Abstract

We study the Rayleigh-Bénard stability problem for a fluid confined within a square enclosure subject to random perturbations in the temperature distribution at both the horizontal walls. These temperature perturbations are assumed to be non-uniform Gaussian random processes satisfying a prescribed correlation function. By using the Monte Carlo method we obtain stochastic bifurcation diagrams for the Nusselt number near the classical onset of convective instability. These diagrams show that random perturbations render the bifurcation process to convection imperfect, in agreement with known results. In particular, the pure conduction state does no longer exist, being replaced by a quasi-conduction regime. We have observed subcritical and nearly supercritical quasi-conduction stable states within the range of Rayleigh numbers $Ra = 0 - 4000$. This suggests that random perturbations in the temperature distribution at the horizontal walls of the cavity can extend the range of stability of quasi-conduction states beyond the classical bifurcation point $Ra_c = 2585.02$. Analysis of the stochastic bifurcation diagrams shows the presence of a stochastic drift phenomenon in the heat transfer coefficients, especially in the transcritical region. Such stochastic drift is investigated further by means of a sensitivity analysis based on functional ANOVA decomposition.

1. Introduction

The classical stability theory of Rayleigh-Bénard convection in an infinite layer of fluid confined between two horizontal isothermal walls with constant but unequal temperatures predicts that the amplitude of the motion undergoes a bifurcation as the Rayleigh number passes through the critical value $Ra_c = 1707.8$ (see, e.g., [1, 2]). Such bifurcation characterizes the transition between a pure conduction state and convection. If the flow is laterally confined by rigid and perfectly insulating sidewalls then the critical Rayleigh number usually increases [3, 4, 5, 6] due to the stabilizing effects of the finite geometry. Furthermore, if there is small heat transfer through these sidewalls so that the boundary conditions are inconsistent with a state of no-motion, then the bifurcation leading to convection is, in general, replaced by a smooth transition to finite amplitude flow [7]. Such a smooth transition has been also predicted theoretically for thermal convection in an infinite fluid layer between two rigid walls with different mean temperatures and small spatially periodic perturbations [8]. Since then, a considerable research effort has focused on examining the stability of different types of natural convective flows subject to deterministic boundary conditions [9, 5, 10, 11, 12]. However, not as much work has been done for the case when the boundary conditions are random processes of finite amplitude, although these results would bear upon the importance of ignoring uncertainty when applying classical stability results in real situations, both in laboratory experiments and elsewhere.

Thus, the purpose of the present paper is to examine the effects of temperature perturbations on the classical Rayleigh-Bénard stability problem, namely an unstably stratified fluid contained between two smooth horizontal walls with different mean temperatures. In particular, we will study the prototype problem of a square enclosure having perfectly insulating lateral sidewalls and determine how the random perturbations in the temperature distributions at the horizontal walls affect the stability and the branch points obtained from classical bifurcation analysis. Clearly, when no variations occur along the boundaries convection is possible only when the Rayleigh number is greater than the classical critical value $Ra_c = 2585.02$ [6, 5, 13]. However, when random temperature variations do occur at the horizontal walls, the bifurcation process leading to convection becomes imperfect [14] and the subcritical pure conduction state no longer exists, being replaced by a quasi-conduction regime [8]. This type of flow is characterized by a finite - though perhaps small - velocity field and it can be observed even at low values of Rayleigh numbers.

Many important questions can be addressed in the context of stochastic thermal convection driven by random boundary conditions. For instance: how do the random temperature perturbations affect stability and branch points obtained from classical bifurcation analysis? Is there any connection between the stochastic properties of the temperature perturbations - such as correlation length and amplitude - and flow stability? Is there a preferential correlation length enhancing the fluid motion and the heat transfer? Is it possible to obtain realizations of stable supercritical quasi-conduction states? In this paper we will provide an answer to all these questions by employing a Monte Carlo numerical approach [15, 16] and ANOVA decomposition [17, 18, 19, 20].

This paper is organized as follows. In section 2 we formulate the governing equations of the system, i.e., the Oberbeck-Boussinesq approximation to convection via the vorticity trans-
Supercritical quasi-conduction states in stochastic Rayleigh-Benard convection

We study the Rayleigh-Bénard stability problem for a fluid confined within a square enclosure subject to random perturbations in the temperature distribution at both the horizontal walls. These temperature perturbations are assumed to be non-uniform Gaussian random processes satisfying a prescribed correlation function. By using the Monte Carlo method we obtain stochastic bifurcation diagrams for the Nusselt number near the classical onset of convective instability. These diagrams show that random perturbations render the bifurcation process to convection imperfect, in agreement with known results. In particular, the pure conduction state does no longer exist, being replaced by a quasi-conduction regime. We have observed subcritical and nearly supercritical quasiconduction stable states within the range of Rayleigh numbers $Ra = 0 \text{ to } 4000$. This suggests that random perturbations in the temperature distribution at the horizontal walls of the cavity can extend the range of stability of quasi-conduction states beyond the classical bifurcation point $Rac = 2585.02$. Analysis of the stochastic bifurcation diagrams shows the presence of a stochastic drift phenomenon in the heat transfer coefficient, especially in the transcritical region. Such stochastic drift is investigated further by means of a sensitivity analysis based on functional ANOVA decomposition.
port equation [21, 22]. In section 3 we characterize the random temperature perturbations at the horizontal walls of the cavity in terms of a Karhunen-Loève expansion satisfying a prescribed boundary conditions. The random perturbations are assumed to be zero mean Gaussian processes. The velocity boundary conditions are of no-slip type, i.e., \( \frac{\partial \psi}{\partial x} = \frac{\partial \psi}{\partial y} = 0 \) at the solid walls.

Figure 1: Schematic of the dimensionless geometry and dimensionless temperature boundary conditions. The random perturbations \( g_1 \) and \( g_2 \) are assumed to be zero mean Gaussian processes. The velocity boundary conditions are of no-slip type, i.e., \( \frac{\partial \psi}{\partial x} = \frac{\partial \psi}{\partial y} = 0 \) at the solid walls.

In section 3 we characterize the random temperature perturbations at the horizontal walls of the cavity in terms of a Karhunen-Loève expansion satisfying a prescribed boundary conditions. The random perturbations are assumed to be zero mean Gaussian processes. The velocity boundary conditions are of no-slip type, i.e., \( \frac{\partial \psi}{\partial x} = \frac{\partial \psi}{\partial y} = 0 \) at the solid walls.

