We consider the problem of distributed estimation in a power constrained collaborative wireless sensor network, where the network is divided into a set of sensor clusters, with collaboration allowed among sensors within the same cluster but not across clusters. Specifically, each cluster forms one or multiple local messages via sensor collaboration (in particular, linear operation is considered) and transmits the messages over noisy channels to a fusion center. The final estimate is constructed at the fusion center based on the noisy data received from all clusters. In this collaborative setup, we study the following fundamental problems. Given a total transmit power constraint, shall we transmit the raw data or some low-dimensional local messages for each cluster? What is the optimal collaboration scheme for each cluster? How do we optimally allocate the power among different clusters? These questions are addressed in this article. We will show that the optimum collaboration strategy is to compress the data into one local message that, depending on the channel characteristics, is transmitted using one or multiple available channels to the fusion center. The optimal power allocation among the clusters is also investigated, which yields a water-filling type of scheme.

Key words: Distributed estimation; wireless sensor network; sensor clusters; power allocation; collaboration strategy; data transmission; estimation distortion.

Distributed estimation has attracted much attention recently. One of the network architectures for distributed estimation involves a set of spatially distributed sensors linked with a fusion center (FC). Each sensor makes a noisy observation of the phenomena of interest and transmits its processed information to the FC, where a final estimate is formed. The problem of optimal power allocation among sensors given a total transmit power constraint was considered in Cui et al. (2007), Li and AlRegib (2007), Wu, Huang, and Lee (2008), and Xiao et al. (2006); the goal was to minimize the estimation distortion at the FC. For most of these works, intersensor communication is not considered. Intersensor collaboration can indeed be exploited to enhance transmission energy efficiency and improve system performance.

In this article, we consider distributed estimation in a hierarchical network architecture with localized collaboration. Specifically, we assume that the network is divided into a number of sensor clusters linked with a FC. The sensors within the same cluster have the communication resources to locally collaborate, whereas no collaboration is allowed across clusters. This might be the case for scenarios where multiple sets of sensors are spatially distributed, with each set of sensors within a small neighborhood. Each cluster

then transmits one or multiple one-dimensional messages, which could be the raw data or obtained via sensor collaboration over noisy channels to the FC where a final estimate is formed based on the data received from all clusters. In this context, the following natural questions arise: Given a fixed amount of total transmit power, how should each cluster process its local measurements such that a minimum estimation distortion can be achieved at the FC? How should we allocate the power among the different clusters in an optimal power-distortion fashion? These questions are be addressed in this article, and we develop a fundamental understanding of this important hierarchical collaborative strategy for distributed estimation. Our work is closely related to the distributed compression-estimation approaches in Fang and Li (2008), Luo, Giannakis, and Zhang (2005), Schizas, Giannakis, and Luo (2007), Song, Zhu, and Zhou (2005), Zhang et al. (2003), and Zhu et al. (2005); their objective is to reduce the transmission requirements via dimensionality reduction. While sharing certain similarities with the distributed compression-estimation approaches, our work focuses on the optimal collaboration among sensors in a power constrained scenario.

**System model and problem formulation**

We consider a wireless sensor network consisting of $N$ spatially distributed sensors, with each sensor making a noisy observation of an unknown random parameter $\theta$: $x = h_n\theta + w_{m,n}$, where $h_n$ denotes the observation gain and $w_{m,n}$ denotes the additive observation noise. The sensors in the network are divided into $M$ sensor clusters (Figure 1). Each cluster, say cluster $m$, consists of $N_m$ closely located sensors. The sensors in each cluster are able to collaborate to form local messages that are sent to the FC, whereas no communication is allowed across different clusters. The objective is to obtain an estimate of the unknown parameter at the FC based on the information received from the clusters. In practice, the sensor collaboration can be easily implemented. For each cluster, we choose one sensor to be the cluster head whose task is to collect the data from other sensors within the same cluster and carry out the collaborative processing. The resultant local messages are then transmitted by the cluster head to the FC. We adopt the following assumptions for this collaborative setting.

A1: The links between sensors and the cluster head within each cluster are ideal. Sensor collaboration is confined to linear operations.

A2: An uncoded analog amplify-and-forward scheme is employed to transmit the local messages from the cluster heads to the FC over noisy, wireless channels.

