RE: DOD Grant W81XWH-07-1-0083

PROGRESS REPORT SUMMARY

INTRODUCTION

The goal of this project is to develop an online adaptive treatment technique for prostate cancer treatments. During the first year, we have developed parallel deformable image registration, parallel dose calculation and plan optimization algorithms. During the second year, we have been focusing on improving the robustness of the algorithms and improving online image quality.

STUDIES AND RESULTS: YEAR 2

A. Improving image quality

Image quality of cone beam CT (CBCT) is a major obstacle in clinical implementation of online adaptive treatment. CBCT images lack of contrast, and therefore it is not possible to delineate some of the region-of-interest (ROI). The main reasons for poor image quality are due to excessive scatter and suboptimal detector performance. We have designed a new online imaging system – Tetrahedron Beam Computed Tomography (TBCT) that can conquer these problems

Figure 1 The new system design for online imaging: Tetrahedron Beam Computed Tomography (TBCT): (a) mounted on radiotherapy treatment machine, (b) diagram of scanning geometry.

Figure 1 shows the design of TBCT. This system uses a linear scan x-ray tube and a linear detector array. Due to its unique geometry, the majority of scatter photons are rejected. In addition, it uses the same type of high quality detector as diagnostic CT scanners. Therefore, it is expected to be able to achieve the same image quality as a diagnostic CT scanner. We have acquired an NIH R21 grant to develop a benchtop system. This project was also presented at the 2008 AAPM annual conference. A manuscript has been submitted to Medical Physics Journal, and is currently under review.
B. Development of a fast treatment delivery method

During the first year, we implemented a fast parallel treatment plan optimization method using a Beowulf cluster with a Message Passing Interface. To prepare for clinical implementation, in the second year, we are focusing on accelerating treatment delivery. While online adaptive planning takes care of interfraction motion, the target may also undergo significant intrafraction motion due to patient and bowel movement. It is also noted that intrafraction motion increases with treatment time. This justifies the importance of a faster treatment delivery method.

VMAT is a new dynamic treatment delivery method which can significantly shorten the treatment time. The treatment planning method for VMAT however is not mature. We are developing a robust VMAT treatment planning method which incorporates MLC constraints into the optimization process.

Figure 2 shows the flow chart of our IMAT treatment planning method. It starts with regular sliding window IMRT treatment planning then corrects the rotation angle difference in iterations. One major advantage of this treatment planning method is the robustness. This is a very important feature for online adaptive treatment since a new plan is generated for every treatment.

Figure 3 compares the difference between the IMAT treatment planning method we developed and regular 7 field IMRT treatment planning. We can see the dose distribution from IMAT treatment planning is very similar to regular IMRT treatment. It is noted that the target dose by IMAT treatment planning is more uniform than IMRT. The overall objective score of IMAT is lower than that from 7 field IMRT (0.0699 vs. 0.0994, respectively). We believe the slight improvement is due to the freedom of selecting optimal angles in IMAT planning. The major improvement in the IMAT method is that it can be delivered within 2-4 minutes, compared to 15 minutes for a regular IMRT treatment.

While primarily developed for prostate online adaptive treatment, the new IMAT treatment planning method shows much broader applications in all treatment sites. Head and neck VMAT treatment planning was difficult because of the difficulty of converting complicated fluences to deliverable MLC leaf sequences. Our new method solves this problem by taking account of MLC constraints during optimization iterations.

Because of the freedom of choosing gantry angles, the IMAT treatment planning is more computationally expensive. This problem can be easily solved by using the parallel dose calculation and optimization algorithms that we have developed previously. Besides that, we are also working on Graphic Processing Unit (GPU)-based parallel computing for dose calculation and optimization. The GPU is a cost effective parallel computing resource. A single GPU may
surpass the computing capacity of a medium scale computer cluster. We expect application of the GPU will further boost the speed of computation for dose calculation and optimization.

Figure 3 Comparison of IMRT treatment planning (top) and IMAT treatment planning (bottom). The dose distributions and DVHs are very similar, but IMAT treatment can be delivered much faster, so the impact of intrafraction motion will be minimized.

We will submit abstracts to AAPM and ASTRO annual conferences in March 2009 regarding to the IMAT treatment planning method. We also plan to submit the implementation of GPU-based parallel optimization and deformable image registration to AAPM. Manuscripts of publication will be prepared and submitted a few months later.

C. Model-based automatic segmentation of ROI for prostate treatment

Previously, we developed intensity-based deformable image registration algorithms\textsuperscript{3,4}. The algorithms have been proven to be very robust in some treatment sites, such as head and neck, breast and lung. However this algorithm is not often successful for organs in the pelvis. This is due to the extremely large deformation of the bladder and large variation of the contents in the rectum.

