Introduction: To understand how mechanical injury affects neural circuits, we 1) built a multi-scale stochastic integrate-and-fire model of network activity, 2) simulated an injured network, 3) predicted an important role for the NR2B-NMDA receptor in mediating network asynchrony, and 4) tested our predictions using in vitro stretch injury.

Methods:

Computational model: Population of pyramidal-like neurons were assembled into a network following the topology found in vitro cultures. Dendritic spines were populated with AMPARs and NR2A- and NR2B-NMDA receptors. Synaptic transmission was simulated by vesicular release of glutamate onto the spine head, and the activation of these receptors was modeled using a stochastic diffusion-reaction scheme. The resulting current, summed at the soma, was used to update the cell membrane potential. Injury was simulated by larger glutamate release and partial loss of NMDAR Mg2+ block, consistent with in vitro and in vivo observations.

In vitro experiments: Primary cortical neurons were plated on silastic membrane. Mature cultures were bulk loaded with fluo4-AM, and the calcium activity of the network was imaged pre- and post-stretch. The relative contribution of NR2A and NR2B receptors in altering network activity, functional connectivity and LTP potential of the post-injured network were assessed using subtype specific antagonists.

Results:

Since calcium is a crucial secondary messenger in neurons and serves as a proxy for underlying electrical activity, we first profiled the source of calcium and the temporal pattern of calcium dynamics of a spontaneously oscillating network. We found that, in mature cultures, the main sources of calcium during spontaneous activity are NR2A-NMDARs and VGCCs. In contrast, acutely (1-hr) following dynamic stretch injury, NR2B containing NMDARs become a significant source of calcium, likely due to partial loss of its native Mg2+ block.

To investigate the effects of enhanced NR2B activity on network dynamics, we built a multi-scale model of network activity (spines -> dendrites -> soma -> network) and simulated activity patterns of a population of neurons and matched to those of an in vitro culture (DIV 18-20). Next, we simulated the activity of an injured network and found that relief of NR2B Mg2+ block at the spine-level results in asynchrony at the network-level. Our simulations also predicted that the asynchronous activity in the simulated-injured region can propagate into adjacent regions in a distance dependent manner, influenced by the topology and connectivity of the network.

We conducted in vitro stretch injury experiments to validate our in silico predictions and found that following injury, 1) there is greater variability in the amplitude of calcium transients for a given neuron, 2) there is loss in synchrony and decline in functional connectivity in the injured
region, 3) synchrony is rescued by antagonizing NR2B-containing NMDARs, and 4) disruptions of network activity in the mechanical penumbra are negligible beyond 700um.

Functionally, synaptic calcium asynchrony limits LTP potential in the injured region. However, NR2B antagonism during LTP induction allows a fraction of injured neurons to undergo chemical LTP as measured by persistent increase in the amplitude of Ca2+ transients.

**Conclusion:** Despite its enormous incidence, mild TBI is not well understood. One aspect that needs more definition is how mechanical energy disrupts neural circuitry, in the absence of overt cell death. In this study, we merged information from different perspectives (*in silico* and *in vitro*) and across different length scales (spines to networks) to uncover an important role of the NR2B-NMDAR in mediating network asynchrony. Traditionally, NR2B antagonism has been used to blunt pro-apoptotic pathways, but we show that in mild injuries, NR2B receptors may be an important target for reverting the injured network to its pre-injury state and rescue plasticity in an injured network.
