LONG-TERM GOALS

The management and depletion of O2 stores underlie the dive capacities of marine mammals and are fundamental to the concept of an aerobic dive limit (ADL, dive duration associated with the onset of post-dive blood accumulation). The ADL, which is often calculated (cADL) on the basis of total body O2 stores and an estimated diving metabolic rate, has become an essential concept in the interpretation of diving behavior and foraging ecology (Kooyman and Ponganis 1998); however, the actual rate and magnitude of O2 store depletion during dives has not been determined in any otariid. This project documented the rate and magnitude of blood O2 store depletion during diving in California sea lions, and this information will be used to develop an experimental approach to assess the aerobic dive limit (ADL) and O2 store depletion in this and other otariid species.

OBJECTIVES

The specific objectives of this project are: 1) Document venous and arterial P02 profiles in lactating California sea lions while diving during foraging trips to sea, 2) Characterize the O2-hemoglobin (Hb) dissociation curve of sea lion Hb, 3) Convert the P02 profiles into % Hb saturation (SO2) profiles with the dissociation curve, and then calculate the rate and magnitude of blood oxygen depletion, and 4) Refine vascular access techniques to allow future investigations of blood N2 kinetics, changes in blood pH, PCO2, P02 and lactate during dives, and stress responses to captivity, training, and/or sound exposure.

APPROACH

Objectives 1 & 4: Backpack recorders measured blood P02 during dives of foraging trips of lactating California sea lions on San Nicolas Island, CA. Females were anesthetized and instrumented with a P02 logger, time depth recorder and radio tag, released, and recaptured after 1-4 foraging trips. With ultrasound guidance over the caudal back, a P02 electrode and thermistor were inserted percutaneously into the vena cava (n = 11) or aorta (n = 2). (key personnel: B.I. McDonald, P.J. Ponganis, Navy Anesthesia resident)
### Report Documentation Page

Public reporting burden for the collection of information is estimated to average 1 hour per response, including the time for reviewing instructions, searching existing data sources, gathering and maintaining the data needed, and completing and reviewing the collection of information. Send comments regarding this burden estimate or any other aspect of this collection of information, including suggestions for reducing this burden, to Washington Headquarters Services, Directorate for Information Operations and Reports, 1215 Jefferson Davis Highway, Suite 1204, Arlington VA 22202-4302. Respondents should be aware that notwithstanding any other provision of law, no person shall be subject to a penalty for failing to comply with a collection of information if it does not display a currently valid OMB control number.

Prepared by ANSI Bal Z39-18
Objective 2: The O₂-Hb dissociation curve was determined at four pH values (7.5, 7.4, 7.3 & 7.2) from blood samples obtained from sea lions at Sea World’s Rehabilitation Program (n = 7) and the National Marine Mammal Foundation (n=4) using the mixing technique. (B.I. McDonald)

Objective 3: The SO₂ values during dives were obtained with application of the dissociation curve analysis to the PO₂ data. These data allowed calculation of maximum and minimum blood O₂ content of a dive, net and rate of blood O₂ depletion and rate of O₂ content depletion, and net contribution of blood O₂ to metabolic rate during diving (ml O₂ kg⁻¹ min⁻¹). (key personnel: B.I. McDonald, P.J. Ponganis)

WORK COMPLETED

We have completed all objectives and are in the process of writing up the results. Over the course of the project we captured, instrumented and recovered backpack PO₂ recorders and Time Depth Recorders from 12 lactating California sea lions. PO₂ electrodes and thermistors were successfully placed in the caudal gluteal vein using sterile techniques in the field in 10 of the females and PO₂ electrodes were successfully placed in an artery in 2 of the females. Processing and analysis of the PO₂ data and dissociation curve analysis is complete. One paper is in press, two papers have been published and currently temperature data are being analyzed.

RESULTS

PO₂ profiles: We obtained 2619 venous PO₂ profiles from 8 sea lions and 1273 arterial PO₂ profiles from one sea lion (dives > 1 min in duration). Minimum venous PO₂ was 5 mmHg in dives greater than 7 min and minimum arterial PO₂ was 10 mmHg in a 4 min dive, consistent with extreme hypoxemic tolerance.

Hb-O₂ dissociation curve: The shape of the curve was typical of mammals; the P₅₀ was 28 ± 2 mmHg (n=11). The Bohr effect was unremarkable (-0.54).

