Abstract
Atomic layer deposition (ALD) was employed to grow coaxial thin films of Al₂O₃ and Al₂O₃/W bilayers on multi-walled carbon nanotubes (MWCNTs). Although the MWCNTs have an extremely high surface area, a rotary ALD reactor was successfully employed to perform ALD on gram quantities of MWCNTs. The uncoated and ALD-coated MWCNTs were characterized with transmission electron microscopy and x-ray photoelectron spectroscopy. Al₂O₃ ALD on untreated MWCNTs was characterized by nucleation difficulties that resulted in the growth of isolated Al₂O₃ nanospheres on the MWCNT surface. The formation of a physisorbed NO₂ monolayer provided an adhesion layer for the nucleation and growth of Al₂O₃ ALD films. The NO₂ monolayer facilitated the growth of extremely conformal coaxial Al₂O₃ ALD coatings on the MWCNTs. Cracks were also observed in the coaxial Al₂O₃ ALD films on the MWCNTs. After cracking, the coaxial Al₂O₃ ALD films were observed to slide on the surface of the MWCNTs and expose regions of bare MWCNTs. The Al₂O₃ ALD film also served as a seed layer for the growth of W ALD on the MWCNTs. The W ALD films can significantly reduce the resistance of the W/Al₂O₃/MWCNT wire. The results demonstrate the potential for ALD films to tune the properties of gram quantities of very high surface area MWCNTs.

1. Introduction
Carbon nanotubes (CNTs) have exceptional properties including low electrical resistance [1, 2], high mechanical strength [3, 4] and high thermal conductivity [5, 6]. CNTs can be used as building blocks for the fabrication of nanodevices including chemical sensors [7] and field-effect transistors [8]. CNTs can also be employed for many purposes such as field-emission electron sources [9] and nanoprobes for scanning probe microscopy [10]. There are many other emerging applications for both individual CNTs and dispersions of CNTs in composite materials [11, 12]. Many of these applications require thin films deposited on the CNTs to insulate, protect or functionalize the CNTs.

Atomic layer deposition (ALD) methods are preferred to obtain conformal and controlled film deposition at the atomic level. ALD is based on sequential, self-limiting surface reactions [13, 14] and has been reported for many materials [15, 16]. ALD can be applied to CNTs because ALD has been demonstrated on very high aspect ratio structures [17] and nanoparticles [18]. Al₂O₃ ALD growth has been reported on individual single-walled carbon nanotubes (SWCNTs) [19, 20] and multi-walled carbon nanotubes (MWCNTs) [21, 22]. The nucleation of Al₂O₃ ALD was identified as a significant problem for ALD on SWCNT surfaces [19, 20]. Fortunately, a functionalization procedure based on the adsorption of NO₂ and trimethylaluminum (TMA)
has been shown to yield an adhesion layer on SWCNTs [20]. This adhesion layer facilitates the nucleation of Al₂O₃ ALD and produces very conformal Al₂O₃ ALD films using TMA and H₂O as the reactants [20].

ALD on CNTs has been developed for CNT nanotube transistors and logic gates [23]. ZrO₂ ALD has been employed to deposit high dielectric constant insulating layers on CNTs to fabricate field-effect transistors [23]. HfO₂ ALD on SWNTs has also been achieved to fabricate high performance thin-film transistors [24]. Nucleation difficulties for ZnO ALD on MWCNTs has been shown to lead to bead-shaped crystalline particles on the surface of the MWCNTs that enhance electron field emission [25]. In contrast, coaxial ZnO/Al₂O₃ heterostructures were fabricated on CNTs after depositing an Al₂O₃ adhesion layer on CNTs [26]. Vanadium oxide ALD has also been employed to fabricate gas sensors from CNTs [27].

Most of the previous applications for ALD on CNTs have been demonstrated using single CNTs. Single individual CNTs avoid the many difficulties that are encountered when attempting ALD on large quantities of CNTs. Dramatic quantities of CNTs have an extremely high surface area of 200–300 m² g⁻¹ and can be entangled to form CNT aggregates. ALD on large quantities of CNTs has the same problems as ALD on particles in particle beds. The CNTs must be agitated to enhance gas conductance of the ALD reactants to the individual CNTs. Likewise, the CNTs must be displaced relative to each other during ALD to prevent the CNTs from being glued together by the ALD film. Enhanced gas conductance and constant CNT motion in the bed of CNTs can be accomplished using fluidized bed reactors [28, 29] or rotary reactors [30, 31].

