Final report
Approved for public release; distribution is unlimited.
Abstract: Effective flood and coastal storm emergency response depends on the ability of emergency managers to obtain information on the condition of flood-damage reduction structures in near real-time. This report describes the results of a geophysical study performed to determine the potential for geophysical methods to provide supplemental geologic data between existing soil borings in a rapid fashion in an area of complex geology. The geophysical study was conducted along 10 km of landside levee toe adjacent to the Feather River, approximately 5 km south of Marysville/Yuba City, CA. Electromagnetic induction, capacitively coupled electrical resistivity, and direct current electrical resistivity survey methods were used to conduct the geophysical study. Survey results were used to classify soil type to depths of approximately 60 m.

Preface

This report describes a research study commissioned by the U.S. Army Corps of Engineers’ Emergency Management Technologies focus area of the Flood and Coastal Storm Damage Reduction (FCSDR) Research Program and conducted by the U.S. Army Engineer Research and Development Center (ERDC) to determine the feasibility of using surface-based geophysical surveys to rapidly map and characterize soils along the toe of a levee. The work was performed during the period 14–21 June 2006 along a selected portion of the Feather River east (left) bank levee approximately 5 km south of Marysville/Yuba City, CA. Dr. Kathleen D. White, ERDC Cold Regions Research Engineering Laboratory, is the Program Manager for the FCSDR Emergency Management Technologies focus area.

The research described herein was conducted by José L. Llopis and Dr. Janet E. Simms of ERDC Geotechnical and Structures Laboratory (GSL). This report was prepared by Llopis and Dr. Simms under the general supervision of Dr. Lillian D. Wakeley, former Chief, Engineering Geology and Geophysics Branch; Dr. Robert L. Hall, Chief, Geosciences and Structures Division; Dr. William P. Grogan, Deputy Director, GSL; and Dr. David W. Pittman, Director, GSL.

COL Richard B. Jenkins was Commander and Executive Director of ERDC. Dr. James R. Houston was Director.

1 Introduction

Background

Levees are a fundamental part of many flood-damage reduction projects that protect life and property. The condition and performance of levees in emergency flooding situations are of utmost importance. The U.S. Army Corps of Engineers (USACE) has conducted research and development activities related to levees in a number of research programs, including the Innovative Flood Protection Program and its successor, the Technologies and Operational Innovations for Urban Watershed Networks (TOWNS) Research Program. Currently, research related to levee condition evaluation and assessment is being conducted under the auspices of the Emergency Management Technologies focus area of the Flood and Coastal Storm Damage Reduction (FCSDR) research program. A primary objective of this research is to develop the capability to rapidly obtain information about levee conditions and convey the data to decision-makers during emergency operations, particularly in cases where levee failure is possible.

Levee failures are governed in large part by the soils that form the embankments and their foundations. Failure of the levee occurs as a result of the river scouring the toe of the levee, causing the embankment to collapse into the channel; by overtopping of the embankment; and by seepage and piping through the embankment or its foundation. Water seepage through the levee embankment (through-seepage) can produce internal erosion of the levee soils. Foundation problems in levees usually are caused by under-seepage and are related to geologic conditions at the site.

Through-seepage is not normally a major concern for levees constructed of clay soils unless flood stage is maintained long enough that the embankment becomes saturated; or when defects in the levee, such as animal burrows or desiccation cracks, allow concentrated flows. Seepage through levees consisting of silt and sand can produce erosion at the landside slope and lead to breaching of the levee if the seepage remains uncontrolled.

Seepage of water beneath a levee constructed on a highly erodible foundation of silt, sand, or gravel deposits, is more critical than through-seepage. Identifying erodible foundation soils is an important step in preventing bank failures. Because floodplain deposits underlie levees, knowledge of
the geology of local floodplain deposits is an important consideration in flood-control management. Levee systems are often built atop highly permeable, relatively coarse-grained river deposits. These sediments represent old channels and courses of the river system abandoned during the river’s history of meandering over the floodplain. These coarse-grained deposits represent the most likely locations for under-seepage in levee systems.

It is imperative that geologic features be identified in the earliest stages of a levee condition assessment so that other exploratory methods can be used to confirm their existence and map their distribution. Knowledge of fluvial processes and the ability to recognize depositional environments in the geologic record are the key to identifying locations along modern levees where under-seepage has the greatest potential to occur. To gain more information about the foundation materials, borings are usually placed at predetermined distances, sometimes hundreds of meters apart, along the levee axis. Through the performance of Standard Penetration Testing (SPT) during the drilling of borings, along with laboratory testing of soil samples, engineering soil properties as a function of depth at a given boring location are obtained; however, soils information between borings must be interpolated. In some geologic conditions, where there are gradual or rather predictable soil changes, the interpolations may be adequate. In areas where the geology is more complex, interpolating the soil properties or conditions between borings may not be adequate. In the case of a geologically complex site, many more closely spaced borings would have to be placed to define the subsurface conditions with sufficient detail for meaningful engineering judgment.

As an alternative to drilling very closely spaced borings, surface geophysical testing can be conducted between the more widely spaced borings to provide cost-effective geologic information. In 2003, personnel of the U.S. Army Engineer Research and Development Center (ERDC) conducted a proof of principle study along U.S. International Boundary and Water Commission levees in the Lower Rio Grande Valley of Texas (Dunbar et al. 2003). The study consisted of first conducting helicopter-borne electromagnetic surveys along the levees to obtain an overall assessment of soil conditions of the levees and their foundation materials. Anomalous areas were identified and investigated in greater detail using ground-based geophysical surveys, a cone penetrometer equipped with an electrical resistivity probe, and soil sampling. The study concluded that the method is eco-
nomical and reliable for assessing materials and condition of levees and their foundations.

Purpose and scope

Potential failure of levees in the Sacramento-San Joaquin delta of California has been identified as a critical engineering problem (Reid 2005, Hess and Sills 2004). Levees along the Feather River have experienced under-seepage during high-water events. Because of the complex geology in this area, it is difficult to predict where under-seepage is likely to occur, and thus where preventative or emergency measures should be prioritized. The purpose of this study was to determine the potential of geophysical methods to provide supplemental geologic data between existing borings rapidly, as would be desired for emergency situations, in a more complex geologic setting than where the concept was previously tested.