2. Governing equations

Let us consider the two-dimensional steady state dimensionless form of the Oberbeck-Boussinesq approximation via the vorticity transport equation in streamfunction-only formulation

\[
-\frac{\partial \psi}{\partial y} \frac{\partial \nabla^2 \psi}{\partial x} + \frac{\partial \psi}{\partial x} \frac{\partial \nabla^2 \psi}{\partial y} = -Pr \nabla^2 \psi + RaPr \frac{\partial T}{\partial x}, \tag{1}
\]

\[
\frac{\partial \psi}{\partial y} \frac{\partial T}{\partial x} - \frac{\partial \psi}{\partial x} \frac{\partial T}{\partial y} = \nabla^2 T, \tag{2}
\]

where \( \psi(x, y; \omega) \) and \( T(x, y; \omega) \) denote the streamfunction and the temperature fields while \( Ra \) and \( Pr \) are the Rayleigh and the Prandtl numbers, respectively. The variable \( \omega \) appearing in \( \psi(x, y; \omega) \) and \( T(x, y; \omega) \) identifies a possible outcome of the streamfunction and the temperature for a specific realization of the random temperature distributions at the horizontal walls. All the quantities have been made dimensionless by scaling lengths with the side length of the cavity \( L \), streamfunction with the kinematic viscosity \( \nu \), time with \( L^2/\nu \) and temperature with a reference temperature difference \( \Delta T_r \), which is defined to be the difference between the spatial averages of the two temperature processes at the horizontal walls. With this rescaling, the Rayleigh and the Prandtl numbers are obtained as

\[
Ra = \frac{gL^3 \Delta T_r}{\nu}, \quad Pr = \frac{\nu}{\alpha}, \tag{3}
\]

where \( g \), \( \beta \), and \( \alpha \) are the acceleration of gravity, the isobaric compressibility coefficient and the thermal diffusivity of the fluid, respectively. We notice, that this type of non-dimensionalization is not effective when the average temperature is the same along the boundaries. Indeed, in this case the reference temperature difference \( \Delta T_r \) becomes 0 but we still could have convection due to temperature variations at the boundary. In figure 1 we show a sketch of the geometry and the boundary conditions associated with the system (1)-(2). As easily seen, the natural convection problem we are examining is a classical one, i.e., an incompressible fluid within a square cavity heated from below and cooled from above. The sidewalls of the cavity are assumed to be adiabatic, while the horizontal walls are subject to random temperature fluctuations whose rigorous mathematical definition will be given in the subsequent section. The velocity boundary conditions are assumed to be of no-slip type, i.e. \( \frac{\partial \psi}{\partial x} = \frac{\partial \psi}{\partial y} = 0 \) at solid walls. At this point it is convenient to transform the non-homogeneous temperature boundary conditions into homogeneous ones. This is easily achieved by defining the new field

\[
T^*(x, y; \omega) = T(x, y; \omega) + (y-1)(g_1(x; \omega) + 1) - yg_2(x; \omega), \tag{4}
\]

where \( g_1(x; \omega) \) and \( g_2(x; \omega) \) are random processes satisfying adiabatic boundary conditions at \( x = 0 \) and \( x = 1 \), i.e.

\[
\left. \frac{\partial g_i}{\partial x} \right|_{x=0,1} = 0, \quad \text{for} \quad i = 1, 2. \tag{5}
\]

Equation (4) can be inverted to give

\[
T = T^* + (1 - y)(g_1 + 1) + yg_2. \tag{6}
\]

From Eq. (6) we obtain

\[
\frac{\partial T}{\partial x} = \frac{\partial T^*}{\partial x} + y \left( \frac{\partial g_2}{\partial x} - \frac{\partial g_1}{\partial x} \right) + \frac{\partial g_1}{\partial x}, \tag{7}
\]

\[
\frac{\partial T}{\partial y} = \frac{\partial T^*}{\partial y} + (g_2 - g_1) - 1, \tag{8}
\]

\[
\nabla^2 T = \nabla^2 T^* + y \left( \frac{\partial^2 g_2}{\partial x^2} - \frac{\partial^2 g_1}{\partial x^2} \right) + \frac{\partial^2 g_1}{\partial x^2}. \tag{9}
\]
Finally, a substitution of Eqs. (7), (8) and (9) into Eqs. (1) and (2), respectively, yields the system
\[-\frac{\partial \psi}{\partial y} \frac{\partial (\nabla^2 \psi)}{\partial x} + \frac{\partial \psi}{\partial x} \frac{\partial (\nabla^2 \psi)}{\partial y} = -Pr\nabla^4 \psi\]
\[+RaPr \left( \frac{\partial T^*}{\partial x} + y \left( \frac{\partial g_2}{\partial x} - \frac{\partial g_1}{\partial x} \right) \right), \quad (10)\]
\[\frac{\partial \psi}{\partial y} \left( \frac{\partial T^*}{\partial x} + y \left( \frac{\partial g_2}{\partial x} - \frac{\partial g_1}{\partial x} \right) \right) + \frac{\partial \psi}{\partial x} \frac{\partial T^*}{\partial y} + \frac{\partial g_1}{\partial y} \left( g_2 - g_1 \right) - 1 \right) + \nabla^2 T^* + y \left( \frac{\partial^2 g_2}{\partial x^2} - \frac{\partial^2 g_1}{\partial x^2} \right) + \frac{\partial^2 g_1}{\partial x^2}. \quad (11)\]

The boundary conditions associated with Eqs. (10) and (11) are homogeneous. In Appendix A we obtain the integral representation of this system in terms of eigenfunctions of proper eigenvalue problems.