ALD on large quantities of CNTs would be useful for preparing CNTs for CNT/polymer composites. CNT/polymer composites should have high mechanical strength, high thermal conductivity and high electrical conductivity. Possible applications for these CNT/polymer composites include transparent conductive coatings, electromagnetic interference shielding and flexible electrostatic dissipation films. There are many previously reported examples of CNT/polymer composites [32–36]. However, dispersion of CNTs in the polymer composite is a difficulty and may limit the properties of the CNT/polymer composite. ALD on the CNTs may help to improve the dispersion and coupling of CNTs in polymers.

The inertness of the surface of the CNT is the cause for the insolubility of CNTs in water and organic solvents [37] and the lack of dispersion of CNTs in polymers. Covalent functionalization can enhance CNT solubility [37] and provide coupling between CNTs and polymers [36]. Unfortunately, covalent functionalization of the CNT surface damages the inherent properties of the CNT [38]. Surfactants can also noncovalently functionalize the surface of CNTs without perturbing the underlying CNT properties [39, 40]. However, covalent and noncovalent functionalization of CNTs both require wet chemical treatment. ALD can deposit ultrathin coatings on CNTs using gas phase procedures that will facilitate CNT dispersion without requiring a solution process.

In this paper, ALD on large quantities of high surface area MWCNTs is demonstrated using a rotary ALD reactor. The nucleation of Al₂O₃ ALD on gram quantities of MWCNTs is achieved using NO₂ and TMA to form an adhesion layer. Without the NO₂ nucleation procedure, the Al₂O₃ ALD grew nanospheres on the MWCNT surface. With the NO₂ nucleation procedure, the Al₂O₃ ALD grew very conformally on the MWCNTs. The ALD-coated MWCNTs were examined using transmission electron microscopy (TEM) and x-ray photoelectron spectroscopy (XPS) versus the number of Al₂O₃ ALD reaction cycles. The Al₂O₃ ALD coating was also used as a foundation for the subsequent growth of W ALD films on the MWCNTs.

2. Experimental details

2.1. MWCNTs and rotary reactor

The MWCNTs used in these experiments were 7000 series MWCNTs from Nanocyl (Sambreville, Belgium). For the Al₂O₃ ALD and W ALD, trimethylaluminum (97%) and WF₆ were obtained from Sigma-Aldrich (St Louis, MO). HPLC grade H₂O was also from Sigma-Aldrich and was further purified by five cycles of freeze–pump–thaw. For the NO₂ nucleation treatment, commercial purity grade NO₂ (99.5%) was acquired from Airgas (Radnor, PA). The Si₂H₆ used for W ALD was from Voltaix Inc. (Branchburg, NJ).

The specific surface areas of MWCNTs are on the order of hundreds of m² g⁻¹ [41–43]. From Brunauer, Emmett and Teller (BET) measurements, the manufacturer reports a specific surface area of 250–300 m² g⁻¹ for the 7000 series MWCNTs. This surface area is approximately an order of magnitude larger than for the nanopowders previously coated with ALD [30]. For equivalent masses of material, larger reactant exposures and purge times are required for the MWCNTs compared with typical nanopowders. BET measurements may also probe the inner surfaces of the MWCNT if the MWCNTs have open ends.

ALD on particles is possible using either fluid bed reactors [28, 29] or rotary reactors [30, 31]. Rotary reactors have an advantage when performing ALD on nanoparticles because the rotary reactors can provide for static reactant exposures [30]. These static reactant exposures can minimize the amount of reactant that is lost to the vacuum pump. Recent work has demonstrated the feasibility of ALD on gram quantities of nanopowders in a rotary reactor [30]. The rotary reactor employed in this study was similar to the rotary reactor employed in the previous work [30, 31].

A schematic of the rotary reactor is shown in figure 1. Each reactant entered the reaction chamber (A) through a needle and pneumatic valves (B) that were attached to 0.25” welded ports on a custom 6’’ weldment (C). During the reaction, the MWCNTs were mechanically agitated in a rotating porous cylinder (D). The rotation was achieved via a magnetically coupled rotary feedthrough (E). The pressure was monitored with 10 and 1000 Torr capacitance manometers (F). A gate valve (G) was opened to exhaust product gases and any excess precursor to the pump (H).

