Cloud Forensics Issues

William R Simpson and Coimbatore Chandersekaran

Abstract— Forensics is undertaken to find out exactly what happened on a computing system and who or what was responsible for it. This is done by a structured investigation while maintaining a documented chain of evidence. Cloud computing is emerging as an attractive, cost effective computing paradigm. The early offerings of cloud capabilities have not provided security, monitoring or attribution that would allow an effective forensics investigation. The high assurance requirement presents many challenges to normal computing and some rather precise requirements that have developed from high assurance issues for web service applications and forensics applications of cloud systems. The challenges of high assurance and the maintenance of a documented chain of evidence associated with cloud computing are primarily in four areas. The first is virtualization and the loss of attribution that accompanies a highly virtualized environment. The second is the loss of ability to perform end-to-end communications. The third is the extent to which encryption is needed and the need for a comprehensive key management process for public key infrastructure, as well as session and other cryptographic keys. The fourth is in monitoring and logging for attribution, compliance and data forensics. Our view of high assurance and the issues associated with web services is shaped by our work with DoD and the Air Force, but applies to a broader range of applications.

1. INTRODUCTION

Cloud computing has come to mean many different things. To some, it is simply putting one’s data on a remote server. However, in this paper, we utilize the definition provided by NIST [1]. They define five essential characteristics of any cloud computing environment:

1. On demand self-service,
2. Broad network access,
3. Resource pooling,
4. Rapid elasticity, and
5. Measured service.

It is important to note that multi-tenancy and virtualization are not essential characteristics for cloud computing.

Cloud computing is, at its core, a service. There are three primary models of this service. In the lowest level Infrastructure as a Service (IaaS), storage, computation, and networking are provided by the cloud provider to the cloud consumer. In level two of the cloud models, Platform as a Service (PaaS), all of the trappings of IaaS plus an operating system and perhaps some application programming interfaces (APIs) are provided and managed by the cloud provider. The highest service model is Software as a Service (SaaS), in which the cloud provider provides an end-user service such as webmail. The higher the service model, the more control the cloud provider has as compared to the cloud consumer. There are four different models for deploying cloud services. Primarily, they are public or private clouds. In a public cloud, the infrastructure—although generally not the data on it—may be used by anyone willing to agree to its terms of use. Public clouds exist off the premises of the cloud consumer. Private cloud infrastructure is used only by one organization. It may exist either on or off the organization’s premises. There are two twists to these infrastructures. In a community cloud, a group of organizations with similar interests or needs share a cloud infrastructure. That infrastructure is not open to the general public. In a hybrid cloud, two or more cloud deployment models are connected in a way that allows data or services to move between them. An example of this would be an organization’s private cloud that makes use of a community cloud during periods of high utilization.

II. CLOUD BENEFITS

Cloud computing benefits emerge from economies of scale [2]. Large cloud environments with multiple users are better able to balance heavy loads, since it is unlikely that a large proportion of cloud consumers will simultaneously have high utilization needs. The cloud environment can therefore run at a higher overall utilization, this may result in better cost effectiveness. In many cloud environments this balancing of resources is done by virtualization and the use of a hypervisor, offering resiliency and agility. In a large cloud computing environment, rather than having a number of information technology generalists, the staff has the ability to specialize and become the experts of their technical areas. With regard to information security, the staff can become ever more specialized and spend more time hardening platforms to secure them from attacks. In the homogeneous cloud environment, patches can be rolled out quickly to the nearly identical hosts. Identically configured hardware elements are not a cloud requirement but do facilitate large-scale administration and focusing of expertise.

III. CLOUD WEAKNESSES

Cloud computing is not without its negatives. In cases where services are outsourced, there can be a loss of control. This can affect compliance with laws, regulations, and organizational policies. Cloud systems have additional levels of complexity to handle intra-cloud communications, scalability, elasticity, data abstraction, and more. To be available to cloud consumers, cloud providers may need to make their services available via the Internet, opening
interfaces that are subject to attack. And critically, many
clouds allow multiple organizations simultaneous use of
a single host and virtualization. If one tenant organization is
compromised or malicious, it may be able to compromise
the data or applications of the other organizations on the
same host. The load balancing may use a single identity for
all instances of a service whether it is virtual or real.