To solve this problem, we decided to change our plan. We are working on combining the model-based automatic segmentation with intensity based segmentation. We represented the organ using an ROI surface mesh. Figure 4 shows the surface mesh of the rectum. The surface mesh
is created on treatment planning CT images, then distance transformations are performed to calculate the distance of pixels to the boundary. With boundary and distance information, we can treat voxels inside and outside organ differently. We can also weight the voxels basing on its distance to the boundary. So we can emphasize image information closer to the boundary. For the shape change, we are currently using penalties on nodal displacement. When we accumulate enough data, we can perform PCA analysis to determine the eigenspace that organs deform and penalize the deformation that is out of the eigenspace.

Figure 4 Surface mesh of the rectum. Using the surface representation, we can use distance information to emphasize on voxels closer to the boundary. We are also able to limit the shape change based on statistical model.

KEY RESEARCH ACCOMPLISHMENT

1. We have invented a new imaging system which can produce diagnostic quality images online for image guided radiotherapy. We are building a benchtop system with an NIH grant. We expect a clinical prototype system will be built within three years.

2. We have developed an IMAT treatment planning method that significantly shortens treatment delivery time. This method can minimize the impact of intrafraction organ motion during online adaptive treatments. We expect clinical implementation of this treatment planning method within 1-2 years.

3. We are currently combining voxel intensity-based deformable image registration with model based image segmentation. This method may overcome the problems of inconsistent rectum filling and large organ deformation. We expect this method can be fully developed within a few months, after which large scale evaluations will be performed.

REPORTABLE OUTCOMES:

Peer reviewed publications:

Conference presentations:

Degrees obtained:
1. Derek Schulze, Master of Science, Department of Medical Physics, Wayne State University, Detroit, Michigan

Funding applied for:
In this proposal, we will develop a novel imaging system using a linear x-ray source and a linear detector. This imaging system may significantly improve the quality of online images, which is critically important for online ROI delineation.

CONCLUSIONS:
During the second year of this study, we are aiming at future clinical implementation of online adaptive treatment. We have invented a new imaging technique (TBCT) to improve online image quality. We have also developed an IMAT treatment planning method which can shorten the treatment time, thereby minimizing intrafraction motion.

Automatic image segmentation of ROIs for prostate treatment remains a very challenging issue. We are developing a model-based segmentation method which may overcome the existing problems. We expect this method can be developed within a few months. We will perform a large-scale evaluation study thereafter.

Title: Tetrahedron Beam CT (TBCT): A New Design of Online Imaging System for IGRT
Authors: Tiezhi Zhang, Derek Schulze

Purpose: Cone-beam computed tomography (CBCT) is an important online imaging modality for image-guided radiotherapy (IGRT) as well as other forms of image guided interventions. However, current CBCT image quality is inferior to that of the diagnostic fan beam CT. We have designed a novel Tetrahedron Beam Computed Tomography (TBCT) imaging system that may achieve the same diagnostic quality as helical CT scanners.

Material and Methods: The TBCT imaging system is comprised of a linear scan x-ray source and a linear discrete x-ray detector array. The axis of linear x-ray tube and the detector array are aligned perpendicular to and within the rotation plane, respectively. The x-ray beams are narrowly collimated into fan beams and focused to the linear detector. Detector and x-ray tube rotate slowly while the fan beams scan quickly along the axis. The TBCT reconstruction geometry is similar to CBCT. Approximate and exact reconstruction algorithms can be modified for TBCT reconstruction.

Results: TBCT will produce diagnostic quality online images due to its scatter rejection mechanism and the use of high-performance discrete x-ray detectors. TBCT also has several other advantages such as larger clearance, ease of performing dynamic field size and mAs controls, etc.

Conclusion: TBCT will significantly improve online image quality. Clinical implementation of TBCT would be of importance in IGRT as well as other forms of image guided interventions.

Title: Techniques of Online IMRT Plan Re-optimization for prostate cancer treatments
Authors: Derek Schulze M.S. and Tiezhi Zhang, Ph.D.

Introduction
Online IMRT treatment plan re-optimization can significantly reduce dose to critical organs. The computation speed of current IMRT treatment planning is not fast enough for online re-planning. We have developed several methods which may dramatically expedite dose calculation and optimization and allow for IMRT plan re-optimization online.

Methods & Materials
Pre-treatment planning was performed. The beamlet doses were calculated and stored for daily re-planning. On the treatment day, a 3D image (such as CBCT) of the patient is acquired. Region-of-interests were automatically contoured using our deformable image registration software. Instead of recalculating dose on the daily images, the pre-treatment beamlets were then loaded. Then for each dose voxel, the dose values were corrected for equivalent radiation path length and inverse square distance change in the online images. The accuracy of the corrected dose was validated using a 3D gamma index evaluation. Traditional dose calculations on the online image (“true dose”) were used as the standards of accuracy. This corrected beamlet dose was then used to perform the daily optimization. For plan re-optimization, Projection Onto Convex Set (POCS) optimization algorithm was implemented on a multi-node Beowulf cluster using Message Passing Interface (MPI) parallel programming package. The speedup factor of the parallel algorithms was benchmarked. After online re-optimization, the new plan can be used for online adaptive treatment.