Before coating the MWCNTs in the rotary reactor, MWCNT quantities from 20 mg to 2 g were placed in the
porous stainless steel cylinder with a pore size of 10 μm. The porous metal cylinder was then attached to the magnetically coupled rotary feedthrough (E). This feedthrough with the porous metal cylinder was then enclosed in the vacuum chamber of the rotary reactor and left to outgas under vacuum for 24 h. Vacuum was obtained using a dual-stage rotary vane pump. Pressure was monitored with a Baratron capacitance manometer (MKS, Andover, MA). For the larger quantities of MWCNTs, the reactant exposures were scaled linearly according to the sample mass. For 1–2 g samples of MWCNTs, multiple doses of precursors were required to achieve the desired reactant exposure [31].

A ceramic heater (Watlow Electric Manufacturing Co., St Louis, MO) on the rotary reactor was employed for reactions performed at elevated temperatures. The temperature was monitored with a thermocouple and was manually controlled by applying a constant voltage to the resistive heating element. During the NO2 functionalization treatment and ALD processing, the porous metal cylinder was rotated in the rotary reactor at ~150 rpm. Given the diameter of the rotating porous cylinder, this rotational frequency is consistent with a centripetal acceleration of ~0.5 g where g is gravitational acceleration. Reasonable results were obtained using rotational frequencies from 140–180 rpm. Rotational frequencies <140 rpm led to less agitation and agglomeration during ALD. Rotational frequencies >180 rpm led to agglomeration resulting from the CNTs staying on the walls of the porous cylinder.

2.2. Al2O3 ALD and surface nucleation chemistry

Al2O3 ALD was performed on gram quantities of MWCNTs in the rotary reactor. The Al2O3 ALD surface chemistry employs Al(CH3)3 (TMA) and H2O as the reactants. The sequential, self-limiting reaction sequence during Al2O3 ALD is [44–46]:

(A) AlOH∗ + Al(CH3)3 → AlO–Al(CH3)∗3 + CH4  (1)
(B) AlCH∗3 + H2O → Al–OH∗ + CH4  (2)

where the asterisks denote surface species. The Al2O3 ALD reaction sequence was: (1) TMA dose to set pressure; (2) TMA reaction time; (3) evacuation of reaction products and excess TMA; (4) N2 dose; (5) N2 static time; (6) evacuation of N2 and any entrained gases; (7) H2O dose to pressure; (8) H2O reaction time; (9) evacuation of reaction products and excess H2O; (10) dose N2; (11) N2 static time; and (12) evacuation of N2 and any entrained gases. This sequence constituted one AB cycle of Al2O3 ALD.

During the NO2 nucleation treatment, an adsorbed functionalization layer was initially formed on the MWCNTs by alternating exposures of NO2 and TMA [20]:

(A) MWCNT∗ + NO2 → MWCNT–NO2∗  (3)
(B) MWCNT–NO2∗ + TMA → MWCNT–NO2∗–TMA∗  (4)

where the asterisks indicate surface species. In this functionalization process, the nitrogen of the NO2 is attracted to the CNT surface and leaves the oxygen atoms accessible. Upon TMA exposure, the oxygen atoms coordinate to the aluminum of the TMA molecule leaving a methyl-terminated surface [20]. The methyl-terminated surface does not interact with subsequent NO2 exposures.

Following the previous nucleation procedure [20], 50 cycles of NO2/TMA were used to functionalize the MWCNTs at room temperature. This NO2 treatment was performed with the following sequence: (1) exposure to NO2 to set pressure; (2) NO2 static reaction time; (3) evacuation of excess NO2; (4) exposure to TMA to set pressure; (5) TMA static reaction time; and (6) evacuation of excess TMA. This sequence defines one AB cycle of the NO2/TMA functionalization layer. For 20 mg of MWCNTs, the dose pressures were 300 mTorr for both NO2 and TMA. The static reaction times for NO2 and TMA were 10 s. The NO2 and TMA purge times were 7 s and 30 s, respectively. The NO2/TMA functionalization layer will desorb at elevated temperatures. Consequently, the adsorbed NO2/TMA layer was stabilized with 5 AB cycles of Al2O3 ALD at room temperature. Al2O3 ALD growth could then be continued at higher reaction temperatures.