For notational convenience, we use $x_{m,n}$ to denote the sensor measurement of sensor $n$ in cluster $m$, where $n \in \{1, \ldots, N_m\}$, $m \in \{1, \ldots, M\}$, and

$$x_{m,n} = b_{m,n}\theta + w_{m,n} \quad (1)$$

in which $b_{m,n}$ and $w_{m,n}$ denote the corresponding observation gain and additive observation noise, respectively. To capture the cluster-based collaborative scenario, we write the measurements within a
individual collaboration matrices $C_m$ arising from this scenario is to find an overall optimal collaboration matrix $C$ where 

$$z_m = C_m x_m,$$  

(3)

where $C_m \in \mathbb{R}^{N_m \times N_m}$ denotes the collaboration matrix for cluster $m$, $p_m = N_m$ is the dimensionality of the message vector $z_m$, whose choice is discussed later. The signal received at the FC from the $m$th cluster is given by

$$y_m = G_m A_m C_m x_m + v_m,$$  

(4)

where $G_m \in \mathbb{R}^{p_m \times p_m}$ denotes a fading multiplicative channel matrix, which can be diagonal or nondiagonal, depending on the transmission scheme (e.g., orthogonal vs. nonorthogonal channel access); $A_m = \text{diag}\{a_1, \ldots, a_{p_m}\}$ is the amplification matrix with $a_i$ denoting the amplification factor used in transmitting the $i$th message of $z_m$; $v_m \in \mathbb{R}^{p_m}$ denotes the additive channel noise vector. Without loss of generality, we assume $G_m = I$ and $A_m = I$, where $I$ denotes the identity matrix, because the multiplicative effect of the channel matrix can be removed by carrying out a matrix inverse using an estimate of the channel matrix $G_m$ at the receiver and the amplification matrix $A_m$ can be absorbed into $C_m$. We have the following assumption regarding observation noise $\{w_m\}$ and channel noise $\{v_m\}$.

A3: Noise $\{w_m\}$ and $\{v_m\}$ are zero mean with positive definite autocovariance $\{R_{w,m}\}$ and $\{R_{v,m}\}$, respectively, which are available at the FC. The noise across different clusters is mutually uncorrelated, i.e.,

$$E[w_i w_j^T] = 0 \quad \text{and} \quad E[v_i v_j^T] = 0 \; \forall \; i \neq j.$$

Let $y = [y_1, y_2, \ldots, y_M]^T$ denote a column vector formed by stacking the data received from all clusters. We have

$$y = Cx + v = C(h_0 + w) + v,$$  

(5)

where $C = \text{diag}\{C_1, \ldots, C_M\}$ is a block diagonal matrix with its $m$th block-diagonal element equal to $C_m$, $x = [x_1, x_2, \ldots, x_M]^T$, $v = [v_1, v_2, \ldots, v_M]^T$, $h = [h_1, h_2, \ldots, h_M]^T$, and $w = [w_1, w_2, \ldots, w_M]^T$. A natural question arising from this scenario is to find an overall optimal collaboration matrix $C$, or equivalently, a set of individual collaboration matrices $\{C_m\}_{m=1}^M$, to achieve a minimum estimation distortion at the FC. Also, because the amplification factors $\{A_m\}$ are incorporated into the collaboration matrices $\{C_m\}$, the overall collaboration matrix $C$ has to satisfy a total transmit power constraint. Specifically, using a Linear Minimum Mean-Square Error (LMMSE) estimator (Kay 1993), it can be readily verified that we are faced with the following optimization problem:

$$\min_C \; E[(\hat{\theta} - \theta)^2] = \sigma_0^2 - \sigma_0^4 h^T (CR_C C^T + R_v)^{-1} C h,$$

subject to \(\text{tr}(CR_C C^T) \leq P\),

(6)

where $\sigma_0^2$ denotes the signal variance; $R_v = E[xx^T]$; \(\text{tr}(CR_C C^T)\) is the average transmit power required to send the local messages from all clusters to the FC; and $P$ is a prespecified power budget for transmission.

**Single cluster case**

The development of the optimal collaboration matrix for the single cluster case is quite involved. Because of space limitations, we only present the main results without providing the proof.