Results
Compared to recalculating dose on the online image, correction of pre-treatment beamlet approach is fast and does not require accurate calibration of CT number which is difficult to achieve on cone beam CT. Although approximate, the corrected dose is very close to the exact dose calculation method. Benchmark results showed that the parallel optimization algorithm is highly scalable. According to Amdahl’s Law, the serial component of the algorithm is only about 2.6%. Based on the result, it is predicted that a computer cluster with 32-core CPU could complete the online prostate IMRT optimization within 17 seconds.

Conclusion
Online re-optimization of prostate cancer treatments is made possible with the presented techniques. The computation time required for treatment plan optimization is sufficiently reduced by our methods to make the process feasible in an online setting.
Title: Online Region-of-Interest Delineation of Daily Head and Neck Images
Authors: Tiezhi Zhang, Yuwei Chi, Douglas Drake, Di Yan and Elisa Meldolesi

Purpose: Online imaging modalities, such as cone beam computed tomography (CBCT) or CT on-rail provide online volumetric images. A fast, automatic and robust region-of-interest (ROI) delineation method is highly desired in image guided radiation therapy (IGRT). We have developed such a method and tested it via segmentation of head and neck (HN) fan beam CT and CBCT images.

Material and Methods: ROIs on planning CT images were manually delineated using commercial treatment planning system. A variational-based deformable image registration algorithm was implemented to register planning CT images to daily CT images. ROIs on planning CT images were automatically mapped to daily images using voxel matching information between planning and daily image datasets. The results were quantitatively and qualitatively validated by comparing to manual delineation. In order to accelerate computing speed, we paralleled the algorithm using message passing interface (MPI) on a Beowulf cluster with 16 processing elements (PE). Speed improvement was benchmarked.

Results: The discrepancies between automatically and manually delineated ROIs on fan beam images were mostly within 2mm. Automatic segmentation of CBCT images was acceptable by visual inspection. Benchmark results showed that paralleling efficiencies were above 95% and speedup factors were approximately equal to the number of PE used. With 16 PEs online delineation of HN images took about 1 minute.

Conclusion: The online ROI delineation method we have developed is robust, fast and is suitable for HN online adaptive radiation treatments.

Purpose: To compare the dosimetric differences of various online IGRT strategies and to predict potential benefits of online re-optimization techniques in prostate cancer radiation treatments.

Materials and methods: Nine prostate patients were recruited in this study. Each patient has one treatment planning CT images and 10-treatment day CT images. Five different online IGRT strategies were evaluated which include 3D conformal with bone alignment, 3D conformal re-planning via aperture changes, intensity modulated radiation treatment (IMRT) with bone alignment, IMRT with target alignment and IMRT daily re-optimization. Treatment planning and virtual treatment delivery were performed. The delivered doses were obtained using in-house deformable dose mapping software. The results were analyzed using equivalent uniform dose (EUD).

Results: With the same margin, rectum and bladder doses in IMRT plans were about 10% and 5% less than those in CRT plans, respectively. Rectum and bladder doses were observed compared to the actual delivered dose with treatment plan prediction. The therapeutic ratio can be improved by 14% and 25% for rectum and bladder, respectively, if IMRT online re-planning is employed compared to the IMRT bone alignment approach. The improvement of target alignment approach is similar with 11% and 21% dose reduction to rectum and bladder, respectively. However, underdosing in seminal vesicles was observed on certain patients.

Conclusions: Online treatment plan re-optimization may significantly improve therapeutic ratio in prostate cancer treatments mostly due to the reduction of PTV margin. However, for low risk patient with only prostate involved, online target alignment IMRT treatment would achieve similar results as online re-planning. For all IGRT approaches, the delivered organ-at-risk doses may be significantly different from treatment planning prediction.

be registered at bony structures due to the high contrast to surrounding soft tissues [6]. Most current IGRT treatments correct only the three translational components of rigid-body motion. Six-degree-of-freedom corrections can be achieved with a robotic couch (Hexpod™, Medical Intelligence GmbH, Schwabmünchen, Germany) [7] or by rotating the couch, collimator and gantry altogether [8]. In the treatment simulation study, we registered the daily treatment images to the planning CT images at the pelvic bones with six degrees of freedom to simulate bony alignment approach.

**Target alignment.** Aligning directly to the target requires better image quality. The boundary of the low contrast (soft tissue) treatment target needs to be identified. For prostate treatments in particular, it may be difficult to align the target in IGRT treatment using CBCT due to its inferior image quality. Another approach to align at the target is to use implanted fiducial markers, which are visible through portal imaging [9]. The basic application of this technology would be to identify the target center-of-mass based on the average position of three markers. In our clinical experience, however, we found that the target motion may include large rotational components. It is unrealistic to fully correct the rotation [10]. Thus, in the simulation study, we only correct the translation component by translating to the center-of-mass.

**Re-planning.** If the target and organs-at-risk (OARs) can be delineated on online volumetric images, it is possible to generate a new plan in each treatment day [11]. For 3D conformal radiation treatment (3D-CRT) plans, the beam aperture can be changed according to the shape of the target seen in the beam’s-eye-view (BEV) [12]. For intensity modulated radiation therapy (IMRT) plans, the beamlet weight can be re-optimized on a daily basis to minimize the dose to the OAR while maintaining the target dose [13,14]. It is reasonable to use rectum and bladder walls during inverse planning of prostate cancer treatments, so long as the intrafraction motion can be limited to a negligible level. With these biologically relevant inverse planning objectives, the dose to the OAR may possibly be further reduced.