3. Characterization of temperature perturbations at the horizontal walls

We shall assume that the temperature perturbations \( g_1(x; \omega) \) and \( g_2(x; \omega) \) are zero mean random processes satisfying adiabatic boundary conditions at \( x = 0 \) and \( x = 1 \). In order to represent these processes let us first consider a suitable orthonormal basis obtained from the Sturm-Liouville eigenvalue problem [23, 24]
\[\frac{d^2 \phi}{dx^2} + \alpha^2 \phi = 0, \quad \text{with} \quad \frac{d \phi(0)}{dx} = \frac{d \phi(1)}{dx} = 0. \quad (12)\]
The normalized eigenfunctions solving (12) are
\[\phi_0(x) = 1, \quad \phi_n(x) = \sqrt{2} \cos(n\pi x) \quad n = 1, 2, 3, \ldots \quad (13)\]
Thus, if \( h(x; \omega) \) is a zero-mean process in \([0, 1]\) satisfying adiabatic boundary conditions at \( x = 0 \) and \( x = 1 \), then we have the following spectral representation \cite{25}
\[h(x; \omega) = \sigma \sum_{k=1}^{\infty} a_k(\omega) \phi_k(x), \quad (14)\]
where \( \sigma \) is a real parameter that characterizes the amplitude of the process while
\[a_k(\omega) = \frac{1}{\sigma} \int_0^1 h(x; \omega) \phi_k(x) \, dx \quad (15)\]
are uncorrelated random variables. The autocorrelation of the process \( h(x; \omega) \) has the obvious representation
\[C(x, x') = \frac{\langle h(x; \omega) h(x'; \omega) \rangle}{\sigma^2} = \sum_{n=1}^{\infty} \langle a_k^2 \rangle \phi_n(x) \phi_n(x'). \quad (16)\]
where \( \langle \cdot \rangle \) denotes the average with respect to the joint probability measure of the variables \( \{a_k(\omega)\} \). An important question at this point is: if we arbitrarily prescribe a symmetric autocorrelation function, say \( C(x, y) \), can we determine a set of uncorrelated random variables \( \{a'_k(\omega)\} \) such that (16) is satisfied? The answer is obviously affirmative, provided the prescribed autocorrelation satisfies the boundary conditions
\[\frac{\partial C(x, y)}{\partial x} = 0, \quad \forall y \in [0, 1] \quad (17)\]
as well as the zero-mean constraint
\[\int_0^1 C(x, y) \, dx = 0 \quad \forall y \in [0, 1]. \quad (18)\]
If \( C(x, y) \) does not satisfy such conditions then it is possible to enforce them through projection. To this end, let us first consider the (positive) Fourier coefficients
\[\langle b_n^2 \rangle \overset{\text{def}}{=} \int_0^1 \int_0^1 C(x, x') \phi_n(x) \phi_n(x') \, dx \, dx', \quad n \geq 1 \quad (19)\]
obtained by projecting the arbitrarily prescribed kernel \( C(x, x') \) onto the basis \( \{\phi_n\} \). This operation basically removes every spatial gradient at the boundaries \( x = 0 \) and \( x = 1 \) and makes the assigned correlation zero spatial mean, in the sense of (18). Next, let us consider the spectral expansion of the kernel \( C(x, x') \) in terms of its (positive) eigenvalues \( \lambda_k \) and eigenfunctions \( \psi_k \)
\[C(x, x') = \sum_{k=1}^{\infty} \lambda_k \psi_k(x) \psi_k(x'). \quad (20)\]
A substitution of this expression into (19) immediately yields
\[\langle b_n^2 \rangle = \sum_{k=1}^{\infty} \lambda_k \left[ \int_0^1 \psi_k(x) \phi_n(x) \, dx \right]^2, \quad n \geq 1. \quad (21)\]
At this point it is easy to check that if \( \{\xi_k(\omega)\} \) is any set of zero-mean and uncorrelated random variables with unit variance (i.e. \( \langle \xi_k^2 \rangle = 1 \)) then the process
\[h(x; \omega) = \sigma \sum_{k=1}^{\infty} (b_k^2)^{1/2} \xi_k(\omega) \phi_k(x) \quad (22)\]
satisfies the boundary conditions at \( x = 0 \) and \( x = 1 \) as well as the zero spatial mean constraint and it has the following correlation function
\[\tilde{C}(x, x') = \sum_{n=1}^{\infty} \langle b_n^2 \rangle \phi_n(x) \phi_n(x'). \quad (23)\]
The technique just discussed can be considered as particular case of the spectral transformation method \cite{26, 27} where an assigned correlation kernel is generated by assigning the spectrum relatively to a specified orthogonal basis. In this paper we will employ the following Gaussian correlation function (see [28])
\[C(x, x') = \exp \left[ -\frac{6(x-x')^2}{l_c^2} \right]. \quad (24)\]
where plots of will assume that different correlation lengths while in table 1 we report on the dimensionality.

This allows us to represent the temperature perturbations $g_1$ and $g_2$ shown in figure 1 as

$$
g_i(x; \omega) = \sigma \sum_{k=1}^{M} (b_k^2)^{1/2} \phi_k(x), \quad i = 1, 2 \quad (25)$$

where $\phi_k$ are standard Gaussian variables. Several samples of the processes (25) are shown in figure 2 (b) for different correlation lengths $l_c$ and perturbation amplitude $\sigma$. In this paper we will assume that $\phi_k$ are standard Gaussian variables. Several samples of the processes (25) are shown in figure 2 (b) for different correlation lengths $l_c$ and perturbation amplitude $\sigma$ set at 5% of reference temperature difference between the horizontal walls. Physically, this means, e.g., a temperature perturbation with amplitude 1 K for temperature differences of about 20 K.

We remark that the truncation process in the series expansion (25) has to be performed with some care, in such a way that the energy of the neglected modes is negligible. To this end, we examine the relative energy of the temperature perturbations $e_f(M) = \frac{E_f(M)}{E_f(\infty)}$, where $E_f(M) = \sum_{n=1}^{M} (b_n^2)$

and choose the total number of terms $M$ in such a way that $e_f$ is greater than a specified cutoff value. In figure 2 (a) we show the plots of $e_f(M)$ corresponding to different dimensionless correlation lengths while in table 1 we report on the dimensionality $M$ - i.e., the total number of terms - of the spectral representation (25) for a 95% cutoff threshold. We notice that as the correlation length goes to zero the temperature perturbation at the boundaries approaches an independent increment process [29].

Even for temperature perturbations having correlation length $l_c$ about 0.1 (scaled on the side length of the cavity) the number of expansion terms for the effective representation of the process becomes relatively large. Specifically, since we have two random boundaries, the case $l_c = 0.1$ results in a stochastic system forced by 44 $(22 + 22)$ random variables (see table 1). The numerical simulation of these high-dimensional problems requires appropriate techniques [20, 30, 31, 32, 33, 34, 35, 36]. In this paper we will employ a Monte Carlo method but also polynomial chaos with adaptive ANOVA can be used [19].

**4. Stochastic bifurcations and stability of steady state convection**

In previous work [6] we have obtained bifurcation diagrams for natural convective flows within square cavities subject to uniform temperature boundary conditions. We have observed the coexistence of multiple stable steady states, in agreement with other results [12, 11, 10, 9], for the same values of Rayleigh and Prandtl numbers, the final asymptotic state depending on the initial flow condition. For random boundary conditions, multiple stable states can still exist but the mechanism of their formation is substantially different. Indeed, as we can see from Eqs. (10) and (11), the random perturbations $g_1$ and $g_2$ break the symmetry of the system, i.e., the steady-state convection pattern in general do not satisfy the discrete symmetry group described in [6]. Therefore, the symmetry-induced multiplicity of supercritical states in this case is replaced by a more physical ensemble of flows in a one-to-one correspondence with specific boundary and initial conditions. We have identified many different steady-state stable convection patterns and corresponding temperature fields. These include subcritical and supercritical quasi-conduction states for which the kinetic energy of the flow turns out to be very small. In figure 3 we show typical temperature fields and flow patterns corresponding to specific realizations of the temperature boundary conditions. The rich variety of flows associated with random boundary conditions should be compared with classical results of convection for uniform temperature distributions (see, e.g., [6, 5]) where only one subcritical solution (pure conduction) and one supercritical solution (one-roll pattern) can develop within the range of Rayleigh numbers considered in this paper, i.e., $Ra = 0 – 4000$.