**Theorem 1**: Consider the optimal collaboration design problem formulated in (6) and described in Figure 1, where the sensor measurements $x_m$, the local messages $z_m$, and the received messages at the FC $y_m$ are given by (2), (3), and (4), respectively. When $M = 1$, the optimal solution to (6) is

$$C^* = \gamma \sqrt{P} U_v[:,1] h^T R_v^{-1},$$

(7)

where $U_v[:,1]$ denotes the first column of $U_v$, $U_v$ is an orthonormal matrix obtained by carrying out the eigenvalue decomposition of $R_v$, i.e., $R_v = U_v D_v U_v^T$; and $\gamma = 1/\sqrt{\text{tr}(h^T R_v^{-1} h)}$. The associated estimation Mean Square Error (MSE), i.e., the value of the minimum objective function of (6), is given by

$$E[(\hat{\theta} - \theta(C^*))^2] = \sigma_0^2 - \sigma_0^4 \frac{P}{\min(d_{m})} h^T R_v^{-1} h,$$

(8)

**Proof**: A rigorous proof is provided in Fang and Li (in press).

The optimal solution (7) has very important implications that we shall explore in the following. Considering the scenario of independent channels, i.e., $R_v$ is diagonal; $U_v = I$ and $U_v[:,1] = e_1$, where $e_1$ denotes the unit column vector with its $i$th entry equal to 1 and its other entries equal to 0. Therefore the optimal collaboration matrix becomes

$$C^* = \begin{bmatrix} \gamma \sqrt{P} h^T R_v^{-1} \\ 0_{(P-1) \times N} \end{bmatrix},$$

(9)

which is a matrix with its first row equal to
\[ \sqrt{\gamma h^T R_x^{-1}} \text{ and all other rows equal to } 0. \text{ The solution suggests that we should compress the measurements into only one local message and transmit it via the best-quality channel (note that the first row corresponds to the first channel, which has the smallest noise variance because the diagonal elements of } R_x \text{ are assumed in an ascending order) to the FC. If the channels have identical qualities, then we can use any of them to send out the local message. Also, by rewriting the collaboration weighting vector } \sqrt{\gamma h^T R_x^{-1}} \text{ as}
\]
\[ \sqrt{\gamma h^T R_x^{-1}} = \sqrt{\gamma \sigma_0^{-2} h^T R_x^{-1}} \]
\[ = \sqrt{\gamma \sigma_0^{-2} R_{00} R_x^{-1}}, \] (10)

where \( R_{00} = E[0x_i^T] \), we can immediately see that the local message is exactly the LMMSE estimate \( R_{00} R_x^{-1} x \) multiplied by a scalar \( \sqrt{\gamma \sigma_0^{-2}} \). This means that when channels are independent, LMMSE estimation followed by an amplification factor is optimal in a power-distortion sense.

We now investigate the case where the channels are correlated, i.e., \( R_x \) is nondiagonal. Each row of the optimal collaboration matrix can be readily expressed as follows by combining (7) and (10):
\[ C_{x,i} = U_{v}[i, 1] \sqrt{\gamma} \sqrt{\sigma_0^2 - R_{00} R_x^{-1}} , \] (11)

where \( U_{v}[i, 1] \) is the \( (i, 1) \)th entry of \( U_{v} \). Therefore, the LMMSE estimate is transmitted by multiple channels with different amplification gains that are proportional to \( \{ U_{v}[i, 1] \} \). The number of local messages to be transmitted, \( p \), \( 1 \leq p \leq N \), should be as large as possible because the more channels employed, the more diversity that can be provided. However, system complexity will also increase as more channels are involved.

**Multiple cluster case**

We now examine a general scenario where the network consists of multiple sensor clusters. In this case, the collaboration matrix \( C \) has a block diagonal structure because intercluster collaboration is not allowed. The approach described in previous subsection, therefore, cannot be directly applied here. To solve (6), we hope to decouple the optimization problem into a set of tractable subtasks. To this goal, we rewrite the estimation MSE as follows (Fang and Li in press).
\[ E[(\hat{x} - \theta)^2] = \sigma_0^2 - \sigma_0^2 h^T C_x^T C_x (C_x R_x C_x^T + R_x)^{-1} C_x \]
\[ = \left( \sigma_0^2 - \sum_{i=1}^{M} h_i^T C_i^T (C_i R_{x,i} C_i^T + R_{x,i})^{-1} C_i h_i \right)^{-1}, \] (12)

where we use the fact that \( R_x = \sigma_0^2 hh^T + R_{x} \), along with the block diagonal structures of \( C, R_{x,i} \), and \( R_x \). Therefore the optimization structures of \( C, R_{x,i} \), and \( R_x \). Therefore the optimization problem (6) becomes
\[ \max_{\{ C_i \}} \sum_{i=1}^{M} h_i^T C_i^T (C_i R_{x,i} C_i^T + R_{x,i})^{-1} C_i h_i \]
\[ \text{s.t. } \sum_{i=1}^{M} \text{tr}(C_i R_{x,i} C_i^T) \leq P \] (13)
in which the power constraint follows from
\[ \text{tr}(C R_{x} C^T) = \sum_{i=1}^{M} \text{tr}(C_i R_{x,i} C_i^T). \]