Re-planning theoretically provides the highest precision and does not need specialized hardware such as the robotic couch. However, online re-planning requires superior online image quality, as well as fast and robust algorithms to perform automatic region-of-interest (ROI) delineation [15], dose calculation, and beamlet weight optimization. We are actively developing the techniques to facilitate online re-planning. In this study, we performed both 3D-CRT and IMRT treatment planning and treatment simulation studies for several online IGRT strategies. The purpose of this study is to investigate the potential benefits of the re-planning approach in prostate cancer treatments, and to characterize the limits of the other IGRT methods.

**Methods and materials**

**Treatment planning**

Image data from nine prostate cancer patients treated at William Beaumont Hospital in Royal Oak, MI, USA, were used in this study. The nine patients were randomly selected from our patient database. We assume the magnitude of organ motions of these randomly selected patients represent typical prostate population. Treatment planning CT images were acquired with a conventional helical CT scanner. There was no bowel preparatory instruction or procedure for any simulation or treatment day images. For each of these images, contours of prostate, seminal vesicles (SV), rectum (volume and wall), and bladder (volume and wall) were handrawn by a single observer. Based upon the contours, treatment plans were generated using the Pinnacle™ treatment planning system (TPS) (Philips Radiation Oncology System, Madison, WI). The patients were planned as if they had intermediate or high risk disease, and therefore the CTV included both prostate and seminal vesicles. The average prostate volume was 40.7 cm³ (range: 22.5–54.4 cm³). OARs were limited to bladder and rectum. The average rectum volume was 120.5 cm³ (range: 45.0–189.5 cm³).

The prostate shows significant movement relative to the pelvic bones [16]. Thus, a uniform 1-cm CTV-PTV margin is used to compensate for interfraction organ motion in both 3D-CRT and IMRT treatment plans which are intended for use with the bony alignment treatment method. Results from these treatments will demonstrate the adequacy of a widely practiced IGRT method.

Since the target alignment treatment method can account for translational interfraction motion, the motion margin can be greatly reduced. In the 3D-CRT re-planning and IMRT re-planning methods, all interfraction motions are expected to be compensated, and so there is no motion margin component in the PTV for these methods. This will also give us a feeling about the dosimetric robustness of various IGRT methods to the target translations, deformations, and to the rotations involved. Intrafraction motion is neglected in this study.

An arbitrary dose of 91.0 Gy was prescribed to the PTV, though results will focus on relative dose values, scalable to any prescription. All treatment plans used five coplanar beams at 0°, 81°, 144°, 216°, and 279°. DVH-based dose-volume objectives were chosen to minimize bladder and rectum doses while maintaining PTV dose uniformity during inverse planning.

The IGRT approaches and the corresponding treatment planning methods are listed in Table 1. Five 3D-CRT and IMRT treatment planning methods formed the bases for the online IGRT treatments:

1. **CRT 1-cm.** 3D-conformal radiotherapy to 95% of the isocenter with 1-cm CTV-to-PTV margin and 6-mm PTV-to-block penumbra. This plan was used for CRT bony alignment IGRT approach (**CRT Bone**).
2. **CRT 0-cm.** 3D-CRT plan to 95% of the isocenter with 0-cm CTV-to-PTV margin and 6-mm PTV-to-block penumbra. This plan was used for CRT re-planning via aperture change approach (**CRT Re-plan**).
3. **IMRT 1-cm.** Inverse-planned IMRT with 1-cm CTV-to-PTV margins and OAR-volume as optimization objectives. This was used for IMRT bone alignment treatments (**IMRT Bone**).
4. **IMRT 0-cm volume.** Inverse-planned IMRT with 0-cm CTV-to-PTV margins and OAR volumes as objectives. This method

was used for both IMRT target alignment (IMRT Target) and IMRT re-planning with OAR volumes as constraints approach (IMRT Volume).

(5) IMRT 0-cm wall. Inverse-planned IMRT with 0-cm CTV-to-PTV margins and OAR walls in optimization objectives. This method was used for IMRT re-planning with OAR walls as constraints approach (IMRT Wall).

Virtual treatment simulations

In addition to treatment planning CT images, 10-treatment-day helical CTs were also acquired for each patient. The treatment-day images were acquired during the 6-8-week treatment courses with intervals of 3-5 days. The 10-treatment-day images were used to simulate 10 treatment fractions for all online IGRT techniques. The daily images were registered to the planning image using bony anatomy in Pinnacle. The ROIs were manually delineated on all daily images after bony registration. As an indication of the range of interfraction motion, Fig. 1 shows a treatment planning image with contours overlaid from bone registered daily images.