**4.1. Bifurcation diagrams for the Nusselt number**

As is well known, a sudden change in the slope of the Nusselt number versus the Rayleigh number usually identifies a transition between different flow states. In the particular case of uniform temperature boundary conditions the first one of these transitions characterizes the onset of convective instability [12, 5] and, for the geometry shown in figure 1, it can be clearly identified at $Ra_c = 2585.02$. However, in the presence of random temperature perturbations along the horizontal walls of the cavity, the precise determination of the critical Rayleigh number becomes relatively large. Specifically, since we have two random boundaries, the case $l_c = 0.1$ results in a stochastic system forced by 44 $(22 + 22)$ random variables (see table 1). The numerical simulation of these high-dimensional problems requires appropriate techniques [20, 30, 31, 32, 33, 34, 35, 36]. In this paper we will employ a Monte Carlo method but also polynomial chaos with adaptive ANOVA can be used [19].

We remark that for very specific realizations of the temperature processes at the horizontal walls, convection can still satisfy the discrete symmetry group described in [6]. However, from a statistical viewpoint the probability that this happens is zero.
number can be rather difficult. In fact, as pointed out by Ahlers et al. in [14], such perturbations render the bifurcation process to convection imperfect and, strictly speaking, a critical Rayleigh number does not exist in the usual sense since convection occurs for all values of $R\alpha$. However, as the Rayleigh number approaches the classical critical value, the amplitude of convection increases greatly, and therefore it still makes sense to define a “critical” regime near the classical bifurcation point.

In figure 4 we show the bifurcation diagrams for the integrated Nusselt number

$$Nu(\omega) = \frac{1}{\lambda} \int_0^\lambda \left. \frac{\partial T(x,y;\omega)}{\partial y} \right|_{y=0} \, dx$$

versus the Rayleigh number. These diagrams are obtained by first sampling the temperature distribution at the horizontal walls for different perturbation amplitudes and correlation lengths and then compute the corresponding stable\(^3\) convective flow through the Galerkin method outlined in Appendix A. In the plots of figure 4 we also include the classical bifurcation diagram for deterministic uniform boundary conditions (dashed lines). This case corresponds to $l_\omega = \infty$. Note that the bifurcation diagrams obtained for temperature perturbations with correlation lengths $l_\omega = 1$ and $l_\omega = 0.5$ are very similar. This can be explained by noting that the temperature perturbations at the horizontal walls of the cavity are quite similar to each other in these cases (see figure 2 (b)). Among many possible convection patterns, our numerical results show that it is possible to obtain realizations of nearly supercritical (stable) quasi-conduction states. In other words, it seems that random perturbations can stabilize the quasi-conduction state beyond the classical bifurcation point. This rather surprising result will be discussed further in the next section.

4.2. Statistical analysis of the heat transfer

In figure 5 (a) we plot the probability density function of the integrated Nusselt number at Rayleigh number 3000 ($Pr = 0.7$) for boundary perturbations with different correlation lengths. Each probability density is estimated through a non-parametric kernel regression method based on the available temperature samples. Specifically, we have computed $10^5$ flow samples at many different Rayleigh numbers, correlation lengths and perturbation amplitudes of boundary processes. As seen from figure 5 (a), random temperature perturbations can increase or decrease the averaged heat transfer relatively to the uniform case. In a mean sense, however, it turns out that the heat transfer is enhanced, especially in the transcritical region (see figure 6). Similarly, in figure 5 (b), we plot the probability density functions of the integrated Nusselt number at different Rayleigh numbers

\(^3\)We report only on stable steady states. Other unstable states are present as well but these are not shown in figure 4.
Figure 4: Bifurcation diagrams near the onset of convective instability for random temperature perturbations of different amplitudes $\sigma$ and correlation lengths $l_c$. Shown are the integrated Nusselt numbers versus the Rayleigh number for different solution samples. The dashed line in each plot represents the classical bifurcation diagram obtained for deterministic uniform temperature conditions. In this case the critical Rayleigh number is $Ra_c = 2585.02$. 
for boundary perturbations with correlation length $l_c = 0.5$ and amplitude $\sigma$ set at 5% of the reference temperature difference. We notice that at $Ra = 1000$ the probability density of $Nu$ is rather peaked around $Nu = 1$, suggesting a high probability of quasi-conduction regime. In the transcritical region we also observe a variation of the probability density function that becomes approximately Gaussian when convection is fully developed.

Note that for supercritical flows, the probability density of the integrated Nusselt number is continuously supported. This suggests that for the correlation lengths and the perturbation amplitudes considered in this paper it seems that there exist only one possible supercritical convection pattern, i.e. a one-roll flow. In other words, for the correlation lengths, the perturbation amplitudes and the range of Rayleigh numbers considered in this paper the ensemble of stable flows is continuous and composed by one-roll patterns, with the exception of some subcritical quasi-conduction states. Next, we determine the average as well as the range of the integrated Nusselt number as a function of the Rayleigh number. This study helps us in clarifying if the correlation length of the temperature perturbations at the horizontal walls has an influence on the averaged heat transfer within the cavity. To this end we examine the case where the perturbation amplitude is set at 5% of the reference temperature difference. The results of our computations are shown in figure 6 (a). As easily seen, random temperature perturbations induce a stochastic drift in the transcritical region yielding to an increment of the average heat flow. This increment depends on the correlation length of the temperature processes, i.e. there are preferential values of temperature correlation lengths that trigger convection patterns that are more effective for what concerns the heat transfer. Note, however, that the heat transfer enhancement is rather weak in all cases we have considered, quantifiable in approximately 10% within the transcritical region. Also, when convection is fully developed the stochastic drift disappears and the probability density of the integrated Nusselt number becomes very similar to a Gaussian distribution (see figure 5 (b)).

It is interesting to study the relation between the integrated Nusselt number and the dimensionless kinetic energy of the fluid in more detail. Our first finding is that the correlation coef-

Figure 5: (a) Probability density functions of the integrated Nusselt number at Rayleigh number $Ra = 3000$ for boundary perturbations of different correlation lengths. The perturbation amplitude is set at 5% of the reference temperature difference. The vertical line indicates the deterministic Nusselt number at $Ra = 3000$ for uniform boundary conditions. (b) Probability density functions of the integrated Nusselt number at different Rayleigh numbers: $Ra = 1000 (- - -)$, $Ra = 2500 (- - - -)$, $Ra = 3000$ (-----) and $Ra = 4000$ (---). The temperature perturbations have correlation length $l_c = 0.5$ and amplitude $\sigma$ set at 5% of the reference temperature difference.