This report describes the results of a geophysical study conducted along a 10-km stretch of the Feather River levee south of Marysville/Yuba City, CA. The study was funded by the USACE’s Emergency Management Technologies focus area of the FCSDR research program.

Study area

The study was conducted along the landside (L/S) levee toe of the east bank of Feather River (Figure 1). The northern end of the site was located approximately 5 km south of Marysville, CA. The survey site extended south from the water treatment plant, located approximately 2 km south of Island Avenue, to just north of the Star Bend boat ramp. The north and south ends of the survey line correspond to approximate USACE Sta. 434+00 and Sta. 106+00, respectively. Positioning is also expressed in this report in river miles (RM). The north and south ends of the survey line correspond to approximate RM 23.8 and 17.5, respectively. The site is located within the Three Rivers Levee Improvement Authority’s Reclamation District 784.

Geologic setting

The study area lies within the upper Sacramento Valley portion of the Great Valley geomorphic province of California. The Sacramento Valley lies between the northern Coast Range to the west and the northern Sierra Nevada to the east, and has been a depositional basin throughout most of
the late Mesozoic and Cenozoic time. A vast accumulation of sediments was deposited during cyclic transgressions and regressions of a shallow sea which once inundated the valley. A thick sequence of clastic sedimentary rock units, derived from erosion of the adjoining highlands from the Late Jurassic to the Pleistocene, and Tertiary volcanics, form the bedrock units now deeply buried in the mid-basin areas of the valley. Late Pleistocene and Holocene (Recent) alluvial deposits now cover the area, consisting of reworked fan and stream material that were deposited by streams prior to the construction of the existing levees (Bookman-Edmonston 2006).

Levees in the upper Sacramento Valley were built on sedimentary deposits that reflect the changes in natural processes caused by human activity. The most recent deposits are sediments generated by hydraulic mining operations in the Sierra Nevada during the mid 1800s. These sediments cover portions of the floodplain with a thickness estimated to range from 3 to 5 m. The main sediment influx occurred between 1853 and 1884, but the maximum aggradation on nearby Yuba River at Marysville was delayed until 1905, where a total of nearly 6.5 m of aggradation was observed. By the late 1860s, aggradation was so extreme that the beds of the Yuba and Feather Rivers were higher than the city streets in Marysville. After mining ceased, the sediment supply was dramatically reduced and Feather River began to incise into the deposited hydraulic mining sediment. Incision continued until the 1960s when the bed began to rest upon pre-hydraulic material that was more resistant to erosion. As a result of the rapid aggradation and subsequent incision, the banks of Feather River are principally composed of hydraulic mining material. The lowest mining deposits (called slickens) are relatively resistant to erosion whereas the upper mining materials are relatively less cohesive and more erodible. Thus, levees were constructed on foundations that are less than ideal in that the materials are coarse grained and laterally discontinuous, an environment in which interpolation between borings can be meaningless. Beneath the mining deposits, the upper native alluvial materials are relatively resistant to erosion, but they are underlain by less erosion resistant sediments (USACE 2006).
Figure 1. Location and layout of geophysical survey line, east bank, land side toe of the Feather River.
2 Geophysical Test Principles and Field Procedures

This section provides a description of the surface geophysical methods and field procedures used for this study. The geophysical methods used include electromagnetic (EM) induction, capacitively coupled electrical resistivity (CCR), and direct current (dc) electrical resistivity.

Geophysical measurements were acquired along a survey line adjacent to the levee toe. The measurements were interpreted to infer lateral and vertical geologic changes beneath the survey line. Also, anomalous areas, which are departures from background conditions, were noted for further exploration.

Each geophysical method uses different physical principles to determine the electrical properties of the subsurface materials. Therefore, each survey method is affected differently by the subsurface material properties and, consequently, each survey type may indicate different anomaly locations. When the surveys are completed, anomalies may be identified for each geophysical method. By using different geophysical methods, areas considered for future exploration can be prioritized on the basis of the number of surveys that agree that a particular location is anomalous. For example, if three different survey methods indicate that a certain area is anomalous, then that area is given a higher priority for future exploration over an area that is considered anomalous on the basis of only one survey method.

Electromagnetic surveys

EM induction is used to measure the apparent electrical conductivity (inverse of electrical resistivity) of subsurface materials and also for detecting buried metallic items. Electrical conductivity is a measure of the degree to which the soil conducts an electrical current and can be used to infer geologic materials and the location of the water table. Conductivity values vary over several orders of magnitude depending on the type of earth material (Table 1). Major factors influencing the conductivity measurement are the amount of pore fluid present, the salinity of the pore fluid, the presence of conductive minerals, and the amount of fracturing.

Source: Keller and Frischknecht 1966.

Table 1 gives the conductivity values of common rocks and soil materials. Sedimentary rocks, because of their higher porosity and greater water content, have higher conductivity values than intact igneous and metamorphic rocks. Wet soils and groundwater have even higher conductivity values. Clayey soil normally has a higher conductivity than a sandy soil (Locke 2000a).

The instrumentation used to measure soil conductivity consists of a transmitter (Tx) and receiver (Rx) coil separated by a certain distance. An alternating current is passed through the Tx coil, thus generating a primary time varying magnetic field. This primary field induces eddy currents in subsurface conductive materials. The induced eddy currents are the source of a secondary magnetic field, which is detected by the Rx coil along with the primary field.

Two components of the induced magnetic field are measured by the EM system. The first is the quadrature phase, sometimes referred to as the out-of-phase or imaginary component. Apparent ground terrain conductivity is determined from the quadrature component. Disturbances in the subsurface caused by compaction, filled-in abandoned channels, soil removal and fill activities, buried objects, or voids may produce
conductivity readings different from background values, thus indicating anomalous areas. The inphase component is very sensitive to metallic objects and, therefore, is useful when looking for buried metal such as metal rails, rebar, or electrical wires.