Ideally, treating a patient positioned by bony landmarks can be simulated by calculating dose on the daily images. However, due to technical issues with Pinnacle, dose calculation on daily images was not possible for the images where non-zero rotational components exist in registration parameters. Previous studies have shown that replacing a daily CT with the planning CT introduces minimal dose calculation error [17]. By using daily images which were registered to the planning image without rotation, we were able to determine that calculating daily dose on the planning image introduces an EUD error in the studied ROIs of less than 1%. Thus in this study, daily treatment dose was calculated using voxel densities from the planning CT, as this method introduces negligible error. Calculating DVHs from dose to daily contours will accurately represent all daily motions, as the rotation present in registered daily images will be preserved in the contour shape.

Retrospective virtual treatment simulations were performed in order to compare different online IGRT treatment methods. Compared to interfraction motion, intrafraction motion is relatively small [16]. In this study, we only focused on interfraction motion, while intrafraction motion was neglected. Treatment methods were simulated that were associated with different levels of image guidance. The relationship between planning methods and treatment methods is summarized in Table 1.

Bony alignment. Bony alignment was simulated by registering the daily treatment images to the planning CT images at the pelvic bones with six degrees of freedom. Doses for CRT Bone and IMRT Bone treatments were calculated using the unmodified CRT 1-cm and IMRT 1-cm plans. This simulates the position correction available from standard imaging systems combined with the robotic couch.

Target alignment. Aligning directly to the target requires better image quality. The boundary of the low contrast (soft tissue) treatment target needs to be identified. For prostate treatments in particular, it may be difficult to align the target in IGRT treatment using CBCT due to its inferior image quality. Another approach is to use a portal imager to visualize implanted fiducial markers [9]. One application of this technology that is possible with CBCT would be to identify the target based on the average 3D position of three markers. In our clinical experience, however, we found that the target motion may include large rotational components. With the standard couch, it is unrealistic to correct the rotation without modifying the treatment plan. Furthermore, the maximum rotation of the Hexapod™ robotic couch is about 2.5–3.0°, and so some large rotations cannot be corrected in this fashion. In this study, we simulated an image-guided treatment available to many institutions by only translating the isocenter of the daily target’s center-of-mass. After moving the isocenter, daily doses were calculated using the original IMRT 0 cm Volume plans. This approximates the use of implanted markers based upon the assumption that marker position accurately reflects target position. For the purposes of this study, this treatment method was labeled IMRT Target.

Re-planning. The CRT Re-plan treatments started from the CRT 0-cm plan. On each treatment day, beam apertures were changed to the daily shape of the target in the beam’s-eye-view (BEV) [12], but the monitor units (MUs) delivered by each beam were kept the same as in the original treatment plan. This makes the re-planning process much simpler from a computational standpoint, as dose re-calculation is unnecessary.

For intensity modulated radiation therapy (IMRT) plans, the beamlet weight can be re-optimized on a daily basis to minimize the dose to the OAR while maintaining the target dose [14]. So long as the intrafraction motion can be limited to a negligible level, it is reasonable to use rectum and bladder walls during inverse planning of prostate cancer treatments. With these biologically relevant inverse planning objectives, the dose to the OAR may possibly be further reduced.

The IMRT Re-plan Volume and IMRT Re-plan Wall treatments involve complete re-planning on each treatment day. Moving beyond the CRT Re-plan method to these treatments requires overcoming the technical challenges of online dose calculation and beamlet weight optimization. To simulate this process, daily doses were calculated after daily re-planning using the IMRT 0-cm Volume and IMRT 0-cm Wall planning methods.

Dose accumulation

All daily doses were exported to an in-house dose accumulation software utility [18]. In this utility, a finite element (FE)-based deformable registration algorithm was used to obtain voxel matching information between daily and planning CT images. FE models were created using ROI contours from planning CT images. The daily contours were used as boundary conditions to limit the organ deformation. The deformation state with minimum internal elastic energy was obtained. The voxel displacements were obtained by interpolating the FE results to the CT voxel grid.

Fig. 1. Planning CT showing bladder (yellow), CTV (red), and rectum (green) contours. Thick lines define contours from the planning day. Thin lines show the positions of the organs on different treatment days. Contours were generated after registration of bony anatomy.
With voxel displacements, dose accumulation is straightforward. The accumulated dose $D$ at position $\tilde{x}$, can be obtained by

$$D(\tilde{x}) = \sum_{j=1}^{N} d_j(\tilde{x} + \tilde{u}),$$

where $N$ is the total number of fractions, $d_j$ the daily dose from the treatment fraction $j$, and $\tilde{u}$ is the daily displacement of the PE subvolume from its original position $\tilde{x}$.

**Evaluation methods**

Dose from treatment planning and simulated delivery was evaluated using the equivalent uniform dose (EUD), as in Eq. (2), where $V$ is the reference volume, and $D(v)$ is the dose to the sub-volume $v$.

$$EUD(V, a) = \left( \sum_{v \subset V} \frac{V}{V} D^a(v) \right)^{1/a}$$

As in the previous studies [19], the volume parameter for prostate and seminal vesicles was chosen as $a = -7$. With regard to normal tissues, values were chosen as $a = 2$ for bladder, and $a = 8.33$ for rectum.