To use the theoretical results obtained for \( M = 1 \), we express the component \( h_i^T C_i^T (C_i R_{x,i} C_i^T + R_{x,i})^{-1} C_i h_i \) in (13) as a function of \( h_i^T C_i^T (C_i R_{x,i} C_i^T + R_{x,i})^{-1} C_i h_i \), which can be done by resorting to the Woodbury identity:
\[ \sigma_0^2 - \sigma_0^2 h_i^T C_i^T (C_i R_{x,i} C_i^T + R_{x,i})^{-1} C_i h_i \]
\[ = (\sigma_0^2 + h_i^T C_i^T (C_i R_{x,i} C_i^T + R_{x,i})^{-1} C_i h_i)^{-1}. \] (14)

For notational convenience, let
\[ \mu_i(C_i) = h_i^T C_i^T (C_i R_{x,i} C_i^T + R_{x,i})^{-1} C_i h_i \]
\[ \eta_i(C_i) = h_i^T C_i^T (C_i R_{x,i} C_i^T + R_{x,i})^{-1} C_i h_i. \] (15)

Therefore (14) can be rewritten as
\[ \mu_i(C_i) = \frac{1}{\sigma_0^2} \left( -\frac{1}{1 - \sigma_0^2 \eta_i(C_i)} - 1 \right). \] (16)

Substituting (16) into (13), we arrive at the following optimization
\[ \max_{\{ C_i \}} \sum_{i=1}^{M} \frac{1}{\sigma_0^2} \left( -\frac{1}{1 - \sigma_0^2 \eta_i(C_i)} - 1 \right) \]
\[ \text{s.t. } \sum_{i=1}^{M} \text{tr}(C_i R_{x,i} C_i^T) \leq P. \] (17)

Clearly, (17) can be decoupled into two sequential subtasks, i.e., a power allocation (among clusters) problem and a set of collaboration matrix design problems that can be solved using the previous results. To see this, suppose \( \{ P_1, P_2, \ldots, P_M \} \) is an optimum power assignment, where
\[ \text{tr}(C_i R_{x,i} C_i^T) \leq P_i \quad \forall i \in \{ 1, \ldots, M \} \]
\[ \sum_{i=1}^{M} P_i \leq P \]
then (17) is simplified into a set of identical problems as
\[
\max_{(C_i)} \frac{1}{\sigma_0^2} \left( \frac{1}{1 - \sigma_0^2 \eta(C_i)} - 1 \right) \quad \text{s.t. } \text{tr}(C_i R_{x,i} C_i^T) \leq P_i^*.
\]
(18)

Note that \(\sigma_0^2 \eta(C_i)\) must lie within the interval \((0, 1)\) because we have \(\eta(C_i) > 0\) and \(\mu_i(C_i) > 0\) from their definitions. Hence (18) is equivalent to
\[
\max_{C_i} \eta(C_i) \quad \text{s.t. } \text{tr}(C_i R_{x,i} C_i^T) \leq P_i^*,
\]
(19)

which is exactly the optimization problem discussed in the previous section. The optimal solution to (19) is given in Theorem 1. The key problem, therefore, is to determine the optimum power assignment \(\{P_1^*, P_2^*, \ldots, P_M^*\}\). To meet this goal, we need to find out the relationship between the maximum objective function value \(\eta(C_i)\) and \(P_i^*\). Recalling Theorem 1, more precisely, (8), we have
\[
\eta(C_i) = \frac{P_i^*}{P_i^* + \min(d_{c,i}) \beta_i} \frac{\beta_i}{\beta_i + P_i^*} = \frac{\alpha_i P_i^*}{\beta_i + P_i^*},
\]
(20)

where we define \(\alpha_i = h_i^T R_{x,i}^{-1} h_i\), \(\beta_i = \min(d_{c,i})\), and \(d_{c,i}\) is a column vector consisting of the eigenvalues of \(R_{x,i}\) (note that \(R_{x,i}\) can be nondiagonal). Substituting (20) into the objective function of (17), we get
\[
\sum_{i=1}^{M} \frac{1}{\sigma_0^2} \left( \frac{1}{1 - \sigma_0^2 \eta(C_i)} - 1 \right) = \sum_{i=1}^{M} \frac{\alpha_i P_i^*}{\beta_i + P_i^*}.
\]
(21)