For the Al2O3 ALD on the untreated MWCNTS and on the NO2/TMA functionalized MWCNTs, the Al2O3 ALD reaction sequence was employed at 180 °C. For 20 mg of MWCNTs, the dose pressures were 1.0 Torr for TMA and H2O and 20 Torr for N2. The reaction times for the TMA and H2O were both 60 s. The N2 static time was 5 s. All purge times were 60 s. Figure 2 displays the ALD reactor pressure versus time for one AB cycle of Al2O3 ALD for (a) untreated MWCNTs and (b) NO2/TMA functionalized MWCNTs. For both the untreated MWCNTs and the NO2/TMA functionalized MWCNTs, the pressure responses during the TMA doses shown in figures 2(a) and (b) are similar. The pressure responses during the H2O doses were different for the untreated MWCNTs and NO2/TMA functionalized MWCNTs. For the untreated MWCNTs, figure 2(a) reveals that the pressure dropped following the H2O dose of 1 Torr. For the NO2/TMA functionalized MWCNTs, figure 2(b) shows that the pressure dipped briefly and then returned to 1 Torr.

The difference in behavior for H2O on the untreated MWCNTs and the NO2/TMA functionalized MWCNTs is accounted for by the difference in reactive surface areas. The
conformally coated MWCNTs have a larger Al$_2$O$_3$ surface area. The H$_2$O reacts nearly completely on this surface area and little extra H$_2$O is available for reabsorption. The pressure stays close to 1 Torr because H$_2$O is converted to CH$_4$ reaction product. For the untreated MWCNTs and an equivalent H$_2$O exposure, the growth of Al$_2$O$_3$ nanospheres only consumes a fraction of the H$_2$O. The excess H$_2$O molecules then slowly adsorb on the Al$_2$O$_3$ surface.

After depositing an Al$_2$O$_3$ ALD layer on the MWCNTs, other ALD coatings can be applied such as W ALD. W ALD was accomplished using WF$_6$ and Si$_2$H$_6$ as the reactants. The sequential, self-limiting reaction sequence for W ALD is [47, 48]

(A) $WF_6^* + Si_2H_6 \rightarrow W - SiH^* + SiHF_3 + 2H_2$  \hspace{1cm} (5)

(B) $WSiH^* + WF_6 \rightarrow W - WF_3^* + SiHF_3$.  \hspace{1cm} (6)

The W ALD chemistry is not a truly self-limiting process. W ALD is dependent on the Si$_2$H$_6$ exposure and the substrate temperature [49]. A typical growth rate for W ALD is $\sim 5$ Å/cycle [50].

For W ALD on the MWCNTs, the W ALD reaction sequence was: (1) dose Si$_2$H$_6$ to set pressure; (2) Si$_2$H$_6$ reaction time; (3) evacuation of reaction products and excess Si$_2$H$_6$; (4) N$_2$ dose; (5) N$_2$ static time; (6) evacuation of N$_2$ and any entrained gases; (7) dose WF$_6$ to set pressure; (8) WF$_6$ reaction time; (9) evacuation of reaction products and excess WF$_6$; (10) dose N$_2$; (11) N$_2$ static time; and (12) evacuation of N$_2$ and any entrained gases. This sequence constituted one AB cycle of W ALD. W ALD was employed at 180°C. For 20 mg of MWCNTs, the dose pressures were 1.0 Torr for the Si$_2$H$_6$ and WF$_6$ and 20 Torr for the N$_2$. The reaction times for the Si$_2$H$_6$ and WF$_6$ were 200 s and the purge times were both 50 s. The N$_2$ static time was 20 s and the purge time was 200 s.

2.3. TEM and XPS analysis

Transmission electron microscopy (TEM) images of the MWNCTs and ALD-coated MWCNTs were collected on a Philips CM10 electron microscope (Mahwah, NJ). A Gatan digital camera (Gatan, Pleasanton, CA) was used to record the images. Measurements of the micrographs were made in Deneba Canvas 9 (ACD Systems, Victoria, British Columbia, Canada). These measurements were used to determine the film thickness.