**Results**

**Comparisons of treatment planning results**

This study included five different treatment planning methods. 3D-CRT and IMRT were used in treatment planning, and different treatment planning methods used different CTV–PTV margins (0-cm and 1-cm). The EUDs of the OARs (rectum and bladder) were calculated and compared to the prostate EUD. Unless otherwise noted, percentage values discussed in the following treatment results are based upon the target (prostate) EUD dose in the respective treatment plan.

In order to provide a complete description of results from one randomly selected patient, Fig. 2 shows the dose-volume histograms (DVHs) of one patient (#9) from the five planning methods studied. It can be seen that IMRT plans have less homogeneous target dose. Bladder dose appears to be similar for both plans with 1 cm margins. IMRT significantly reduces rectum dose. Rectum dose is similar between the CRT 0-cm method and the IMRT 1-cm method, even though the latter one has a 1-cm interfraction margin.

The planned bladder and rectum EUDs for all patients are summarized in Table 2. For the same patient, OAR doses by all treatment planning methods were also normalized to the IMRT 1-cm plan. When rectum and bladder walls were used in IMRT optimization, the shapes of the dose distributions look different as compared to using the volumes. The top panels of Fig. 3 show the fluence maps of the anterior–posterior (AP) beam and isodose distributions from IMRT 0-cm Volume and IMRT 0-cm Wall plans. In the volume-based plan, fluence is decreasing where the beam passes a greater distance through the whole organ, while intensity in the wall-based plan is decreased only in a ring where pathlength through the bladder wall is greater. The isodose lines form a “W” shape as they first retract along the walls, then extend into the center of bladder and rectum in IMRT Wall plan. On the contrary, the IMRT Volume plan has lower weightings for the beamlets through the center of the bladder, with isodose lines extending a minimum distance into any part of the sensitive organs. Despite this obvious qualitative difference, the improvement of the bladder and rectum EUD dose (as a percent of prostate dose) from IMRT Volume to IMRT Wall plans is barely noticeable at 1.01 ± 0.97% and 1.71 ± 1.53%, respectively.

Selecting an altogether different planning method has a greater impact on the OAR dose than changing the particular definition of the normal tissue volume. With the same 0-cm margin, IMRT plans...
(IMRT Volume and IMRT Wall) reduced bladder dose by an average of only 3% compared to 3D-CRT plans (CRT-0-cm), and rectum doses were reduced by 11%. When using a 1-cm margin, there are decreases when changing from CRT to IMRT plans in rectum and bladder doses, by about 7% and 6% of target dose, respectively. The choice of an appropriate CTV–PTV margin is a more important factor that determines OAR doses. For the same planning method, the rectum dose in 0-cm margin plans is, respectively, 10% and 11% lower using CRT and IMRT methods than their corresponding plans with 1-cm margins. The bladder dose reductions are even larger, at 15% and 14% when a 0-cm margin is used instead of a 1-cm margin for CRT and IMRT, respectively.

Virtual treatment simulation results

Fractional dose

The fractional doses for different online IGRT strategies were calculated using the methods described in previous sections. Histograms of differences of the individual fraction dose from the planned EUD can be seen in Fig. 4 for all treatment fractions ($N = 90$). All IGRT strategies were able to deliver consistent dose to the prostate. However, dose to the seminal vesicles (as a fraction of planned seminal vesicle dose) was reduced by more than 20% in one fraction from the IMRT Target method. On this day, the prostate had moved 0.17 cm to the posterior from the planning position while the seminal vesicles had moved 1.35 cm in the anterior

The values are expressed as percentages of target (prostate) EUD dose.

Fig. 3. Top: AP beam fluences from treatment plans optimized with OAR volume (left) and OAR wall (right). Bottom: Isodose profiles from IMRT treatment plans using (a) organ volumes and (b) organ walls. Bladder wall, seminal vesicles, and rectum wall are contoured in dark blue, light blue, and green, respectively. Isodose levels range from 55% to 105% of the isocenter dose.
direction. There were several fractions where IMRT Bone delivered a seminal vesicle dose that was at least 5% less than planned. Bladder dose deviation appears to be similarly random for all treatment methods. In the rectum, only the two 3D-CRT methods delivered...
dose that was consistently within ±10% of the planned amount. Despite this benefit in treatment consistency, CRT plans resulted in larger rectum dose than IMRT plans with the same margin.

**Accumulated dose**

The fractional doses were accumulated using in-house FE-based dose accumulation software. Fig. 5 shows the DVH of accumulated dose for Patient #9. Fig. 6 shows the accumulated doses for all patients after ten fractions. The EUD values were normalized to the target (prostate) EUD in the treatment plan of the same patient with the same IGRT strategy. The prostates were all well covered, with only one patient’s EUD value at about 97% in the IMRT target alignment approach. Seminal vesicles, however, showed a larger difference, with the IMRT target alignment approach showing more severe underdose than other methods. The delivered EUD was only about 93% of the planned value on patient #2. Even with 1-cm CTV–PTV margin, the IMRT bone alignment showed slight underdose on patients #2 and #9. The accumulated dose results support the conclusion derived from individual fraction doses that IMRT is more sensitive to organ motion than 3D-CRT treatments.