Geonics Ltd. EM31 and EM34 and a Geophex GEM-2 EM induction instrument were used in this investigation. The Tx and Rx coils for the EM31 were set at a fixed distance of 3.67 m. The EM31 has a nominal depth of investigation of about 6 m. The EM31 was placed on an electrically non-conductive sled and towed behind a vehicle along the survey line at a normal walking speed to acquire continuous (approximately every 0.3 m) data. The data were transmitted to an external logger via an RS-232 data link, thus allowing the unit to be integrated into a GPS- (global positioning system) based survey system. A Trimble AG-132 GPS, in conjunction with the Omnistar satellite differential positioning information service, was used to obtain sub-meter positioning accuracy. The data can be plotted in profile form showing conductivity values versus distance. The EM31 is shown in operation in Figure 2.

![Figure 2. Sled-mounted Geonics Ltd. EM31 EM induction instrument being used during a typical survey.](image)
Unlike the EM31 with a fixed coil separation, the EM34 can be operated at Tx-Rx coil separations of 10, 20, or 40 m. The greater the Tx-Rx coil separation, the greater is the depth of investigation. EM34 data are collected in the vertical dipole mode (coils parallel to the ground surface) or in the horizontal dipole mode (coils perpendicular to the ground surface and coplanar). The vertical dipole mode allows for a greater depth of investigation and is less sensitive to near-surface materials. For this investigation, the vertical dipole mode and coil separations of 10, 20, and 40 m were used, which allows for nominal depths of exploration of about 15, 30, and 60 m, respectively (McNeil 1980). Sleds were specially designed and constructed for this study using electrically non-conductive materials. The sled system allows the EM34 coils to sample data several times per second while being towed along the survey line. The sled system consists of three sleds, one each for the EM34 transmitter and receiver coils and one sled for the GPS placed halfway between the other two sleds. Ropes were used between the sleds to keep them a constant distance apart during the survey. Figure 3 shows the EM34 in operation. Data along the profile lines were collected approximately every 0.3 m. In contrast, a hand-carried EM34 usually results in coarser (larger) data spacing.

The GEM-2 is a handheld, digital, multi-frequency EM induction instrument (Won 2003). It operates in a specified frequency range of 330 Hz to 48 kHz with a waveform containing multiple frequencies. The GEM-2 contains Tx and Rx coils separated by 1.67 m (Figure 4). It can also collect data in the horizontal or in the vertical dipole mode. A selectable set of frequencies is used to measure changes in electrical conductivity as the instrument is moved along the survey line. A GPS was used with the GEM-2 to provide real-time position information. The exploration depth of EM instruments varies as a function of frequency and ground conductivity. All other factors being equal, low frequency EM signals have greater exploration depths than higher frequency signals. For a given frequency, resistive ground has a greater exploration depth than conductive ground (Keller and Frischknecht 1966, Huang 2005). Therefore, the 330-Hz data will theoretically have a greater exploration depth than the 48-kHz data. The program WinGEM, available from Geophex, was used to convert the GEM-2 quadrature and inphase data to units of electrical conductivity.
dc electrical resistivity surveys

Electrical resistivity measurements are made by injecting current into the ground through two current electrodes (C1 and C2) and measuring the resulting voltage difference at two potential electrodes (P1 and P2). From the current and voltage values, an apparent resistivity value is calculated. The calculated resistivity value is not the true resistivity of the subsurface, but an apparent value because the subsurface is non-homogeneous. The relationship between apparent and true resistivity is complex. A mathematical analysis or an inversion of the measured apparent resistivity values using a computer program is performed to determine the true resistivity. The inversion program RES2DINV (Geotomo Software, Locke 2000b) was also used to process the resistivity data.

The arrangement of the electrodes used for this survey is shown in Figure 5. The spacing between the current electrodes pair, C1-C2, is given as “a,” which is the same as the distance between the potential electrodes
Figure 4. A sled-mounted Geophex GEM-2 multi-frequency EM induction instrument being prepared for surveying.

Figure 5. The Dipole-Dipole electrical resistivity profile array.

This array has another factor marked as “n*a” in Figure 5. This is the ratio of the distance between the C2 and P1 electrodes to the C1-C2 (or P1-P2) dipole separation “a.” For surveys with this array, the “a” spacing is initially kept fixed and the “n” factor is increased from 1 to about 6 in order to increase the depth of investigation. The dipole-dipole array is very sensitive to horizontal changes in resistivity but relatively insensitive to vertical changes in the resistivity. Consequently, the dipole-dipole array is good in mapping vertical structures but relatively poor in mapping horizontal structures such as sills or sedimentary layers. The
One possible disadvantage of this array is the very small signal strength for large values of the “n” factor. The voltage is inversely proportional to the cube of the “n” factor. This means that for the same current, the voltage measured by the resistivity meter drops by about 200 times when “n” is increased from 1 to 6. One method to overcome this problem is to increase the “a” spacing between the C1-C2 (and P1-P2) dipole pair to reduce the drop in the potential when the overall length of the array is increased to increase the depth of investigation.

A Scintrex Automated Resistivity Imaging System (SARIS) (Scintrex Ltd.) was used in this investigation (Figure 6). A resistivity cable providing the ability to connect to 25 electrodes was connected to the meter. An “a” spacing of 5 m and “n” factors of 1 through 6 were used to collect the data. A roll-along method was used to advance the profile line. The sequence of measurements, array type, and other survey parameters were entered into the SARIS resistivity meter. A program in the meter then automatically selected the appropriate electrodes for each measurement. The measurements were taken in a systematic manner and all possible measurements were made. At the end of the survey, the data were transferred to a computer for further processing.