A PHI 5600 x-ray photoelectron spectrometer was used to obtain x-ray photoelectron spectra (XPS) of the ALD-coated MWCNTs. The powder samples were pressed into pellets with a thickness of 0.7 mm and a diameter of 5.5 mm and affixed to the sample puck with carbon tape. Monochromatic Al K$_\alpha$ x-rays (1486.6 eV) were used for the XPS analysis. The pass energy was 58.7–93.9 eV and the step size was 0.250–0.400 eV. An electron beam neutralizer was employed at 17.8 mA. Data was collected with Auger Scan (RBD Enterprises, Inc., Bend, OR). XPS data was analyzed in CASA XPS (Casa Software Ltd, UK). Peak fits for the W 4f peaks were obtained using a linear background and a 70:30 Gaussian:Lorentzian peak.

3. Results and discussion

3.1. Entangled MWCNT clusters

Transmission electron microscopy (TEM) images were used to characterize the MWCNTs and the ALD film growth on the MWCNTs. The uncoated MWCNTs were a fine powder. These uncoated MWCNTs displayed a range of tube diameters as observed by TEM. The manufacturer reported an average tube diameter of 10 nm. The nanotubes were also agglomerated in entangled clusters prior to the ALD coating. A TEM image of these uncoated entangled clusters of MWCNTs is displayed in figure 3. The diameter of these entangled clusters was $\sim 2–3 \mu m$. 

Figure 2. Reactor pressure versus time for one AB cycle during Al$_2$O$_3$ ALD for (a) untreated MWCNTs and (b) NO$_2$/TMA functionalized MWCNTs.

Figure 3. TEM image of an uncoated entangled cluster of MWCNTs.
TEM images of the coated MWCNTs were typically imaged on the edge of a μm-scale entangled cluster. Further agglomeration of the MWCNTs during ALD was prevented by performing the ALD in the rotary reactor under agitation by rotation [30]. There were still μm-scale agglomerates of MWCNTs after ALD processing. Some of these agglomerates were mechanically crushed prior to TEM analysis to obtain MWCNTs from the center of the entangled clusters. MWCNTs from the edge and center of the entangled clusters were all found to be coated with Al2O3 ALD.

3.2. Al2O3 ALD nanospheres on untreated MWCNTs

ALD Al2O3 on untreated MWCNTs resulted in the growth of Al2O3 nanospheres. A TEM micrograph of these nanospheres after 50 AB cycles is shown in figure 4. The nanospheres are fairly spherical and monodisperse. The radii of the nanospheres are in the range of 11–13 nm. The TEM images suggest that Al2O3 ALD growth nucleates at specific sites on the MWCNT surface during the initial Al2O3 ALD cycles. The nanospheres then grow isotropically versus the number of AB cycles to yield fairly monodisperse sphere diameters. Very similar Al2O3 nanospheres were observed earlier after Al2O3 ALD on individual SWCNTs [19].

Figure 5 shows TEM images of the Al2O3 nanospheres after 100 AB cycles. There is an increase in the nanosphere diameter and the number of nanospheres after 100 AB cycles. However, the nanospheres are not as monodisperse compared with the nanospheres after 50 ALD cycles. The radii of the nanospheres range from 11–20 nm. This finite range indicates that the Al2O3 ALD nanospheres do not all nucleate at the same time. Sites that nucleate later should experience fewer Al2O3 ALD cycles and produce nanospheres with smaller radii. For adjacent nanospheres, the spheres eventually begin to coalesce to form a rough, pseudo-continuous Al2O3 film.

Previous studies of Al2O3 ALD on individual MWCNTs have observed conformal growth on nanotube surfaces that were not intentionally functionalized [21, 22]. In contrast, figures 4 and 5 reveal that the Al2O3 ALD growth was not conformal in this study. Distinct nanospheres are observed that are similar to the Al2O3 nanospheres observed after Al2O3 ALD on unfunctionalized SWCNTs [19]. A possible explanation for this difference in growth involves the presence of defects or inadvertent chemical functionalization on the earlier MWCNT surfaces.