Table 3 summarizes rectum and bladder doses achieved by different online IGRT approaches. Remarkable differences in OAR doses are observed when choosing different online IGRT strategies. The CRT Bone approach delivered the highest OAR doses, with the bladder and rectum, respectively, on the average receiving 91% and 71% of target dose. IMRT re-planning approaches obtained the lowest bladder and rectum doses, with average values of 68–69% of target dose to rectum and 49–50% to the bladder. The IMRT target alignment approach obtained OAR doses that are similar to though slightly (1–5%) higher than the IMRT re-planning approaches on most patients. It should be noted that even though the IMRT target alignment method results in similarly low OAR dose, it did not deliver as reliable seminal vesicle dose as re-planning approaches. However, if only the prostate is the target, the IMRT target alignment method would be closer to the re-planning approach.

**Difference from treatment plan prediction**

A major purpose of treatment planning is to predict OAR doses. With an estimate of the risk of complication based on this dose, an appropriate maximum prescription dose can be determined. However, due to the organ motion, the actual delivered dose may be very different from the prediction in the treatment plan. We plotted the discrepancies between treatment plan prediction and accumulated dose after virtually simulated delivery in Fig. 7. For all IGRT approaches, the deviation of prostate dose is small. Online
IMRT re-planning approaches show small but noticeable target dose variations. This is due to the daily geometry changes that altered the weightings of optimization components. Thus, it may be necessary to re-scale the monitor units (MUs) based on the prostate dose in daily re-optimization. The seminal vesicles show large variations from IMRT bone and target localization approaches. The rectum doses show large plan-delivery discrepancies in all IMRT treatments. Although the mean discrepancy across all patients is close to zero, the standard deviation is larger than 5%. The standard deviation is slightly smaller in IMRT re-planning approaches, but not very significant. The 3D-CRT treatments are more consistent, as the mean of discrepancies is close to zero and standard deviation is smaller than 3%. For bladder, all online IGRT approaches show large variations from treatment plan predictions. The standard deviation of plan-delivery discrepancies for this organ is large, around 15% in most IGRT approaches, while the standard deviations for IMRT re-planning approaches are smaller, at about 10%.

Discussion

Traditional radiation treatments strategically treat volumes greater than the clinical target tissues to the prescription dose in order to achieve a high probability of treatment success in spite of daily tumor position uncertainty. Many studies have been done to typify organ motion, and a number of CTV-to-PTV margin recipes [20,21] have been devised to make the selection of margin size a more informed decision. Schaly [2] found that normal tissue dose is not reduced with image guidance alone, but by with the combination of image guidance with smaller CTV–PTV margins. This result is supported by our study.

Interfraction motion has been recognized as the largest contributor to target position uncertainty in tumors unaffected by respiration.

</table>

The values are expressed as percentages of target (prostate) dose.

The rectum doses show large plan-delivery discrepancies in all IMRT treatments. Although the mean discrepancy across all patients is close to zero, the standard deviation is larger than 5%. The standard deviation is slightly smaller in IMRT re-planning approaches, but not very significant. The 3D-CRT treatments are more consistent, as the mean of discrepancies is close to zero and standard deviation is smaller than 3%. For bladder, all online IGRT approaches show large variations from treatment plan predictions. The standard deviation of plan-delivery discrepancies for this organ is large, around 15% in most IGRT approaches, while the standard deviations for IMRT re-planning approaches are smaller, at about 10%.

Fig. 7. Discrepancies of cumulative delivered doses from treatment plan prediction, expressed as mean and standard deviation of all patients. The columns are the mean and the error bars are the standard deviation of the difference.

tory motion [16]. In this study, intrafraction motion was not simul-
ated. Ghilezan et al. showed that prostate intrafraction motion
related with rectal filling [19] and the amplitude of motion in-
creased with elapsed time. This suggested the importance of short-
ening treatment time. Recently, study by Nijkamp et al. shows
that the diet and laxatives can reduce prostate motion during treatment
[22]. The patients in this study had no special procedures to limit
rectal filling, so our results represent an upper limit of therapeutic
ratio which may be lower for patients who do use methods to con-
trol rectal volume. Also, a realistic margin would compensate for
other uncertainties, such as errors in contouring, image registra-
tion, and position alignment.

Due to limited image datasets, only 10 treatment fractions were
simulated in this study. The results of this study may be directly
applied to hypo-fractionated treatment. However, care should be
taken when extrapolating beyond our results, as a regularly frac-
tionated prostate treatment may involve 35–40 fractions. In that
case, we expect the target underdosing will be reduced if the mo-
tion is mostly random and the CTV definition in treatment is close
to the mean position. However, if the target motion has a trend or
the CTV definition is deviated from mean position, dose coverage
would not improve with more fractions. To illustrate the change
of accumulated dose during treatment course, Fig. 8 shows daily
doses and accumulated doses of patient #6 for 10 fractions. The
coverage is improved during the first three fractions and then sta-
bilized after that.