Figure 6: (a) Mean of the integrated Nusselt number versus the Rayleigh number for boundary perturbations of different correlation lengths. The perturbation amplitude is set at 5% of the reference temperature difference in all cases. We see that random temperature perturbations induce a stochastic drift phenomenon in the transcritical region. (b) Integrated Nusselt number versus the dimensionless kinetic energy ($\epsilon_c$) of the fluid at Prandtl number 0.7. The amplitude of the boundary perturbations is set at 5% and the correlation length is $l_c = 1$. We show the mean (-----) and the min-max band (---) which is parametrized with the Rayleigh number $Ra$. The curves at constant $Ra$ (---) are simple lines due to the very high correlation coefficient between $Nu$ and $\epsilon_c$ at Prandtl number 0.7.
cient between these two quantities is approximately one in all cases we have considered in this paper. This suggests that there exists a linear relation between the Nusselt number and dimensionless kinetic energy for stochastic convection within square cavities at fixed Rayleigh number Prandtl number \( Pr = 0.7 \). This relation is shown in figure 6 (b) where we plot the integrated Nusselt number versus the kinetic energy of the fluid for different Rayleigh numbers. The existence of a linear relation between the integrated Nusselt number and the dimensionless kinetic energy implies that heat transfer is primarily determined by advection, even in the quasi-conduction regime.

5. Subcritical and supercritical quasi-conduction states

The existence of subcritical quasi-conduction states has been theoretically predicted by Kelly & Pal in [8] for an infinite layer of fluid with small periodic temperature variations at the horizontal walls. By means of perturbation analysis, they have found that convection can occur even for Rayleigh numbers less than the critical one (\( Ra_c = 1707.8 \) for the infinite layer). The corresponding Nusselt number in this case is a function of the parameter quantifying the “amplitude of convection” \( \tilde{\omega} \). A criterion to identify a quasi-conduction state may be based on the analysis of the dimensionless temperature field within the cavity. In particular, a comparison between the pure conduction solution and the convection solution can reveal if there is a significant temperature transport associated with the fluid motion. The steady state pure conduction solution can be easily obtained by integrating the Poisson’s equation

\[
\nabla^2 T^* = -\gamma \left( \frac{\partial^2 g_2}{\partial x^2} - \frac{\partial^2 g_1}{\partial x^2} \right) - \frac{\partial^2 g_1}{\partial x^2} \quad (28)
\]

with homogeneous boundary conditions (\( T^* = 0 \) at the horizontal walls and \( \partial T^*/\partial x = 0 \) at the sidewalls of the cavity). Equation (28) follows from Eq. (2) by setting \( \psi \equiv 0 \). The analytical solution to (28) can be represented in terms of an eigenfunction expansion as

\[
T^*(x, y; \omega) = \sum_{k=1}^{\infty} \frac{\Gamma_k(x, y)}{\gamma_k} \int_0^1 \int_0^1 \mathcal{F}(x', y') \Gamma_k(x', y') \, dx' \, dy' , \quad (29)
\]

where

\[
\mathcal{F}(x, y) = \gamma \left( \frac{\partial^2 g_2}{\partial x^2} - \frac{\partial^2 g_1}{\partial x^2} \right) + \frac{\partial^2 g_1}{\partial x^2} . \quad (30)
\]

\[
4\text{From a theoretical viewpoint, a supercritical stable state might be investigated by analyzing the Oberbeck-Boussinesq system, in any representation. In particular, one can consider the integral representation obtained in appendix A, expand the solution near } a_k \equiv 0 \text{ and } b_k \equiv 0 \text{ and try to determine whether there exist a set of coefficients for which the real part of the largest Jacobian eigenvalue is negative. This leads to a complex relation between the forcing (buoyancy) term in the Navier-Stokes equations and the Rayleigh number.}
\]

In these equations \( \gamma_k \) and \( \Gamma_k \) denote the eigenvalues and the eigenfunctions of the Helmholtz operator, respectively (see Appendix A.1 for further details). Finally, the temperature field associated with the pure conduction state corresponding to the perturbations \( g_1(x; \omega) \) and \( g_2(x, \omega) \) is obtained by substituting Eq. (29) into Eq. (6). A simpler criterion to identify a quasi-conduction regime is based on the integrated Nusselt number itself. In practice, we can define a threshold for \( Nu \) below which we can state that convection is neglectable. At Prandtl number 0.7, this is equivalent to selecting a threshold for the dimensionless kinetic energy of the fluid. In fact, as we have pointed out in the previous section, the integrated Nusselt number and the dimensionless kinetic energy of the fluid are extremely well correlated in all cases we have considered in this paper. The selection of a threshold value for the integrated Nusselt number, however, introduces some arbitrariness in the definition of quasi-conduction states. This arbitrariness is of the same type as that of defining a critical Rayleigh number in the presence of random boundary conditions.

Given these remarks, let us set the threshold \( Nu_{tr} = 1.02 \)
for quasi-conduction states. This choice is based on a careful analysis of the temperature fields of many flow samples corresponding to different realizations of boundary conditions. It is clear that the threshold $Nu_{tr} = 1.02$ discriminates among those flows with heat transfer different at most by 2% with respect to pure conduction. In figure 7 we sketch the procedure for the identification of quasi-conduction states according to the proposed criterion. Clearly, the threshold $Nu_{tr} = 1.02$ is also associated with a quasi-conduction kinetic energy band. An analysis of the stochastic flow field near the onset of convection reveals that random temperature perturbations at the horizontal boundaries can stabilize a nearly supercritical quasi-conduction regime. This region is indicated in figure 7 (b) for boundary perturbations having correlation length $l_c = 0.5$ and perturbation amplitude set at 5% of the reference temperature difference. Thus, random perturbations basically extend the domain of stability of quasi-conduction states beyond the classical bifurcation point. The flow field and the temperature of a supercritical quasi-conduction state is shown in figure 3 (b) at Rayleigh number 2650. An important question at this point is: What is the probability that a supercritical stable quasi-conduction state develops within the cavity?

In order to answer this question, in figure 8 we plot the probability of occurrence of quasi-conduction states within the whole range of Rayleigh number considered in this paper, for boundary perturbations of different correlation lengths. This probability function is estimated by counting the relative number of quasi-conduction states, i.e., the states whose energy is within the quasi-conduction energy band, for each Rayleigh number. As easily seen, the probability curve is monotonic and it reaches the value zero (impossible event) approximately at $Ra \approx 2800$ in all cases. We also notice that the occurrence of a nearly supercritical quasi-conduction state is rather unlikely (see figure 8 (b)) and it depends on the correlation length of the temperature perturbations at the horizontal walls. In particular, smaller correlation lengths yield to higher probabilities of supercritical quasi-conduction states. Clearly, all these results depend on the choice of the quasi-conduction energy band. In other words, a different selection of the threshold for the Nusselt number or the kinetic energy of the fluid yields quantitatively different but qualitatively similar conclusions.