The density of defects and chemical functional groups on the MWCNT surface may be related to the method of MWCNT synthesis and subsequent cleaning and purification methods [51]. The growth of nanospheres may be expected for a low density of defects or active chemical species on the MWCNT surface. If the density of defects or active chemical species is much higher, the larger density could lead to a conformal Al2O3 ALD film. The defect density may have been significantly lower for the MWCNTs utilized in this study compared with MWCNTs used in previous studies [21, 22].

3.3. Conformal Al2O3 ALD growth on NO2/TMA functionalized MWCNTs

To grow conformal Al2O3 ALD coatings on gram quantities of MWCNTs, a functionalization layer of adsorbed NO2 and TMA was initially formed at room temperature. This adsorbed layer is not stable at the elevated temperatures typically used to grow Al2O3 ALD. However, this adsorbed layer can be stabilized with an Al2O3 passivation layer consisting of 5 AB cycles of Al2O3 ALD at room temperature. The Al2O3 ALD chemistry readily nucleated and grew conformally on this adsorbed layer.

Additional Al2O3 ALD cycles were performed at 180 °C to achieve the desired Al2O3 ALD film thickness. Figure 6 displays a TEM image after 50 AB cycles of Al2O3 ALD on the NO2/TMA functionalized MWCNTs. In contrast to the nanospheres observed in figure 4 after 50 AB cycles, the Al2O3 films are smooth and conformal after 50 AB cycles on the NO2/TMA functionalized MWCNTs. A second TEM image showing a larger portion of the entangled MWCNT
Figure 6. TEM image of NO$_2$/TMA functionalized MWCNTs after 50 AB cycles of Al$_2$O$_3$ ALD.

Figure 7. TEM image of NO$_2$/TMA functionalized MWCNTs after 50 AB cycles of Al$_2$O$_3$ ALD at lower magnification.

Figure 8. TEM image of NO$_2$/TMA functionalized MWCNTs after 40 AB cycles of Al$_2$O$_3$ ALD at higher magnification.

Figure 9. TEM image of NO$_2$/TMA functionalized MWCNTs after 60 AB cycles of Al$_2$O$_3$ ALD showing evidence for Al$_2$O$_3$ ALD film cracking and sliding on MWCNTs.

3.4. ‘Macaroni’ on MWCNT string

According to the proposed NO$_2$ nucleation mechanism, the Al$_2$O$_3$ ALD films are grown on an adsorbed layer of NO$_2$/TMA on the CNTs [20]. This adsorbed layer is not covalently attached to the surface of the CNT. Consequently, the coaxial Al$_2$O$_3$ ALD film on the CNTs should be free to slide along the CNTs. TEM images reveal this ‘sliding’ behavior. Locations where the Al$_2$O$_3$ ALD film has broken on the MWCNT show evidence for the sliding of the Al$_2$O$_3$ ALD film along the MWCNT. Broken Al$_2$O$_3$ ALD films that have moved to reveal bare MWCNTs are indicated by the arrows in figures 6 and 7.

These broken sections of coaxial Al$_2$O$_3$ ALD film on the MWCNT are like ‘macaroni’ on an MWCNT string. A TEM image that captures a segment of an Al$_2$O$_3$ ALD film on the MWCNT is displayed in figure 9. This Al$_2$O$_3$ ALD film was deposited using 60 AB cycles. The mechanical tumbling of the entangled clusters of MWCNTs may facilitate the breaking of the Al$_2$O$_3$ ALD films at the ends of MWCNTs.
ALD segments may then slide off the MWCNTs to reveal bare MWCNTs at the edge of an entangled cluster. Figure 10 shows a TEM image that reveals a number of bare MWCNTs dangling at the perimeter of an entangled MWCNT cluster.

3.5. Bilayers of W ALD/Al2O3 ALD on MWCNTs

The conformal coaxial Al2O3 ALD coating on MWCNTs can serve as a substrate for the subsequent growth of another ALD material. W ALD was performed on the Al2O3 ALD coating to deposit a W/Al2O3 bilayer on the MWCNTs. The initial Al2O3 ALD film was prepared using the NO2/TMA nucleation procedure and then 50 cycles of Al2O3 ALD. Subsequently, W ALD was grown on the Al2O3 ALD surface. Figure 11 displays a TEM image after 60 cycles of W ALD using WF6 and Si2H6. The W ALD leads to an increase in diameter of the coated MWCNTs. Bare MWCNTs where the W/Al2O3 bilayer has slipped off the ends of the MWCNTs are also indicated by the arrows.