Figures 7 and 8 show the excellent conformity of our treatments.
Technologies such as EPIDs, CALYPSO, CBCT, and CT-on-rails al-
low accurate tracking of the target on a daily basis, and their use
justifies reduction of the margin size. With no margins, the IMRT
Target simulations essentially treated only the CTV. While there
was underdosing in the seminal vesicles, satisfactory prostate dose
was achieved for most patients. This result indicates that much
smaller margins are justified around the prostate than the seminal
vesicles, and that when treating prostate alone by this method, the
size of the motion margin can be dictated only by the extent of
intrafraction motion. For low risk patients, using implanted mark-
ers to locate the target each day can significantly reduce normal
tissue dose while maintaining target coverage. For patients with
high risk disease, the chance of microscopic or occult disease is in-
creased. In the case of prostate patients, this is evidenced by extra-
capsular extension [23] and seminal vesicle involvement [24].
While the CTV–PTV margin has nominally accounted for target
motion, its unintentional function has been to also treat these cells
that are not traditionally included in the CTV. Therefore, this extre-
mely conformal approach, which does not account for target rota-
tions and deformations, is expected to be less successful in high
risk patients.

Increasing levels of image guidance complexity provide more
information with which to re-evaluate the treatment on a more
frequent basis. The CRT Re-plan method using aperture change
makes easy use of this information, as it simply shapes the blocks
each day to the new PTV. After ten treatment fractions, the rectum
dose from this method was very similar to that from the more
standard IMRT Bone method. Also, Fig. 7 shows that all patients re-
ceived adequate seminal vesicle dose and 8 of 9 patients received
lower bladder dose by the CRT re-planning method. Though nor-
tal tissue sparing is limited by the convexity of the dose distribu-
tion and the penumbra size, this treatment provides very con-
sistent target coverage. In reality, this treatment is not feasible
in the absence of robust automatic contouring technology. How-
ever, since this method requires no further optimization, it is prob-
ably the least computationally intensive online adaptation that can
be performed with this image data.

The most computationally intensive adaptation would involve a
complete IMRT re-optimization of the original treatment plan.
Compared to the IMRT Bone treatments, target coverage was main-
tained for all patients, while bladder and rectum doses were,
respectively, reduced by approximately 16% and 11%. This ap-
proach requires online ROI delineation and online plan re-optimi-
tization techniques. Although challenging, it is feasible to achieve
these goals in the near future. We have developed an automatic
ROI delineation method for HN images [15]. In principle, the same
method can also be used on prostate images, but CBCT image qual-
ity is a major obstacle. In order to perform IMRT re-planning online,
high performance computing techniques can be employed to accel-
erate computation. We were able to accelerate the deformable im-
age registration speed by a factor close to the number of processing
elements using a Beowulf cluster. Wu et al. showed that online
IMRT re-optimization and MLC leaf conversion are achievable
within 2–3 min [13].

In this study, we employed online IMRT re-planning approaches
in which bladder and rectum volumes or walls were used as opti-
mization constraints. The resulting difference between the two
approaches, IMRT Re-plan Volume and IMRT Re-plan Wall, was shown
to be small. When choosing OAR walls instead of the standard vol-
umes, reduction of doses to bladder and rectum is limited to less
than 1% on average, though using this approach does not drasti-
cally increase technical complexity. Extracting bladder and rectum
walls from volumes would be straightforward, so it would be rea-
soneable to employ the IMRT-wall approach for a small but cost-
free improvement. This conclusion applies specifically to online re-
planning methods, as any benefit from standard planning meth-
ods is expected to be negated by interfractional tissue shape changes.

An interesting result of this study is that IMRT techniques are
much more sensitive to organ motion than CRT techniques. This
is because the IMRT plan is more conformal, meaning that the dose
gradient surrounds the target more tightly. Even with a 1-cm mar-
gin, underdoses in SV were still observed in several patients. Thus,
regardless of margin size, high precision image guidance is more
important in highly conformal treatment techniques. From this re-
result, we would expect image guidance and intensity/energy modu-
lation to be a decisive factor in proton prostate cancer treatments,
where sharp dose gradients beyond the Bragg peak combined with
particle penetration depth uncertainties create opportunities for
significant dosimetric consequences.

We noticed that even in the online re-planning techniques,
large discrepancies are shown between planning and accumulated
bladder and rectum doses. This encourages a close-loop adaptive treatment technique with dose tracking, in which the re-planning takes account of accumulated dose up to that point in the treat-
ment course [25,26]. Otherwise, while OAR doses may meet con-
straints in treatment planning, they are likely over the limits in actual treatments.

Conclusions

Online treatment plan re-optimization may significantly im-
prove therapeutic ratio in prostate treatments when semi-
nal vesicle is involved mostly due to the reduction of PTV margin. However for low risk patient with only prostate involved, online target alignment IMRT treatment would achieve similar re-

sults as online re-planning. For all IGRT approaches, the delivered organ-at-risk doses may be significantly different from treatment planning prediction.