6. Sensitivity analysis

In this section we employ the ANOVA technique [20, 17, 37, 38, 32] (see also appendix B) in order to quantify which harmonic in the Fourier series representation of the random temperature boundary conditions enhances the heat transfer and triggers the transition from quasi-conduction to fully developed convection regimes. This sensitivity study allows us to make inferences about the most important unstable modes and, in some sense, it is similar to the perturbation approach adopted by Kelly & Pal [8] for the infinite fluid layer.

Let us consider an ANOVA expansion of the Nusselt number in terms of the set of random variables representing the amplitude of boundary conditions

$$N_u(\zeta) = Nu_0 + \sum_{i=1}^{2M} Nu_i(\zeta_i) + \sum_{i<j}^{2M} Nu_{ij}(\zeta_i, \zeta_j) + \sum_{i<j<k}^{2M} Nu_{ijk}(\zeta_i, \zeta_j, \zeta_k) + \cdots ,$$

(31)

where

$$\zeta \equiv [\zeta^{(1)}, \ldots, \zeta^{(1)}, \zeta^{(2)}, \ldots, \zeta^{(2)}].$$

(32)

We recall that $M$ depends on the spatial correlation length of the temperature process. Specifically, for $l_c = 0.5$ - which is the case we examine here - we obtain a total number of 10 (5 + 5) random variables. In other words, the nominal dimension [32] of the parameter space here is 10 (see table 1).

The sensitivity (in the sense of Sobol [39]) of the integrated Nusselt number with respect to the amplitude of the boundary modes can be studied as a function of the Rayleigh number. This provides an insight, e.g., on which harmonic of the temperature distribution at the boundaries (first-order interaction) or combination of harmonics (higher-order interactions) are most important in the transition from quasi-conduction to fully developed convection. The results of this study are summarized in figure 9 where we plot the averaged global sensitivity factors for first-, second- and third-order interaction terms corresponding to all five parameters $[\zeta^{(1)}, \ldots, \zeta^{(2)}]$ defining the random temperature process at the lower horizontal wall. These sensitivity

![Figure 8: Probability that a stable quasi-conduction state develops within the cavity as a function of the Rayleigh number and the correlation length of the temperature processes at the horizontal walls of the cavity. The perturbation amplitude is set at 5% of the reference temperature difference. Figure (b) is a zoom-in of figure (a).](image-url)
identifies the classical bifurcation point at $Ra \approx 3000$. This suggests that in such region the Nusselt number is equally sensitive to variations in the amplitude of different harmonics of the temperature expansion at the lower wall. This is expected since the heat transfer in the fully developed convection region is primarily determined by advection.

7. Summary

We have studied the Rayleigh-Bénard stability problem for fluid confined within a square enclosure subject to non-uniform random perturbations in the temperature distribution at the horizontal walls. These temperature perturbations were modelled as Gaussian processes satisfying a Gaussian correlation function. We have simulated the Oberbeck-Boussinesq equations and computed many ensembles of realizations of the natural convective flow within the cavity by sampling the temperature processes at the boundaries for different correlation length and amplitude. This allowed us to obtain stochastic bifurcation diagrams for the integrated Nusselt number near the classical onset of convective instability. These diagrams show that random factors are explicitly defined as

$$Z_i^{(1)} \equiv \frac{\sigma^2[Nu_i]}{\sigma^2[Nu]}$$

$$Z_i^{(2)} \equiv \sum_j \frac{\sigma^2[Nu_{ij}]}{\sigma^2[Nu]}$$

$$Z_i^{(3)} \equiv \sum_{jk} \frac{\sigma^2[Nu_{ijk}]}{\sigma^2[Nu]}$$

where $Nu_i$, $Nu_{ij}$ and $Nu_{ijk}$ are the interaction terms in Eq. (31) while $\sigma^2[\cdot]$ denotes the variance operator (see Appendix B for further details).

As seen from the plots of $Z_i^{(k)}$ ($k = 1, 2, 3$), the subcritical quasi-conduction region ($Ra < Ra_c$) is sensitive to variation in the amplitude of all the boundary modes. Beyond the classical bifurcation point we also see that there is transcritical region (between $Ra \approx 2700$ and $Ra \approx 3000$) which is very sensitive to variations in the amplitude of the first boundary mode, i.e. $\cos(\pi x)$. We recall that this is the region where we have the stochastic drift phenomenon for the Nusselt number (see section 4.2). Therefore, we can conclude that the average heat transfer enhancement in the transcritical region is due to a low frequency boundary mode.

Note that the global sensitivity indices associated with the first-order interaction terms do not allow us to identify the flow transition in a clear manner. This objective is achieved indeed by looking at the higher-order interaction terms. In fact, as seen from figure 9(b) and figure 9(c) the global sensitivity factors of second- and third-order interactions terms undergo a sudden jump exactly in correspondence with the classical bifurcation point. This suggests that the interaction between different boundary modes is switched on by the transition and the resulting flow becomes rather sensitive to variations in the amplitude of the terms associated with the corresponding harmonics. We also notice that there is a bulk phenomenon in the sensitivity factors within the region of fully developed convection, i.e. for $Ra > 3000$. This suggests that in such region the Nusselt number is equally sensitive to variations in the amplitude of different harmonics of the temperature expansion at the lower wall. This is expected since the heat transfer in the fully developed convection region in primarily determined by advection.
perturbations render the bifurcation process to convection imperfect, in agreement with known theoretical results [14]. In particular, the pure conduction state does no longer exist, being replaced by a quasi-conduction regime. We have observed sub-critical and nearly supercritical quasi-conduction stable states within the range of Rayleigh numbers \(Ra = 0 - 4000\). This suggests that random temperature perturbations at the horizontal walls can extend the range of stability of quasi-conduction states beyond the classical bifurcation point. However, the probability that these states develop within the cavity is rather low. A statistical analysis of the bifurcation diagrams near the classical onset of convection shows the existence of a stochastic drift phenomenon in the heat transfer coefficient, especially in the transcritical region. The increment we have observed in the mean Nusselt number is about 10% for temperature perturbations having a correlation length comparable with the side-length of the cavity. In order to obtain a better understanding of this phenomenon, we have performed a sensitivity analysis of the integrated Nusselt number based on the functional ANOVA decomposition. This allowed us to identify which harmonics in the random temperature distributions at the horizontal walls are most effective in enhancing the heat transfer coefficient. The sensitivity factors corresponding to first-, second- and third-order interaction terms suggest that the lowest-wavelength harmonic is the most effective. In addition, the flow transition from quasi-conduction to fully developed convection is found to be accurately captured by the second- and the third-order interaction terms.