Clearly, the optimal power allocation \(\{P_1^*, P_2^*, \ldots, P_M^*\}\) must be the one, among all feasible power assignments, that maximizes (21). Therefore, it can be found out by
\[
\min_{\{P_1, \ldots, P_M\}} \sum_{i=1}^{M} \frac{\alpha_i P_i}{(1 - \sigma_0^2 \alpha_i) P_i + \beta_i} \quad \text{s.t. } \sum_{i=1}^{M} P_i \leq P \quad P_i \geq 0 \quad \forall i \in \{1, \ldots, M\}.
\]
(22)

It is easy to verify that the optimization problem (22) is convex because its Hessian matrix, which is a diagonal matrix in this case, is positive semidefinite on the convex set defined by the linear constraints. Although (22) is efficiently solvable by numerical methods, it can also be solved analytically by resorting to the Lagrangian function and Karush-Kuhn-Tucker conditions, which leads to a water-filling type power allocation scheme. The details are omitted here because of space limita-
tions. Briefly speaking, for a threshold \(\lambda\), we have
\[
P_i = \begin{cases} \frac{1}{\phi_i} \left( \sqrt{\frac{\phi_i}{\lambda}} - 1 \right) & \phi_i \geq \lambda \\ 0 & \text{otherwise} \end{cases}
\]
(23)

where \(\phi_i = \alpha_i / \beta_i\), \(\phi_i = (1 - \sigma_0^2 \alpha_i) / \beta_i\). It is easy to see that each cluster can decide whether to transmit or keep silent by the criterion \(\phi_i \geq \lambda\). Note that \(\phi_i\) is the ratio of \(h_i^T R_{x,i}^{-1} h_i\) to \(\min(d_{c,i})\), with the former is a measure of the cluster’s estimation quality (a larger value indicates a better estimation accuracy) and the latter a measure of the cluster’s channel quality (a smaller value indicates a better channel quality).

So far we have developed an analytical approach that leads to an optimal solution to (6). For clarity, we now summarize the steps of our proposed method.

1. Given the prior knowledge of the autocorrelation matrices \(\{R_{w,i}\}_{i=1}^{M}\), \(\{R_{x,i}\}_{i=1}^{M}\), and the observation gain vectors \(\{h_i\}_{i=1}^{M}\), compute \(\{\alpha_i\}_{i=1}^{M}\), and \(\{\beta_i\}_{i=1}^{M}\), where \(\alpha_i = h_i^T R_{w,i}^{-1} h_i\) and \(\beta_i = \min(d_{c,i})\).
2. Given the total power constraint \(P\), find the optimal power allocation among clusters via (22).
3. With the optimal power assignment \(\{P_1, P_2, \ldots, P_M\}\) derived in the previous step, determine the optimal collaboration matrices \(\{C_i\}_{i=1}^{M}\) via (19), whose solution is detailed in Theorem 1.

**Simulation results**

We consider the single cluster case and carry out a simple performance analysis to corroborate our theoretical results (more analysis and simulation results are available in Fang and Li [in press]). We compare our optimal collaboration strategy with the scheme proposed in Cui et al. (2007), where there is no intersensor collaboration and each sensor transmits its observation to the FC with optimally assigned power. For simplicity, we consider a homogeneous environment with identical observation and channel qualities, where \(\sigma_v^2\) denotes the observation noise variance and \(\sigma_w^2\) represents the channel noise variance. Also, all observation and channel gains are assumed to be unitary, i.e., \(g = 1\), throughout all examples in the article. Clearly, an equal power allocation is optimum for Cui et al. (2007) and the corresponding estimation MSE can be shown to be
\[
\text{MSE}_{\text{NC}} = \frac{P \sigma_v^2 \sigma_w^2 + N \sigma_v^2 \sigma_w^2 + N \sigma_v^2 \sigma_w^2}{PN \sigma_v^2 + P \sigma_w^2 + N \sigma_v^2 \sigma_w^2 + N \sigma_v^2 \sigma_w^2}.
\]
(24)

where the subscript NC denotes noncollaboration. For our collaboration strategy, the estimation MSE can be
computed by using (8), which reduces to
\[
\text{MSE}_{OC} = \frac{P \sigma_w^2 \sigma_v^2 + N \sigma_v^2 \sigma_0^2 + \sigma_v^2 \sigma_0^2 \sigma_w^2}{PN \sigma_0^2 + P \sigma_w^2 + N \sigma_v^2 \sigma_0^2 + \sigma_v^2 \sigma_w^2}, \tag{25}
\]
whence the subscript OC denotes optimal collaboration.