A. Changes in the Threat Model
There are clear differences in many of the threat scenarios
as detailed below [3]:
1. Loss of governance (or visibility and/or control of the
governance process)
2. Lock-in (threats may be present and locked into the
cloud environment and shared among all tenants).
3. Isolation failure (e.g., hypervisor attack, lack of
accountability – lack of distinction between virtualized
instances of services).
4. Compliance risks (if provider cannot provide
compliance evidence or will not permit audit by customer,
lack of accountability)
5. Management interface compromise (and or inheritance
of threats and/or malicious code from other users of the
cloud).
6. Data protection (how does customer verify protection,
lack of accountability)
7. Insecure or incomplete data protection and/or data
deletion
8. Malicious insider (often the cloud insider is not vetted
as well as the organizational insider, and insiders from other
customers could bring in contagious viruses – see 5 above.)
9. Unprotected or ineffective key management for
cryptography.

B. Traditional Data Centers versus Cloud Computing
Cloud computing relies on much of the same technical
infrastructure (e.g., routers, switches, operating systems,
databases, web servers) as traditional data centers and as a
result, many of the security issues are similar in the two
environments. The notable exception in some cases is the
addition of a hypervisor for managing virtual machines. The
Cloud Security Alliance’s security guidance states “Security
controls in cloud computing are, for the most part, no
different than security controls in any IT environment.
Cloud computing is about gracefully losing control while
maintaining accountability even if the operational
responsibility falls upon one or more third parties.” While
many of the controls are similar, there are two factors at
work that make cloud computing different: perimeter
removal and trust. With cloud computing, the concept of a
network or information perimeter changes radically. Data
and applications flow from cloud to cloud via gateways
along the cloud perimeters. However, since the data may be
stored in clouds outside the organization’s premises or
control, perimeter controls become less useful. In exchange
for the lack of a single perimeter around one’s data and
applications, cloud consumers must be able to trust their
cloud providers. A lack of trust in a cloud provider does not
necessarily imply a lack of security in the provider’s
service. A cloud provider may be acceptably secure, but the
novelty of cloud computing means that many providers
have not had the opportunity to satisfactorily demonstrate
their security in a way that earns the trust of cloud
consumers. Trust must be managed through detailed Service
Level Agreements (SLAs), with clear metrics and
monitoring mechanisms, and clear delineation of security
mechanisms [4].

IV. A PARADIGM FOR HIGH ASSURANCE
While the current implementations of cloud computing
provide efficient and operationally friendly solutions to data
computing and content distribution, they are not up to the
challenge of high assurance.
In certain enterprises, the network is continually under
attack. Examples might be:
• Banking industry enterprise.
• Defense industry applications.
• Credit card consolidation processes.
• Commercial point-of-sale processes.
• Medical – privacy and statutory requirements,
• Content Distributor’s -- rights in data, theft of content.
The attacks have been pervasive and often include
previously unseen attack vectors and they continue to the
point that nefarious code may be present, even when regular
monitoring and system sweeps clean up readily apparent
malware. This omnipresent threat leads to a healthy
paranoia of many threats including resistance to
observation, intercept and masquerading. The web interface
is the best way to provide access to many of its users despite
this highly active threat environment. One way to maintain
capability in this type of environment is to not only know
and vet your users, but also your software and devices.
Even that has limitations when dealing with the voluminous
threat environment. Today we regularly construct seamless
encrypted communications between machines through SSL
or other TLS. These do not cover the “last mile” between
the machine and the user (or service) on one end, and the
machine and the service on the other end. This last mile is
particularly important when we assume that malware may
exist on either machine, opening the transactions to exploits
for eaves dropping, ex-filtration, session high-jacking, data
corruption, man-in-the-middle, repeat replay, masquerade,
blocking or termination of service, and other nefarious
behavior. Before we examine the challenges of cloud
computing systems, let us first examine what high assurance
architecture might look like.