A. Integral representations

Let us consider an expansion of random temperature and velocity fields in terms of normalized eigenfunctions \(\psi_n(x,y)\) and \(\Gamma_m(x,y)\)

\[
\psi(x, y; \omega) = \sum_{n=1}^{N} a_n(\omega) \tilde{\psi}_n(x,y), \tag{36}
\]

\[
T^*(x, y; \omega) = \sum_{n=1}^{N} b_n(\omega) \tilde{\Gamma}_m(x,y). \tag{37}
\]

The advantage of using such representations is that they automatically satisfy all the boundary conditions as well as the continuity equation [40, 21]. A substitution of Eq. (36) and Eq. (37) into (10)-(11) and subsequent Galerkin projection onto \(\tilde{\psi}_k\) and \(\tilde{\Gamma}_k\), respectively, gives the following system of algebraic equations (repeated indices are summed unless otherwise stated)

\[
-a_n b_m \mathbf{E}_{mnk} - Pr a_n C_{nk} + \Pr b_n \mathbf{D}_{nk} + \mathbf{N}_k = 0, \tag{38}
\]

\[
-a_n b_m \mathbf{E}_{mnk} - a_n (\mathbf{F}_{nk} + \mathbf{P}_{nk}) - \gamma^2 b_n + \mathbf{M}_k = 0, \tag{39}
\]

where the coefficients \(\mathbf{N}_k, \mathbf{M}_k, \text{etc.}, \) are, defined as

\[
\mathbf{N}_k \equiv \int_0^1 \int_0^1 \left[ \left( \frac{\partial \tilde{\psi}_m}{\partial x} - \frac{\partial \tilde{\gamma}_1}{\partial x} \right) + \frac{\partial \tilde{\gamma}_1}{\partial x} \right] \tilde{\psi}_k dxdy,
\]

\[
\mathbf{M}_k \equiv \int_0^1 \int_0^1 \left[ \left( \frac{\partial^2 \tilde{\gamma}_2}{\partial x^2} - \frac{\partial^2 \tilde{\gamma}_1}{\partial x^2} \right) + \frac{\partial^2 \tilde{\gamma}_1}{\partial x^2} \right] \tilde{\Gamma}_k dxdy,
\]

\[
\mathbf{A}_{nk} \equiv \int_0^1 \int_0^1 \nabla^2 \tilde{\psi}_n \tilde{\psi}_k dxdy, \quad \mathbf{C}_{nk} \equiv \int_0^1 \int_0^1 \nabla^4 \tilde{\psi}_n \tilde{\psi}_k dxdy,
\]

\[
\mathbf{D}_{nk} \equiv \int_0^1 \int_0^1 \nabla^2 \tilde{\psi}_n \tilde{\psi}_k dxdy, \quad \mathbf{F}_{nk} \equiv \int_0^1 \int_0^1 \frac{\partial \tilde{\psi}_n}{\partial x} \tilde{\psi}_k dxdy,
\]

\[
\mathbf{P}_{nk} \equiv \int_0^1 \int_0^1 \left[ \frac{\partial \tilde{\gamma}_n}{\partial x} \left( \frac{\partial \tilde{\psi}_m}{\partial x} - \frac{\partial \tilde{\gamma}_1}{\partial x} \right) + \frac{\partial \tilde{\gamma}_1}{\partial x} \right] \tilde{\psi}_k dxdy,
\]

\[
\mathbf{B}_{mnk} \equiv \int_0^1 \int_0^1 \left[ \left( \frac{\partial \tilde{\psi}_m}{\partial y} \frac{\partial \tilde{\gamma}_2}{\partial x} - \frac{\partial \tilde{\psi}_m}{\partial y} \frac{\partial \tilde{\gamma}_1}{\partial x} \right) \right] \nabla^2 \tilde{\psi}_m dxdy,
\]

\[
\mathbf{E}_{mnk} \equiv \int_0^1 \int_0^1 \left[ \frac{\partial \tilde{\psi}_m}{\partial y} \frac{\partial \tilde{\gamma}_2}{\partial x} - \frac{\partial \tilde{\psi}_m}{\partial y} \frac{\partial \tilde{\gamma}_1}{\partial x} \right] \tilde{\Gamma}_k dxdy.
\]

Also, \(\gamma^2\) denote the eigenvalues of the Helmholtz equation (see Appendix A.1). The nonlinear system (38)-(39) can be solved numerically with accuracy in order to obtain the Fourier coefficients \(a_n(\omega)\) and \(b_m(\omega)\) for each realization of the boundary conditions. Once these coefficients are available, the streamfunction and the temperature fields may be easily recovered from (36) and (37).

A.1. Temperature expansion

We consider an eigenfunction expansion based on a classical diffusion problem in Cartesian coordinates

\[
\nabla^2 T^* + \gamma^2 T^* = 0 \tag{40}
\]

with homogeneous boundary conditions

\[
T^*(x,0) = T^*(x,1) = 0. \tag{41}
\]

A separation of variables in Eq. (40) gives the following two Sturm-Liouville problems

\[
\frac{d^2 X}{dx^2} + a^2 X = 0, \quad \frac{dX(0)}{dx} = \frac{dX(1)}{dx} = 0, \tag{42}
\]

\[
\frac{d^2 Y}{dy^2} + b^2 Y = 0, \quad Y(0) = Y(1) = 0, \tag{43}
\]

whose solutions are the well known [23, 24] normalized eigenfunctions

\[
X_n(x) = \begin{cases} 1 & \text{if } n = 0 \\ \sqrt{2} \cos(n\pi x) & \text{if } n = 1, 2, 3, \ldots \end{cases} \tag{44}
\]

\[
Y_m(y) = \sqrt{2} \sin(m\pi y) \quad m = 1, 2, 3, \ldots \tag{45}
\]
while the eigenvalues are
\[ a_n = \pi n \quad \text{for} \quad n = 0, 1, 2, \ldots, \tag{46} \]
\[ b_m = \pi m \quad \text{for} \quad m = 1, 2, \ldots. \tag{47} \]
This implies that the eigenvalues of (40) are
\[ \gamma_{nm}^2 = \pi^2 \left( n^2 + m^2 \right). \tag{48} \]
Thus, the two-dimensional temperature basis function can be written as
\[ X_n(x, y) = X_{i(n)}(x)Y_{j(n)}(y), \tag{49} \]
where \(i(n)\) and \(j(n)\) are suitable subsequences obtained according to an ordering of \(\gamma_{ij}^2\).

