M. Bradford, S. Lord, M. Malkan, G. Mehlick, G. Stacey, H. A. Smith, L. Spinoglio, G. Stacey, and S. Unger, for their contributions to the work reviewed here, some still in press or in preparation, and to S. Malhotra and S. Madden for access to preprints before publication. I would also like to acknowledge the skill and dedication of the LWS instrument and data analysis teams at Vilspa, RAL, and IPAC.