The surface of the W/Al2O3 bilayer film is rougher and more granular than the Al2O3 ALD film on MWCNTs. The surface roughness may be caused by the polycrystal W ALD film or difficulties for the W ALD nucleating on the Al2O3 ALD surface [52–54]. Both of these factors are believed to affect the roughness of W ALD layers in W/Al2O3 nanolaminates [53, 55]. In spite of the increased roughness, the W/Al2O3 bilayer film is still conformal to the MWCNTs. TEM measurements of the W ALD film thickness were difficult because of the lack of a distinct boundary between the Al2O3 ALD film and the W ALD film. While the density disparity between Al2O3 ALD and W ALD should be evident, the geometry of the two coaxial nested cylinders prevented this distinction.

X-ray photoelectron spectroscopy (XPS) was used to analyze: (a) the uncoated MWCNTs; (b) the Al2O3 ALD on the untreated MWCNTs; (c) the Al2O3 ALD on the NO2/TMA functionalized MWCNTs; and (d) the W ALD on the Al2O3 ALD on the NO2/TMA functionalized MWCNTs. The XPS spectrum of uncoated MWCNTs shown in figure 12(a) displayed a distinct C 1s peak with a full width at half-maximum (FWHM) of 1.5 eV. The XPS spectrum of Al2O3 ALD on untreated MWCNTs shown in figure 12(b) also displayed peaks for Al, C and O. All of these peaks had a broader FWHM of ∼2.6 eV. This slight broadening may result from charging effects attributed to the presence of Al2O3 on the MWCNTs. The typical ratio for Al:O was 2:2.6 determined from the Al 2p and O 1s XPS signals.

The XPS spectrum of Al2O3 ALD on the NO2/TMA functionalized MWCNTs is displayed in figure 12(c).
Al, C and O peaks had an average FWHM of $\sim 2.5$ eV. The typical ratio of Al:O was 2:2.7. The presence of C in the XPS spectrum exceeded the level of expected adventitious C on the surface of the Al$_2$O$_3$ film. The extra C content may result from locations where the Al$_2$O$_3$ ALD film had cracked on the MWCNTs during sample preparation.

The XPS analysis of the NO$_2$/TMA functionalized MWCNTs did not detect N. No N was observed for samples before or after argon sputtering. For a monolayer of NO$_2$ on the MWCNT surface, the expected N signal should be approximately at the XPS detection limit. However, the NO$_2$ molecules may also desorb from the surface of the MWCNTs. This NO$_2$ desorption may occur after the Al$_2$O$_3$ ALD films crack on the MWCNTs during mechanical agitation in the rotary reactor at 180 $^\circ$C.

The XPS spectrum of the W/Al$_2$O$_3$ bilayers on the MWCNTs is shown in figure 12(d). This spectrum reveals Al, C, O and W and trace quantities of F and Si. F was present at less than 2 at.% and Si was observed in trace amounts at the noise limit. The W 4f$_{5/2}$ and W 4f$_{7/2}$ XPS signals were also examined in more detail at 30–40 eV as displayed in figure 13. The presence of a quadruplet instead of a doublet for W 4f$_{5/2}$ and W 4f$_{7/2}$ indicates the existence of a WO$_x$ film in combination with metallic W.

The WO$_x$ layer on the W ALD film occurs because tungsten metal is not stable in air. When the W/Al$_2$O$_3$/MWCNT samples were removed from the rotary reactor and exposed to the atmosphere, a tungsten oxide layer forms on the surface of the W ALD film. After accounting for O bonded to Al, the W:O ratio of 1:3.1 was determined from the WO$_3$ 4f and O 1s XPS signals. This ratio is consistent with tungsten oxidizing to WO$_3$. An Al$_2$O$_3$ ALD coating on top of the W ALD could serve to passivate the W ALD film and prevent the W film oxidation in the atmosphere.

Models for determining film thickness from XPS analysis rely on smooth, flat samples for accurate measurements [56]. The entangled cluster agglomerates of coated MWCNTs are more like a powder sample. Models can be employed that were developed for analyzing the XPS signals from powder samples. Based on these models [56], the thickness of the WO$_3$ from XPS measurements is estimated to be $\sim 10–25$ Å. This thickness is close to previously reported values for the thickness of WO$_3$ on W ALD surfaces [57, 58].