A. A Comprehensive Set of Tenets
We have implemented twelve tenets that guide decisions
in an architectural formulation for high assurance
approaches [5]. These tenets are distinct from the functional
requirements normally associated with specific software
component(s) (e.g., a name(s) need to be unique or
identities need to be established); they relate more to the
goals of the solution that guide its implementation.
• The zeroth tenet is that the malicious entities are present
and can look at all network traffic and may attempt to
modify that traffic by sending virus software to network
assets. In other words, rogue agents (including insider
threats) may be present and to the extent possible, we
should be able to operate in their presence, although this
does not exclude their ability to view some activity. Assets
are constantly monitored and cleaned, however new attacks may be successful at any time and nefarious code may be present at any given time.

- The first tenet is simplicity. This seems obvious, but it is notable how often this principle is ignored in the quest to design elegant solutions with more and more features. That being said, there is a level of complexity that must be handled for security purposes and implementations should not overly simplify the problem for simplicity’s sake.
- The second tenet, and closely related to the first, is extensibility. Any construct we put in place for an enclave should be extensible to the domain and the enterprise, and ultimately to cross-enterprise and coalition. It is undesirable to work a point solution or custom approach for any of these levels.
- The third tenet is information hiding. Essentially, information hiding involves only revealing the minimum set of information to the outside world needed for making effective, authorized use of a capability. It also involves implementation and process hiding so that this information cannot be farmed for information or used for mischief. Its corollary in software design provides only information that is needed to a software segment or process.
- The fourth tenet is accountability. In this context, accountability means being able to unambiguously identify and track what active entity in the enterprise performed any particular operation (e.g., accessed a file or IP address, invoked a service). Active entities include people, machines, and software process, all of which are named registered and credentialized. By accountability we mean attribution with supporting evidence. Identity is a key attribute here and virtual elements must have unique identities. Without such an identity process and detailed logging, it is impossible to establish a chain of custody or do effective forensic analysis to investigate security incidents.
- This fifth tenet is minimal detail (to only add detail to the solution to the required level). This combines the principles of simplicity and information hiding, and preserves flexibility of implementation at lower levels. For example, adding too much detail to the access solution while all of the other IA components are still being elaborated may result in wasted work when the solution has to be adapted or retrofitted later.
- The sixth is the emphasis on a service-driven rather than a product-driven solution whenever possible. Using services makes possible the flexibility, modularity, and composition of more powerful capabilities. Product-driven solutions tend to be more closely tied to specific vendors and proprietary products. That said, commercial off-the-shelf (COTS) products that are as open as possible will be emphasized and should produce cost efficiencies. This means that for acquisition, functionality and compatibility are specified as opposed to specific reference to current implementations such as “must operate in a Microsoft forest” [6] environment.
- The seventh tenet is that lines of authority should be preserved and IA decisions should be made by policy and/or agreement at the appropriate level. An example here is that data owners should implement sharing requirements even when the requirements come from “higher authority.”
- The eighth tenet is need-to-share as overriding the need-to-know. Often effective health, defense, and finance rely upon and are ineffective without shared information.
- The ninth tenet is separation of function, this makes updates easier, isolates vulnerabilities and aids in forensics.
- The tenth tenet is reliability; it needs to work even if adversaries know how the process works. In setting up a large scale enterprise we need to publish exactly how things work and this should not create additional vulnerabilities.
- The eleventh tenet is to trust but verify (and validate). This essentially precludes the use of identity by self-attestation which is unverified.

B. Element of the High Assurance Architecture

In order to build an architecture that conforms to these tenets, there must be elements that ensure that they are built into the systems. In the architecture we describe, the basic formulation follows a web 2.0 approach and uses Organization for the Advancement of Structured Information Standards (OASIS) standards of security [7]. These elements are listed below:

Identity derives from accountability. Identity will be established by the requesting agency. To avoid collisions, the identity used by all federated exchanges shall be the distinguished name as it appears on the primary credential provided by the certificate authority. The distinguished name must be unique and space which means that retired names are not reused and ambiguities are eliminated. Naming must be applied to all active entities (persons, machines, and software).