A.2. Velocity expansion
All the velocity boundary conditions are of no-slip type. This means \(\partial \psi / \partial x = \partial \psi / \partial y = 0\) everywhere at the boundary.
In order to generate a divergence free basis for the velocity representation satisfying such boundary conditions it is convenient to consider the following eigenvalue problem [40, 41, 21, 12]
\[
\frac{\partial^4 \psi}{\partial x^4} + \frac{\partial^4 \psi}{\partial y^4} = \Lambda^4 \psi, \tag{50}
\]
\[
\psi(x, 0) = \frac{\partial \psi}{\partial x} = 0, \quad \psi(x, 1) = \frac{\partial \psi}{\partial x} = 0, \tag{51}
\]
\[
\psi(0, y) = \frac{\partial \psi}{\partial y} = 0, \quad \psi(0, y) = \frac{\partial \psi}{\partial y} = 0. \tag{52}
\]
This eigenvalue problem is symmetric\(^6\) and separable. A substitution of the ansatz
\[ \psi(x, y) = X(x)Y(y) \tag{53} \]
into (50) yields two equivalent eigenvalue problems for \(X(x)\) and \(Y(y)\) in the form
\[
\frac{d^4 X}{dx^4} = \alpha^4 X, \tag{54}
\]
\[
X(0) = X(1) = \frac{\partial X(0)}{\partial x} = \frac{\partial X(1)}{\partial x} = 0. \tag{55}
\]
The general integral of (54) is easily found\(^7\) as
\[
X(x) = a \sin(\alpha x) + b \cos(\alpha x) + c \sinh(\alpha x) + d \cosh(\alpha x). \tag{56}
\]
By enforcing the boundary conditions (55) we obtain the following normalized set of eigenfunctions
\[ X_i(x) = \begin{cases} 
\cos[\alpha_i(x - 1/2)]/\cos[\alpha_i/2] - 
\cos[\alpha_i(x - 1/2)]/\cos[\alpha_i/2] & i = 1, 3, 5, \ldots \\
\sin[\alpha_i(x - 1/2)]/\sin[\alpha_i/2] - 
\sinh[\alpha_i(x - 1/2)]/\sinh[\alpha_i/2] & i = 2, 4, 6, \ldots 
\end{cases} \]
where the eigenvalues \(\alpha_i\) are solutions of the transcendental equation
\[
\tanh\left(\frac{\alpha_i}{2}\right) = \begin{cases} 
-\tan(\alpha_i/2) & \text{for} \ i = 1, 3, 5, \ldots \\
\tan(\alpha_i/2) & \text{for} \ i = 2, 4, 6, \ldots 
\end{cases} \tag{57}
\]
A similar solution can be obtained for \(Y(x)\). A normalized basis for the two-dimensional streamfunction can be obtained as a tensor product of one-dimensional bases as
\[ \Psi_n(x, y) = X_{i(n)}(x)Y_{j(n)}(y), \tag{58} \]
where \(i(n)\) and \(j(n)\) are suitable subsequences obtained according to an eigenvalue ordering
\[ \Lambda_n^4 = \alpha_{i(n)}^4 + \beta_{j(n)}^4. \tag{59} \]

B. ANOVA decomposition for sensitivity analysis
The key idea of ANOVA is to represent a high-dimensional function \(f(x_1, x_2, \cdots, x_N)\) in terms of a superimposition of functions involving a lower number of variables (interaction terms), and then truncate the series at specific interaction order. Specifically, the ANOVA expansion of an \(N\)-dimensional scalar function \(f\) takes the form [42]
\[
f(x_1, x_2, \ldots, x_N) = f_0 + \sum_{i=1}^N f_i(x_i) + \sum_{i<j} f_{ij}(x_i, x_j) + \cdots. \tag{60}
\]
The function \(f_0\) is a constant. The functions \(f_i(x_i)\), which we shall call first-order interactions, give the overall effects of the variables \(x_i\) in \(f\) as if they were acting independently of the other input variables. The functions \(f_{ij}(x_i, x_j)\) describe the interaction effects of the variables \(x_i\) and \(x_j\), and therefore they will be called second-order interactions. Similarly, higher-order terms reflect the cooperative effects of an increasing number of variables. From a practical viewpoint, the computation of the various terms in the ANOVA expansion can be performed by selecting a suitable measure space, e.g., the space of \(\mu\)-integrable functions in the hypercube \([0, 1]^N\), where \(\mu\) denotes an integration measure. In this case we have
\[
f_0 = \int_0^1 \cdots \int_0^1 f(x_1, \ldots, x_N) d\mu(x_1, \ldots, x_N), \tag{61}
\]
\[
f_i(x_i) = \int_0^1 \cdots \int_0^1 f(x_1, \ldots, x_i-1, x_{i+1}, \ldots, x_N) d\mu(x_1, \ldots, x_{i-1}, x_{i+1}, \ldots, x_N) - f_0, \tag{62}
\]
\[
\cdots
\]
For instance, if the measure \(\mu\) is selected as
\[ d\mu(x_1, \ldots, x_N) = \prod_{i=1}^N dx_i \]
then we obtain the classical ANOVA-HDMR method [20]. Similarly, if we set
\[ d\mu(x_1, \ldots, x_N) = \prod_{i=1}^{N} \delta(x_i - c_i) dx_i, \quad c_i \in [0, 1] \]  
(63)
then we obtain the so-called anchored ANOVA [43] decomposition. The vector \((c_1, \ldots, c_N)\) in this case is known as anchor point and it can be selected according to many different criteria (see, e.g., [18]). The ANOVA representation of a field can be effectively used as a tool for sensitivity analysis [39, 44]. To this end, let us first recall that all the interaction terms (60), (61), etc., in the ANOVA expansion (59) are mutually orthogonal with respect to the measure \(\mu\). This implies that the variance of \(f\), here denoted as \(\sigma^2[f]\) is simply the sum of the variances associated with each interaction term, i.e.,
\[ \sigma^2[f] = \sum_{i=1}^{N} \sigma^2[f_i] + \sum_{i<j} \sigma^2[f_{ij}] + \cdots, \]
(64)
where
\[ \sigma^2[f] \overset{\text{def}}{=} \int f^2 d\mu - \left( \int f d\mu \right)^2. \]
(65)
The integrals appearing in Eq. (64) can be computed by using a multi-element quadrature formula [32]. Following Sobol [39], we shall define global sensitivity indices as the ratio between the variance of each term in the ANOVA decomposition and the total variance of the function \(f\), i.e.,
\[ R_i \overset{\text{def}}{=} \frac{\sigma^2[f_i]}{\sigma^2[f]}, \quad R_{ij} \overset{\text{def}}{=} \frac{\sigma^2[f_{ij}]}{\sigma^2[f]}, \quad \ldots \]
(66)
From Eq. (64) it easily follows that
\[ \sum_{i=1}^{N} R_i + \sum_{i<j} R_{ij} + \cdots = 1. \]
(67)
Moreover, we shall define the following averaged global sensitivity indices
\[ Z_{i}^{(1)} \overset{\text{def}}{=} R_i, \quad Z_{i}^{(2)} \overset{\text{def}}{=} \sum_{j} R_{ij}, \quad Z_{i}^{(3)} \overset{\text{def}}{=} \sum_{j<k} R_{ijk}, \quad \ldots \]
(68)
representing the relative importance of one specific parameter overall the others at a prescribed interaction level. With the aid of Eqs. (68) we can study which input variable has more influence on the response of the system. For instance, we can quantify which harmonic in the Fourier series representation of the random temperature boundary conditions triggers the transition from quasi-conduction to convection or affects the heat transfer coefficient to the greatest extent.