**Capacitively coupled conductivity surveys**

An instrument using the CCR principle of operation was also used in this investigation to collect soil conductivity information. The CCR principle of operation is very similar to the dc resistivity method. Instead of using metal electrodes that have to be hammered into the ground as a means to inject current into the subsurface, as is the case in dc resistivity surveying, the CCR method capacitively injects the current into the ground. A transmitter electrifies two coaxial cables (transmitter dipole) with a 16.5-kHz alternating current (ac) signal. The dipole electrodes consist of coaxial cables in which the coaxial cable shield acts as one plate of a capacitor and the earth as the other plate. A matched receiver, automatically tuned to the transmitter frequency, measures the associated voltage picked up on the receiver’s dipole cables. The receiver then transmits a voltage measurement, normalized to current, to the logging console.
A Geometrics OhmMapper capacitively coupled resistivity system was used to collect the resistivity data. The system used in this investigation can use from one to five receivers allowing for multiple n-spacings to be collected per survey pass. Figure 7 shows the OhmMapper being used at the Feather River site with a five-receiver setup and being vehicle-towed. The “a” spacing or dipole length was 5 m and “n” factors of 3.0, 3.5, 4.0, 4.5, and 5.0 were used. Using this configuration the length of the array was in excess of 35 m. The OhmMapper was set to collect data once every second. Data positioning was achieved by means of a GPS. The data were collected at a slow walking pace of approximately 2 km/hr.

At the end of each survey, field data were transferred to a laptop computer for analysis. The data were analyzed using program MagMapper 2000 (Geometrics 2004) to ensure the proper geometry of the survey lines. MagMapper was also used to convert the resistivity data into a format compatible with the resistivity inversion program RES2DINV.
Figure 7. Geometrics OhmMapper capacitively coupled resistivity system being vehicle-towed.
3  Geophysical Test Results, Interpretation and General Discussion

Geophysical test results

EM31 and EM34 results

Data were collected in approximately 3 days using the EM31 and EM34. Because this was the first time this sled system had been used, considerable part of this time was spent configuring it for the different EM34 Tx-Rx coil separations. The sled system worked well in this environment and no major problems were encountered while towing. Not having wheels on the sleds kept them from running into each other when the tow vehicle slowed down or stopped along the survey line. At some road crossings and when inaccessible areas were encountered, the sled system had to be dismantled, hauled to the next start location, and set up again.

The EM31 and EM34 electrical conductivity results are presented together in three fashions: (a) plan view, (b) profile format, and (c) as a pseudosection, shown in Appendix A, B, and C, respectively. The plan views (Appendix A, Figures A1–A20) show a color-coded representation of the subsurface electrical conductivity along the survey line. Plan views are presented for the EM31 and EM34 (10-, 20-, and 40-m) data, which provide conductivity information for different depths of investigation. The plan views are superimposed on digital aerial images and provide a spatial sense of where anomalous conditions exist. Comparison of the different plan views for a given location shows how conductivity values vary as a function of depth (coil separation).

The profile plots (Appendix B, Figures B1–B18) show the electrical conductivity readings collected for the EM31, as well as for each EM34 intercoil configuration, versus Universal Transverse Mercator (UTM) northing. With the exception of Figure B1, which covers a distance of 650 m, each figure covers a distance of 500 m.

The pseudosections (Appendix C, Figures C1–C18) present a two-dimensional (2-D) representation of the subsurface conductivity values. Data for apparent conductivity from the EM31 and EM34 are contoured on the assumption that the EM31 has a nominal depth of investigation of 3 m
and that the EM34 intercoil spacings of 10, 20, and 40 m have nominal depths of investigation of 15, 30, and 60 m, respectively. The contoured values shown in the pseudosections are apparent conductivities and not true conductivities. Although the pseudosection may not present true conductivity values or accurately portray layering depth, they are useful in determining general trends and the locations of anomalous areas. To produce an image of true depth and true formation conductivity, the observed data must be processed using an inversion algorithm.

In general, the EM data show that the greater the depth of investigation i.e., longer intercoil spacing, the greater the conductivity values. Table 2 shows average and median conductivity values increasing as a function of coil separation (depth). This indicates that there is a general trend of finer grained materials increasing with depth. Electrical conductivity is a positive valued parameter; however, because of instrument design negative values are measured when passing over a metallic object.

The plots shown in the appendixes use the same linear color bar scale, which allows for direct comparison of conductivity values for the different plot types. The red and pink colors are relatively high conductivity values associated with clayey soil, whereas the dark green and blue colors, low conductivity values, are indicative of a soil with a greater proportion of sands and gravels.

The EM31 data, which have a depth of investigation of approximately 6 m, show an area of relatively high conductivity materials at the northern end of the survey site (Figure A1). The data south of approximate Station 4327000 are generally green and blue in color, representative of materials that are predominantly sands and gravels (Figures A2–A4). At the extreme southern end of the survey line there is a pink-colored zone indicating a clayey area (Figure A5). The EM34 10-m data, Figures A6–A10, are in general the same or show slightly higher conductivity values.

</table>
than the EM31 data, indicating no significant material type differences between the upper 6 and 15 m. The 20- and 40-m plan view data show a slight general increase in conductivity values as compared to the EM31 and EM34 10-m data, indicating an increase in silt and/or clay between approximate depths of 30 and 60 m (Figures A11–A20). A predominant, relatively low, conductivity area indicated by the EM31, EM34 10-m and EM34 20-m data occurs from approximately Anderson Ave., Station 4322200, south to the approximate location of a water pumping plant near Station 4319775.

Referring to Figure B1, the conductivity values show some variability. Between Stations 4328150 and 4328100, there is an indication that the near surface materials (upper 15 m) are quite clayey compared with the near surface materials encountered along the rest of the survey line. Between Stations 4327950 and 4327850, the EM31 and the EM34 10-m profile lines show relatively low conductivity readings, indicating the presence of a layer of coarse-grained materials in the upper 15 m. Of particular interest is the anomalous area between Stations 4327475 and 4327150 (Figure B2). There is a very significant positive-valued spiking of all the EM data. The EM31 and the EM34 10- and 20-m surveys show three distinct spikes centered on Stations 4327400, 4327280, and 4327180, whereas the EM 34 40-m data show one very broad spike between Stations 4327475 and 4327250 and a much smaller one centered at Station 4327180. The broad, relatively high conductivity spike is an indication of an increase in conductive (fine-grained) materials with depth. This may be caused by a clay-filled abandoned channel. The area between approximate Stations 4327900 and 4327250 show higher conductivity values (more fine-grained material) in comparison to the rest of the survey line. Between approximate Stations 4327000 and 4322800, the readings for the EM31 and the three EM34 spacings are fairly consistent with some localized fluctuations (Figures B3–B11). Along this stretch, the EM31 and the EM34 10-m readings range roughly between 10 and 30 mS/m, the EM34 20-m readings range between approximately 35 and 40 mS/m, and the EM34 40-m readings range between approximately 40 and 50 mS/m.