For notational convenience, let \(a = P \sigma_w^2 \sigma_0^2 + N \sigma_v^2 \sigma_0^2 \sigma_w^2\) and \(b = PN \sigma_0^2 + P \sigma_w^2 + N \sigma_v^2 \sigma_0^2\). It can be easily verified that
\[
(a + N \sigma_v^2 \sigma_0^2 \sigma_w^2)(b + \sigma_v^2 \sigma_0^2) \\
\geq (a + \sigma_v^2 \sigma_0^2 \sigma_w^2)(b + N \sigma_v^2 \sigma_0^2), \tag{26}
\]
where (26) becomes an equality only when \(N = 1\).

Hence as expected, the relationship MSE_{ENC} \gtrless\text{MSE}_{OC}\text{ holds, which means that the optimal collaboration scheme should always outperform the noncollaboration scheme.}

Figure 2 depicts the estimation MSEs of the two schemes as a function of \(N\) under a total transmit power constraint, with \(\sigma_w^2 = 0.2\) and \(\sigma_v^2 = 1\), respectively. From Figure 2, we see that both schemes benefit from an increasing number of sensors; as \(N\) increases, the estimation MSEs will asymptotically approach certain values that, however, are nonzero. This observation can be readily verified from (24)–(25). Also, it can be seen that the noncollaborative scheme is sensitive to the value of \(\sigma_v^2\); as the observation quality deteriorates, its performance degrades considerably. In contrast, the collaborative strategy demonstrates a certain degree of robustness against the observation quality deterioration. In Figure 3, we plot the estimation MSE versus the total transmit power. We see that the performance gap between the two strategies shrinks as the transmit power increases. In fact, from (24)–(25) we observe that as the transmit power goes to infinity, these two strategies approach identical performance. This suggests that the collaborative strategy should be preferred especially when the sensor observation qualities are bad and transmit power is severely constrained.

**Conclusion**

We studied an optimal collaboration and power allocation problem for distributed estimation in a power-constrained collaborative sensor network, where the network consists of a number of sensor clusters, and collaboration is allowed within the same cluster but not across clusters. Our theoretical results showed that, given a specified total transmit power, the power should be assigned among the clusters in a water-filling manner, with each cluster deciding whether to transmit or keep silent by comparing with a threshold the ratio of a measure of the cluster’s estimation quality to a measure of the cluster’s channel quality. Also, for each cluster, if the channels from this cluster to the FC are independent, then an optimal collaboration yields only one local message, which is sent from the best channel
within the cluster to the FC; otherwise the local message has to be sent across all channels within the cluster at different power levels matched to their channel quality. Specifically, in either case, the compressed local message is exactly the local LMMSE estimate multiplied by an amplification factor. Simulation results have been presented to corroborate our theoretical analysis.

C JUN FANG received a bachelor’s of science and a master’s of science degree in electrical engineering from Xidian University, Xi’an, China, in 1998 and 2001, respectively, and earned a doctor of philosophy degree in electrical engineering from the National University of Singapore, Singapore, in 2006. During 2006 he was with the Department of Electrical and Computer Engineering, Duke University, as a postdoctoral research associate. Currently he is a postdoctoral research associate with the Department of Electrical and Computer Engineering at the Stevens Institute of Technology. His research interests include statistical signal processing, wireless communications, and distributed estimation and detection with their applications on wireless sensor networks. He received his undergraduate education in applied physics with a concentration in laser optics from the Changchun Institute of Optics and Fine Mechanics in Changchun, China, with a bachelor’s of engineering degree. In 1981 he came to the United States for graduate study as one of the first group of Chinese physics students in the CUSPEA program, obtaining a doctor of philosophy degree in theoretical condensed matter physics in 1987 from Stevens Institute of Technology, where he has been on the faculty ever since. His research efforts have been concentrated in the areas of solid-state electronics/nanoelectronics, optical communications and sensing, electromagnetic wave propagation, and interaction with matters such as chemical and bioagents, and high-performance computing approach to modeling of physical devices and phenomena. His work has been funded by NSF, ARO, ONR, and DARPA. He has published more than 190 research papers in peer-reviewed scientific journals, holds 9 U.S. patents, and guided more than 30 doctoral dissertations to completion. He holds membership in the American Physical Society, the Institute of Electrical and Electronics Engineers, the Optical Society of America, and Sigma Xi. E-mail: Hong-Liang.Cui@stevens.edu