SO₂ profiles and O₂ depletion: Arterial and venous minimum SO₂ were routinely greater than 50% and variable during routine shallow dives (Fig 1, 2). In deep dives greater than 4 min in duration, minimum venous SO₂ reached values below 10%, and in dives over 6 min, were as low as 1% (Fig 1, 3A). The latter are consistent with near complete venous blood O₂ depletion (Fig 3). In a 6-min dive, such depletion of venous blood O₂ would contribute 2.7 ml O₂ kg⁻¹ min⁻¹ to dive metabolic rate.

During deep dive bouts, both arterial and venous SO₂ increased during ascent (Fig 1, 3). The increase in arterial and venous SO₂ during ascent from deep dives suggests that re-expansion of collapsed lungs and resumption of gas exchange during the “ascent tachycardia” allows for lung-to-blood O₂ transfer.

Arterial PO₂ and SO₂ depletion patterns of serial deep dives differed from shallow dives and isolated deep dives with abrupt declines and increases at about 200m depth during descent and ascent, respectively (Fig 3B). We suggest this is due to cessation of gas exchange at depth and that an O₂ reservoir in the collapsed lungs serves to supplement blood O₂ levels during ascent.

Conclusions: Although California sea lions have extreme hypoxemic tolerance and the blood O₂ store contributes significantly to metabolic rate during a dive, the lung O₂ store may play a greater role than previously suspected in serial deep dives (arterial SO₂ is maintained). In addition, given these findings,
we hypothesize that the most significant limit to dive performance and aerobic dive capacity may be depletion of the muscle O2 store.

Figure 1. (A) Minimum venous $S_O2$ & (B) End-of-dive (final) venous $S_O2$ vs. dive duration in 8 sea lions. As dive duration increases, minimum and final $S_O2$ decrease, but are variable in short duration dives. In dives > 4 min, minimum $S_O2$ is often < 10%. At the end of long deep dives, final $S_O2$ is > minimum $S_O2$, suggesting resumption of gas exchange and/or increased arterio-venous shunting.

Figure 2. Minimum arterial SO2 vs. dive duration. Minimum $S_O2$ is highly variable in short dives, but decreases with duration in most dives > 3 min. In serial deep dives minimum $S_O2$ is consistently high suggesting different O2 management strategies.
Figure 3 (A) Venous $S_O2$ profiles and (B) Arterial $P_O2$ and $S_O2$ profiles from serial deep dives. (A) During the last minute of the dive venous $S_O2$ increased suggesting resumption of gas exchange or arterio-venous shunting. (B) The abrupt declines and increases in arterial $P_O2$ and $S_O2$ occur at approximately 200-m depth during descent and ascent, respectively, consistent with cessation of gas exchange below that depth.

IMPACT/APPLICATIONS

This project directly assesses blood O2 depletion in diving California sea lions and develops catheterization techniques (including ultrasound guidance) for these animals. These findings thus extend beyond just the foraging ecology of sea lions, and are relevant to many important topics in diving physiology including: a) the role of the diving bradycardia in gas exchange, reduction of organ blood flow, and management of O2 stores (Davis et al. 1983; Scholander 1940), b) the significance of myoglobin, hydrodynamics, and locomotory swim patterns in depletion of the muscle O2 store and the ADL (Noren et al. 2001; Williams et al. 2000), c) time partitioning of energetic demands into different dive types or surface intervals in order to conserve O2 stores during diving (Sparling et al. 2007; Williams et al. 2004), d) the role of neuroglobin and cytoglobin in hypoxemic tolerance (Williams et al. 2008), e) the role of free radicals and oxidative stress in diving mammals (Elsner et al. 1998) and f) the basic assumptions of many recent computer models of the uptake and distribution of N2 during diving (Fahlman et al. 2009; Houser et al. 2001).

Refinement of vascular access techniques in this project also provides the groundwork to apply this technology to other otariids, and possibly other marine mammals, including dolphins. Development of such approaches is especially pertinent to the question of nitrogen uptake and its role in beaked whale strandings after exposure to naval sonar (Cox 2006). And, in fact, given that access to cetaceans for physiological investigations is so difficult, the sea lion, with a lung O2 store as significant as that in cetaceans (Ponganis et al. 2003), may be an appropriate surrogate model for further investigation of blood N2 uptake during diving.

RELATED PROJECTS

Deep-diving California sea lions: Are they pushing their physiological limit? (Award #: N000141210633) is a continuation of this project. The research questions we are addressing in the new project are building upon the results from this study.