Between approximate Stations 4322800 and 4320000 (Figures B11 and B16), the conductivity values show a general decline. In this area, the EM31 and the EM34 10-m readings range roughly between 10 and 20 mS/m, the EM34 20-m readings range between approximately 20 and 30 mS/m and the EM34 40-m readings range between
approximately 30 and 40 mS/m. This area exhibited the lowest conductivity values of the entire survey line. It is presumed that this is an area with extensive sands and gravels.

Between approximate Stations 4320000 and 4319000 (Figures B17 and B18), the conductivity values for the EM31 and the EM34 10- and 20-m readings show a general increase. The EM34 40-m conductivity values in this area are about the same as the previous area to the north. It appears that fine-grained materials in the upper 20 m may be increasing in this area. The conductivity values of the deeper materials interrogated by the EM34 40-m test show values of about 40 mS/m, which are higher than the previous area to the north but not as high as the northern portion of the survey line.

**GEM-2 results**

User-selected GEM-2 frequencies for this survey were 9810, 6390, 1590, and 390 Hz and were chosen to correspond with the EM31 (9800-Hz), EM34 10-m (6400-Hz), 20-m (1600-Hz), and 40-m (400-Hz) intercoil spacings, respectively. It took approximately 1 day to collect the GEM-2 data. The GEM-2 results are plotted in profile fashion and to the same scale as the EM31 and EM34 plots to aid in comparing the results of the three different instruments (Appendix D). The GEM-2 390-Hz data are not shown because the data were too noisy. The 9810- and 6390-Hz data are almost identical with the main difference between the two frequencies being that the 9810-Hz data are consistently about 1 to 2 mS/m less than the 6390-Hz data. The 1590-Hz GEM-2 data do not appear to realistically represent the conductivities of the subsurface materials but they do respond very well to nearby metallic features. The GEM-2 9810-Hz and 6390-Hz profile data closely match the EM31 and EM34 10-m data. Table 3 presents some selected statistical values for the four GEM-2 frequencies. The table shows that the median values for the 9810-Hz and 6390-Hz data compare favorably with the EM31 and EM34 10-m median values.

The GEM-2 survey was run to obtain conductivity versus depth data and to compare with the EM31 and EM34 data. Unfortunately, because the 1590-Hz and the 390-Hz data are considered to be unreliable and the difference between the 9810- and 1590-Hz data generally varies by only

1 to 2 mS/m, the relationship of changes in soil type as a function of depth cannot be determined. Because the only two GEM-2 frequencies that appear to have realistic results are the 9810- and 1590-Hz data, the most similar frequencies to the EM31 and EM34 10-m spacing, it would be reasonable to assume that the GEM-2 data are providing conductivity values for the upper 5 to 15 m of material.

The GEM-2 data show relatively elevated conductivity values ranging generally between 30 and 100 mS/m between approximate Stations 4328100 and 4327000 (Figures D1 and D2). There is one exception to these high conductivity values occurring at approximate Station 4327900 where there is an anomalously low conductivity area with an approximate conductivity range of 10 to 15 mS/m. With the exception of the anomalously low conductivity area, one should expect a relatively high proportion of silty and/or clayey material in the upper 5 to 15 m between Stations 4328100 and 4327000. Between approximate Stations 4327000 and 4326600 (Figures D2 and D3), conductivity values are fairly consistent with values ranging between 15 and 20 mS/m, indicating the presence of rather coarse materials. Between approximate Stations 4326600 and 4326250, it is presumed that the percentage of sands and gravels in the upper 5 to 15 m increases because the conductivity values drop to about 5 to 10 mS/m (Figures D3 and D4). Conductivity values between approximate Stations 4326250 and 4324500 generally have values between 20 and 30 mS/m (Figures D4–D7). In this section, there are some areas where conductivity values exceed 30 mS/m, but only for relatively short distances. Between approximate Stations 4326050 and 4325700, there are numerous large spikes that are presumably caused by metallic debris visible on the ground surface (Figures D4 and D5). The large spikes observed at approximate Stations 4325275, 4325115, 4325075, and 432500 are probably caused by buried metallic irrigation pipes (Figure D6). The spike at Station 4325170 is caused by a vertical 1.2-m-diam corrugated steel standpipe located about 2 to 3 m west of the survey line. Another area with
relatively large spiking values is encountered between Stations 4324125 and 4324300, and it is an area where there are many visible trash piles adjacent to the survey line (Figure D8). South of Station 4324300 to about Station 4323100 conductivity values range roughly between 10 and 20 mS/m (Figures D9 and D10). Between Stations 4323100 and 4322950, just to the north of Broadway Road, there is an area with fairly high conductivity values of about 80 mS/m (Figures D10 and D11). South of this area, a relatively high conductivity area to Anderson Avenue, Station 4322200, conductivity values range between approximately 20 and 30 mS/m (Figures D11 and D12). With the exception of an area between Stations 4321750 and 4321650 with conductivity values of about 25 mS/m, the area between 4322000 and 4321500 has relatively low conductivity values ranging between approximately 5 and 15 mS/m, indicative of sandy and/or gravelly material (Figure D13). The conductivity values encountered in this area are some of the lowest for the entire survey line. Another area with relatively low conductivity values ranging between 10 and 20 mS/m is found between Stations 4321050 and 4320000 (Figures D14–D16). Between Station 4320000 and the south end of the survey line, conductivity values are significantly higher generally ranging between 20 and 40 mS/m (Figures D17 and D18).

**OhmMapper results**

The results of the OhmMapper CCR survey are shown in Appendix E (Figures E1–E18). The data are presented as a 2-D cross section with northing shown along the X-axis and depth along the Y-axis. In these cross sections, the contoured values represent the true electrical conductivity. The OhmMapper transmitter-receiver distances used in this investigation provided conductivity information for depths between approximately 1 and 11 m. Whereas the EM data provide a greater depth of information at the expense of being able to resolve relatively small subsurface features, the OhmMapper provides detailed conductivity information in the upper 11 m, thus complementing the EM data. Even with an array in excess of 35 m in length, the array tracked well behind the tow vehicle. The shallow ruts in the unpaved levee-toe road appear to have helped keep the array on track especially around curves.