Credentials derive from identity, reliability, trust but verify, and malicious entities. Credentials are an integral part of the federation schema. Each identity (all active entities) requiring access shall be credentialing by a trusted credentialing authority. Further, a Security Token Server (STS) must be used for storing attributes associated with access control. The primary exchange medium for setting up authentication of identities and setting up cryptographic flows is the Public Key Infrastructure (PKI) embodied in an X.509 certificate.

Authentication derives from accountability and malicious entities. The requestor will not only authenticate to the service (not the server), but the service will authenticate to the requestor. The preferred method of communication is secure messaging, contained in Simple Object Access Profile (SOAP) envelopes.

Confidentiality in transit derives from malicious entities and reliability. All messages are encrypted for delivery to the recipient of the message.

Authorization derives from accountability, malicious entities, lines of authority, trust but verify, and extensibility. Authorizations will be through the use of SAML packages in accordance with the SAML 2.0 specification provided by OASIS [8].

V. CLOUD AND HIGH ASSURANCE

Despite the obvious advantages of cloud computing, the large amount of virtualization and redirection poses a number of problems for high assurance. In order to
understand this, let’s examine a security flow in a high assurance system.

![Diagram of High Assurance Security Flows]

The application system consists of a web application (for communication with the user), one or more aggregation services that invoke one or more exposure services and combines their information for return to the web application and the user. As a prerequisite to end-to-end communication an SSL, or other suitable TLS is set up between each of the machines.

The exposure services retrieve information from one or more Authoritative Data Sources (ADSs). Each communication link in Fig. 1 will be authenticated end-to-end with the use of public keys in the X.509 certificates provided for each of the active entities.

This two-way authentication avoids a number of threat vulnerabilities. The requestor initially authenticates to the service provider. Once the authentication is completed, an TLS connection is established between the requestor and the service provider, which will be authenticated end-to-end with the use of public keys in the X.509 certificates provided for each of the active entities.

This two-way authentication avoids a number of threat vulnerabilities. The requestor initially authenticates to the service provider. Once the authentication is completed, an TLS connection is established between the requestor and the service provider, within which a WS-Security package will be sent to the service. The WS-Security package contains a SAML token generated by the Security Token Server (STS) in the requestor domain. The primary method of authentication will be through the use of public keys in the X.509 certificate, which can then be used to set up encrypted communications, (either by X.509 keys or a generated session key). Session keys and certificate keys need to be robust and sufficiently protected to prevent malware exploitation. The preferred method of communication is secure messaging using WS Security, contained in SOAP envelopes. The encryption key used is the public key of the target (or a mutually derived session key), ensuring only the target can interpret the communication.

The problem of scale-up and performance is the issue that makes cloud environments and virtualization so attractive. The cloud will bring on assets as needed and retire them as needed. Let us first examine scale-up in the unclouded secure environment. We will show only the web application, although the same rules apply to all of the communication links between any active elements shown in Figure 1. The simplest form of dividing the load is to stand up multiple independent instances and divide users into groups who will use the various instances. Dependent instances that extend the thread capabilities of the server are considered single independent instances. Remember, all independent instances are uniquely named and credentialled and provisioned in the attribute stores.

![Diagram of High Assurance Virtualized Hypervisor Activity]

A traffic cop (hypervisor) monitors activity and posts a connection to an available instance. In this case all works out since the new instance has a unique name, end-point, and credentials with which to proceed. All of this, of course needs to be logged in a standard form and parameters passed to make it easy to reconstruct for forensics. We have shown a couple of threats that need mitigation where one eavesdrops on the communication and may actually try to insert himself into the conversation (man-in-the-middle).

This highlights the importance of bi-lateral authentication and encrypted communications. The second is present on instance 4 and highlights the need to protect caches and memory spaces.

When a cloud environment runs out of resources for computing, it builds additional instances, some of these may be thread extension schemas, and some may be independent instances. The traffic cop here is often called a hypervisor and it keeps track of the instances and connections. Figure 2 shows notionally how this operation works. When thread capacity is saturated at the server, the hypervisor would nominally redirect the request to an independent virtual or real instance of the web application. If none exists, it will build one from elements in the resource pool as depicted in instance 4 on the chart. If the last requester signs off of an independent virtual or real instance (instance 3 in the figure), the hypervisor tears down the instance and places the resources back into the resource pool. This provides an efficient re-allocation of resources.