A schematic of a W/Al$_2$O$_3$ bilayer on a CNT is shown in figure 14. An additional insulating Al$_2$O$_3$ ALD film on this W/Al$_2$O$_3$ bilayer would produce a nanocoaxial cable [21]. The CNT is the center conductor, the Al$_2$O$_3$ ALD layers are insulators and the W ALD layer is the metallic shield. These nanocoaxial cables may be useful as electrical nanoprobes. Similar nanocoaxial cables have been fabricated by sputtering Al$_2$O$_3$ and Cr on vertically aligned MWCNTs and then coating with spin-on glass [59]. The W ALD film thickness in the W/Al$_2$O$_3$ bilayer can also be increased to decrease the resistance of a W/Al$_2$O$_3$/CNT wire. The W ALD thickness can tune the resistance of the CNT over a wide range.

Using a four-point probe technique, the resistivity of individual single-walled CNTs (SWCNT) was $< 10^{-4}\Omega$ cm for nanotubes with a diameter of 13.8 $\pm$ 2 Å [60]. From these measurements, the resistance per unit length is $R/L < 167 \Omega$ nm$^{-1}$. In comparison, W metal has a resistivity of $5.44 \times 10^{-6}$ $\Omega$ cm [61]. Assuming a SWCNT with a diameter of 13.8 Å and $R/L = 167 \Omega$ nm$^{-1}$, figure 15 compares the resistance per unit length for a bare SWCNT and a SWCNT coated with various W thicknesses. For the W-coated SWCNT,
the resistance per unit length is progressively reduced versus W thickness. The resistance per unit length is reduced by almost two orders of magnitude with a W thickness of only \( \sim 10 \, \text{Å} \). Note that the calculations did not account for W oxidation or electron scattering at the surface or grain boundaries [62, 63]. Figure 15 serves to illustrate the ability of thin metal films to reduce significantly the resistance of CNTs.

4. Conclusions

Atomic layer deposition (ALD) was performed on quantities of multi-walled carbon nanotubes (MWCNTs) in a rotary reactor. The uncoated and ALD-coated MWCNTs were characterized with transmission electron microscopy and x-ray photoelectron spectroscopy. \( \text{Al}_2\text{O}_3 \) ALD grew as nanospheres on quantities of untreated MWCNTs because of nucleation difficulties. After the NO\(_2\)/TMA nucleation treatment, the \( \text{Al}_2\text{O}_3 \) ALD film grew conformally on the MWCNTs. In addition, the coaxial \( \text{Al}_2\text{O}_3 \) ALD growth on the MWCNTs was approximately linear versus the number of \( \text{Al}_2\text{O}_3 \) ALD reaction cycles.

The \( \text{Al}_2\text{O}_3 \) ALD films were observed to crack on the MWCNTs. More cracking was monitored after crushing and increased mechanical agitation. The coaxial \( \text{Al}_2\text{O}_3 \) ALD films were observed to slide on the surface of the MWCNTs and expose regions of bare MWCNTs. This ease in sliding after cracking of the \( \text{Al}_2\text{O}_3 \) ALD film is consistent with a noncovalently bonded \( \text{Al}_2\text{O}_3 \) ALD film. The \( \text{Al}_2\text{O}_3 \) ALD film also served as a foundation for coaxial W ALD film growth on the MWCNTs. XPS analysis indicated that the W/\( \text{Al}_2\text{O}_3 \) bilayer on the MWCNTs was covered with a native WO\(_3\) layer. This WO\(_3\) layer results from the exposure of the W ALD film to the atmosphere. The coaxial W ALD film growth on the MWCNTs should significantly reduce the resistance of the W/\( \text{Al}_2\text{O}_3 \)/MWCNT wire.

Acknowledgments

This research was initially supported by a subcontract from an NSF Phase I SBIR grant to ALD NanoSolutions, Inc. (Broomfield, CO). Subsequent support was provided by the DARPA N/MEMS S&T Fundamentals Program (award no. HR0011-06-1-0048) at the University of Colorado. The authors thank Dr Tom Giddings for his assistance with the TEM. The authors also thank Drs Jarod A McCormick and Arrelaine A Dameron for helpful discussions.