The OhmMapper data compare favorably with the results of the EM data. Between approximate Stations 4328000 and 4326950, there is a fairly thin, approximately 5-m thick, layer with low conductivity values overlying a much higher conductivity valued layer (Figures E1–E3). This is the same
area where relatively high conductivity values are detected with the EM instruments. Between approximate Stations 4326950 and 4323150, the materials in the upper 5 to 10 m generally have conductivity values that increase with depth and range between approximately 5 and 25 mS/m (Figures E3–E10). In this area, zones of higher conductivity materials are detected at depths greater than 10 m. Between approximate Stations 4326600 and 4326450, the true conductivity values in the upper 11 m are extremely low and do not exceed 5 mS/m (Figures E3 and E4). These low conductivity values are indicative of loose sandy and/or gravelly material. Between approximate Stations 4323150 and 4322600, the conductivity values in the upper 11 m appear to increase slightly, suggesting an increase in fine-grained material in this area (Figures E10 and E11). With the exception of an area between Station 4321800 and 4321700, the area between approximate Stations 4322550 and 4320000 generally exhibits rather low true conductivity values of less than 25 mS/m (Figures E11–E16). Conductivity values tend to increase south of Station 4320000, indicating an increase in fine-grained soil.

SARIS results

A 1055-m-long dc electrical resistivity line was run near the northern end of the site between approximate Stations 4327744 and 4326795. Inversion results provide conductivity information between approximate depths of 1 and 8.5 m. The dc resistivity survey method is the slowest and most labor intensive of all of the survey methods used in this investigation; however, it provides very detailed lateral and vertical material information. The approximate 1-km-long dc resistivity line took about 1 day to collect. An inspection of the data showed considerable noise that is presumed to be caused by the high contact resistance between the ground and the resistivity electrodes. The data points considered to be “bad” were removed prior to processing.

The dc resistivity results are shown in Appendix F (Figures F1–F3). Between approximate Stations 4327700 and 4327450, the conductivity values are less than 25 mS/m in the upper 2 to 3 m and are underlain by more conductive (clayey) materials (Figures F1 and F2). However, between Stations 4327450 and 4327200 (Figure F2), the conductivity values are greater than 50 mS/m in the upper 2 m and are underlain by less conductive materials. Further to the south along the survey line, between approximate Stations 4327000 and 4326800 (Figure F3), the conductivity values
are generally less than 10 mS/m, indicative of dry sandy soil in the upper 8.5 m.

**Interpretation of results**

The results of the EM, OhmMapper, and dc resistivity surveys, in general, agree very well. Soil distribution maps for the survey site were created based on an interpretation of the geophysical data (Figures 8 through 10). Six soil classes were used to create the maps; sand/gravel (<10 mS/m), sand (10–19 mS/m), silt/sand (20–34 mS/m), silt (35–49 mS/m), silt/clay (50–59 mS/m), and clay (>59 mS/m). The site can be generally be characterized as consisting of sands and gravels from the surface to depths of approximately 5 to 15 m underlain by silt/sand and silt to depths of approximately 40 to 50 m, which in turn are underlain by silt/clay.

The survey results also indicate seven anomalous zones (Table 4). Anomalous Zone I extends from the north end of the survey line, Station 4328000, south to approximate Station 4327450 (Figure 8). Anomalous Zone I is an area with a thinning, or an absence, of low conductivity soil in the near surface which is replaced with predominantly higher conductivity soil. Nearby borings indicate the presence of shallow, thick clay lenses and/or layers. These clays are the probable cause for the higher conductivity values found in Zone I.

![Interpreted Soils Map](image-url)
The second anomalous zone, Zone II, is located between approximate Stations 4327450 and 4327250 and is an area of relatively high soil conductivity as shown in Figure 8. The high conductivity soil is interpreted as clay, which extends from the very near surface to a depth exceeding 60 m.

</tbody>
</table>

Figure 8 shows the location of anomalous Zone III, which extends between approximate Stations 4326600 and 4326150 and has extremely low (less than 10 mS/m) conductivity values in the upper 10 to 15 m. These low conductivity values are indicative of a zone of dry coarse soil such as sand and/or gravel. Borings near this zone show that the predominant soils are sand and silty sand that extend to depths of approximately 10 m. These
soils are underlain by gravels and sands that are about 6 to 8 m thick. The sands and gravels are underlain by clays and silts.

Anomalous Zone IV consists of three positive-valued conductivity spikes located between approximate Stations 4325275 and 4325080 (Figure 8). The data spikes are presumed to be caused by metallic pipes buried beneath or adjacent to the survey line.

Anomalous Zone V, shown in Figure 9, is an area located north of Broadway Road, between approximate Stations 4323050 and 4322950, exhibiting relatively high conductivity values. The anomalous zone is approximately 100 m in length and about 5 m deep and is interpreted as being composed chiefly of clay.

The most extensive anomalous zone, Zone VI, is located between approximate Stations 4322200 and 4319800, which corresponds roughly to the area between Anderson Avenue and a pumping plant located at approximate Station 4319775 (Figure 10). This zone consists of a layer of low conductivity soil with values of less than 20 mS/m, which extends to a depth of approximately 20 to 30 m and which is underlain by soils exhibiting conductivity values of 20 to 35 mS/m to depths in excess of 60 m. The uppermost layer is interpreted as consisting of sand and gravel soil whereas the underlying soil is interpreted as consisting of silt and sand. Boring logs from this area show silty sands, sands, silts, and clays in the upper 3 to 4 m. Underlying soils consist of sands and gravels with a combined thickness of approximately 8 to 18 m which are underlain by clay. High conductivity values, which would be anticipated for the surficial clays and silts, were not measured probably because they are relatively thin and thus do not contribute significantly to the overall signal and/or because the lack of moisture in these materials causes them to exhibit low conductivity values.