VI. ACCOUNTABILITY, MONITORING AND FORENSICS

The goal of computer forensics is to perform a structured investigation while maintaining a documented chain of evidence to find out exactly what happened on a computing system and who or what was responsible for it [11]. There are several steps that must be taken to preserve the state, if we are interested in a forensics reconstruction of the computing.
A. Accountability

In order to ensure accountability, the number of independent instances must be anticipated. Names, credentials and end points must be assigned for their use. The attribute stores and HSMs must be provisioned with properties and key to be used. The simple re-direct must be changed to a re-post loop as in Figure 2. The requester will then have a credentialed application to authenticate with bilaterally and an end point for end-to-end message encryption. Key management is complex and essential. When a new independent instance is required, it must be built and activated (credentials and properties in the attribute store, as well as end point assignment). All of these activities must be logged in a standard format with reference values that make it easy to reassemble the chain of events for forensics. When a current independent instance is retired, it must be disassembled, and de-activated (credentials and properties in the attribute store, as well as end point assignment).

B. Monitoring

All of these activities must be logged in a standard format with reference values that make it easy to reassemble the chain of events for forensics. The same threats exist, and the same safeguards must be taken. In fact, in Figure 2 nefarious code is built right into the virtual or real instance 4, which underscores the need for trusted and verified software to do the virtualization, and protection of the resources while they are in the resource pool.

C. Knowledge Repository

The knowledge repository (KR) is a single integrated source of all information on the operation of the cloud. Instrumented agents feed the data base on a schedule or on demand. The knowledge base is where all information related to the enterprise SOA is stored. This will include the following:

- Hardware/software current status from cloud or enterprise
- Current reports on test activities including response times, frequency of test, etc.
- Current reports of usage data from service agent monitors and service logs, including number of users, session times, response times, etc.
- Hardware/software historical data
- A list of current alerts for the entire enterprise
- Historical data on alerts
- Current monitoring records

Many of these feed status displays for the network monitoring and the enterprise support desk. They can provide a basis for real-time management and network defenses as well as forensics.

D. Forensic Tools

Tools are needed for KB query, correlation, and anomaly detection. Each tool should be functionally specified together with outputs and based upon the standard defined records described in the next section.

VII. STANDARDS REQUIREMENTS FOR CLOUD FORENSICS

Standards provide a basis for commercial applications as well as a market for developed tools and provide an interoperability process for generated files. Standards need to be developed, and are required for a number of cloud operations:

1. Standards for identity issuance of virtual objects. Current practice of overloading the identity makes the development of forensic strategies difficult or problematic. The standard should include credentialing and establishment of identity attributes.

2. Standards are required for a number of details associated with cloud monitoring. These requirements are based upon monitoring requirements derived for enterprise application and shown in Figure 4.

   - Standard lists of events that must be logged and alerting including event specific data (these may be separated into minimal, rich, and robust categories). The events should include all of the agility events such as stand-up and tear-down of services as well as credentialing and establishment of identity attributes.

   - A standard process for automatic escalation of monitoring under pre-defined circumstances.

   - Standard monitoring record content (that is separate from event specific content) including: Date/time, Record Number, Thread Number, Sequence Number, Active Entity Name, Event Name, ID of Service Requestor.

   - Standard identifiers for monitoring content (to assist upload to a centralized KR).

   - Standard processes for protection, access and integrity of monitor records.

   - Standards for continuous operations and recovery of the monitoring system and its records.

4. Standards for protection, access and integrity of stored resources that will be used in agile virtualization.

VIII. SUMMARY

We have reviewed the basic approaches to clouds and their potentials for savings in computing environments. We have also discussed high assurance architectures and their requirements which provide direct challenges to the way cloud computing environments are organized. Notably the extensive use of virtualization and re-direction is severe enough that many customers who need high assurance and forensics capabilities have moved away from the concept of cloud computing [12 - 14]. We believe, however, that a precise statement of the high assurance and forensics requirements will lend themselves to solutions in the cloud computing environment, and expand the potential use of this technology. This work is part of a body of work for high assurance enterprise computing using web services. Elements of this work are described in [15-21].