Anomalous Zone VII (Figure 10) is located at the southern end of the survey line between approximate Stations 4319150 and 4319000. This is an area with anomalously high conductivity values. This is presumed to be a zone with an abundance of clay soil approximately 20 m thick.

It is noted that the soil classes shown in the interpreted soil maps (Figures 8 through 10) depict average soil types. The conductivity values obtained from the geophysical surveys used in this study are a volume-averaged
conductivity. For example, the area under the survey line may consist predominantly of sand with interbedded thin clay and silt layers. Because the volume of the clay and/or silt is much less than that of the host sand, the clay and silt layers make a small contribution to the measured conductivity values. The surveyed area exhibits low conductivity values and is interpreted as sand. As the amount of silt and clay increases, the conductivity values correspondingly increase and the soil class would then be interpreted as one with greater fines, i.e., silt/sand. Also, the greater the depth of investigation for a geophysical instrument the greater is the volume of soil being measured. This means that, as the depth of investigation increases, the ability to resolve relatively small features decreases. Conversely, small features can be more easily resolved at relatively shallower depths of investigation. This explains why relatively small features are interpreted only in the near-surface in Figures 8–10.

**General discussion**

The Geonics EM and the OhmMapper instruments are considered the most useful in characterizing this site (Feather River, Marysville/Yuba City, CA) because of their ability to provide electrical conductivity data for various depths and rapid data acquisition rate. The dc electrical resistivity provides very detailed information between depths of approximately 1 and 8 m; however, the slow data collection rate, as compared with the EM and CCR surveys, and high contact resistance problems make this a secondary survey method for this site. It is noted that all the surveys were conducted using a two-person field crew. An increase by one or two field personnel would significantly increase the rate at which dc resistivity readings could be collected and slightly increase the EM and CCR data collection rate.

In this investigation the EM34 was used with the coils parallel to the ground surface (vertical dipole) using three intercoil spacings, thus providing conductivity information at estimated depths of 15, 30, and 60 m. By configuring the coils perpendicular to the ground surface and coplanar, horizontal dipole data could be collected for three additional depths. The depth of exploration is 0.75 times the intercoil distance when the EM34 is used in the horizontal dipole mode (McNeil 1980). This would allow conductivity values for three additional depths, for a given location, to be input into an inversion program. The inversion program could then output true electrical conductivity values and layer depths, thus allowing conductivity depth sections to be plotted. Similarly, the EM31 can also be used with horizontal dipoles simply by rotating it 90 deg about its long axis. The
combination of the EM31 and EM34 used in horizontal and vertical dipole modes can provide eight conductivity values per location, which would improve the inversion results.

The OhmMapper CCR instrument proved to be very effective in mapping soil conductivity values. The instrument, as configured in this survey, provided conductivity data between depths of approximately 1 and 11 m. The five-receiver version of the OhmMapper used in this investigation made it possible to collect sufficient data in one survey pass to produce conductivity depth sections. The software provided with the OhmMapper was used to convert the collected data into a format compatible with the inversion program RES2DINV. The very low conductivity soils encountered at this site were ideal field conditions for the OhmMapper. The 35-m-long array used in this survey tracked well behind the tow vehicle along the slightly rutted unpaved levee-toe road. The tire ruts in the sandy road acted as a guide for the instrument array.

The GEM-2 did not perform well. It was hoped that the GEM-2 would provide enough information to make it possible to perform an inversion of the data. Only two of four programmed frequencies, 6390 and 9810 Hz, were regarded of any use, and they showed nearly identical results. No conclusions on how soil conductivity varied as a function of depth could be made from the values collected with this instrument. Information from only two frequencies is not sufficient to perform an inversion of the data. However, the GEM-2 is useful for mapping lateral conductivity differences. The data from the other two frequencies used, 1590 and 390 Hz, were noisy and unusable. It is not known whether these frequencies are beyond the instrument’s capabilities for this site or whether lack of experience in using the GEM-2 by the field researchers may have contributed to the collection of poor data.

This study shows that geophysical surveys are useful for rapidly mapping long reaches of levees. This site was particularly amenable to the geophysical methods used because of good site access, no vehicular traffic, minimal interference from cultural features, and low electrical conductivity soils. It is important to have good access to the levee toe for long uninterrupted stretches to prevent data gaps, make interpretation of test results easier, and minimize the time to break down and set up equipment when circumventing obstacles along a survey line. EM geophysical survey methods, such as used in this study, are prone to
interference from nearby metallic objects (such as buildings, cars, and culverts) and power lines; this interference is referred to as cultural clutter. Survey lines that run through areas with large amounts of cultural clutter, such as found in a highly urbanized environment, may prove to be problematic for EM methods. In such cases, other methods that are less susceptible to cultural clutter may have to be used. These include dc resistivity, CCR, and seismic surveying methods.

The EM34 conductivity meter is the instrument that has the greatest depth of investigation potential. At sites having ideal soil conditions (soil conductivity values less than 10 mS/m) the EM34 has a depth of investigation of approximately 60 m. However, as soil conductivity values increase, the depth of investigation decreases.

Geophysical data can be arranged, by conductivity value, into different classes or ranges that, when correlated to nearby borings, can be used as a means to classify soil. By examining the EM pseudosections and electrical conductivity plots, presented in the appendixes, geotechnical engineers and geologists can visualize the lateral and vertical extent of the different soil types at the site.

Also, during this study, an emergency management exercise was conducted. As part of the exercise, geophysical data were collected along the levee toe during a simulated flooding event, electronically uploaded from the field to the USACE’s Integrated Levee Assessment Utility Web site, and saved in a database. The data were tabulated and made accessible in near real-time via the Web to emergency operations personnel. Anomalies along the survey line, suggesting areas of sands and gravels, which are prone to under-seepage, were quickly identified. The exercise showed that providing access to near real-time data, regarding levees and levee foundation conditions, to emergency operations personnel can allow for enhanced situational awareness during times of crisis. Figure 11 shows an example of the type of data available from the USACE Web site.
Figure 11. Example of a portion of EM34 data plot posted on the Integrated Levee Assessment Utility Web site.
4 Conclusions and Recommendations

Conclusions

Geophysical surveys were conducted along the Feather River levee approximately 5 km south of Marysville/Yuba City, CA, during the period 14–21 June 2006. The purpose of this study was to determine the potential of rapidly assessing levee foundations using geophysical methods. The study was funded by the USACE’s Emergency Management Technologies focus area of the FCSDR research program.

The test site was located on the landside toe of the levee on the east side of the Feather River. The survey site extended south from the water treatment plant located approximately 2 km south of Island Avenue, to just north of the Star Bend boat ramp. The approximate northern and southern UTM coordinates, in meters, of the survey site are 622435, 4328000 and 622802, 4319000, respectively. The north and south ends of the survey line correspond to approximate USACE Sta. 434+00 and Sta. 106+00, respectively. The north and south ends of the survey line correspond to approximate RM 24.9 and 18.0, respectively. The site is located within Reclamation District 784. The materials underlying the site are alluvial in nature and consist of clay, silt, sand, and gravel.

Three geophysical survey methods were used to collect soil conductivity information: electromagnetic (EM) induction, capacitively coupled electrical resistivity, and direct current electrical resistivity. Boring logs from nearby borings were used to correlate soil type with soil electrical conductivity values. Soil conductivity maps were generated and used to infer soil type and anomalous conditions to depths of approximately 60 m along the 10-km-long survey line. Geophysical data to sufficiently characterize this site can be collected in approximately 1 day.

The combination of the geophysical instruments used in this survey provided useful data, which were used to assess soil type along the survey line. The interpreted survey data indicate that, in general, the site consists of dry silty sandy material from the surface to approximately 10 m in depth. These soils are interpreted to be underlain by material that is more clayey in nature. Seven zones with anomalous survey results were interpreted. The first anomalous zone (Zone I), which extends from the north end of
the survey line (UTM coordinate 622435, 4328000) south to approximate UTM coordinate 622297, 4327450, consists of a 20-m-thick layer of silt overlying soil materials with a higher clay content. Anomalous Zone II (located between coordinates 622297, 4327450 and 622187, 4327250) is interpreted as an extensive clay lens that is approximately 100 m long and 60 m deep. The third zone (Zone III) extends between approximate UTM coordinates 621851, 4326600 and 621660, 4326150. The soils in this area are interpreted as consisting chiefly of sands and/or gravels in the upper 10 to 15 m and underlain by clays. The fourth anomalous zone (Zone IV) extends between UTM coordinates 621208, 4322200 and 621167, 4325080. There are numerous positive-valued electrical conductivity spikes within this zone, presumably caused by buried metallic pipes. Anomalous Zone V (located between approximate coordinates 620994, 4323050 and 620990, 4322950) is composed chiefly of clay soil that extends from the surface to a depth of approximately 5 m. Anomalous Zone VI is located between approximate coordinates 621017, 4322200 and 622030, 4319800 or roughly the area between Anderson Avenue and south to Pump Station No. 3. This anomalous zone indicates a high proportion of sands and gravels from the surface to depths in excess of 30 m. This is an area where the levee failed in 1997. Anomalous Zone VII is located at the southern end of the survey line between approximate coordinates 622631, 4319150 and 622802, 4319000. This anomalous zone is presumed to consist of clay soil approximately 20 m thick. The geophysical interpretations were compared with nearby borings, which were mainly located along the crest of the levee, and showed very good agreement.

Two Geonics Ltd. EM conductivity meters (Geonics EM31 and EM34 conductivity meters), a Geometrics OhmMapper CCR system, a Geophex GEM-2 EM induction tool, and a Scintrex dc resistivity system were used to collect electrical conductivity data. The use of a vehicle-towed sled-mounted EM34 using three different intercoil spacings and the ability to collect continuous data made it possible to rapidly collect information at different depths of investigation. This allowed inferences about material type changes to be made laterally, as well as vertically. Estimated depths of exploration for the EM31 and the EM34 10-, 20-, and 40-m intercoil spacings are 6, 15, 30, and 60 m, respectively.

The OhmMapper CCR system provided detailed depth and electrical conductivity information between depths of 1 and 11 m for this site. Although
the OhmMapper may have a depth of exploration less than that of the EM34, the five-receiver model used in this investigation has the advantage of being able to collect sufficient data in one survey pass to rapidly produce a conductivity depth section using a commercial resistivity inversion program.

Data collection problems encountered with the Geophex GEM-2 EM instrument prevented an inversion of the data to be performed. Only two of four programmed frequencies were considered useful, and they showed nearly identical results. The GEM-2 data were useful in determining lateral but not vertical soil variability. The depth of investigation for the GEM-2 is unknown.

**Recommendations**

Based on the results of this investigation, the following recommendations are made:

1. Conduct further studies using the Geonics EM31 and EM34 with horizontal and vertical dipole configurations. This should provide sufficient data for use in an inversion program.
2. Modify the EM34, making it possible to obtain data from the three different intercoil distances and both dipole configurations in one survey pass.
3. Identify commercial off-the-shelf inversion programs or take steps to develop a computer program that can quickly invert EM31 and EM34 data.
4. Identify sources of alternative ground-based multi-coil frequency-domain EM induction systems for testing.
5. Perform further studies using the Geophex GEM-2 EM induction instrument to determine depth of exploration capabilities and to provide resistivity depth sections.
6. Georeference all soil borings within a survey area. Much of the boring information that exists is referenced to stationing, river miles, or to a reclamation district’s levee mile designation, making it difficult to compare the geophysical data to the boring data.

Effective flood and coastal storm emergency response depends on the ability of emergency managers to obtain information on the condition of flood-damage reduction structures in near real-time. This report describes the results of a geophysical study performed to determine the potential for geophysical methods to provide supplemental geologic data between existing soil borings in a rapid fashion in an area of complex geology. The geophysical study was conducted along 10 km of landside levee toe adjacent to the Feather River, approximately 5 km south of Marysville/Yuba City, CA. Electromagnetic induction, capacitively coupled electrical resistivity, and direct current electrical resistivity survey methods were used to conduct the geophysical study. Survey results were used to classify soil type to depths of approximately 60 m.
